**Human Lung Flukes.** The human lung fluke, *Paragonimus westermani*, lives in the lungs of man and a variety of other mammals, including the dog, cat, and pig. Infection of the final host comes from the ingestion of the encysted stages in freshwater crabs or crayfish. The intermediate hosts are several species of large operculate snails of the genus *Melania*.

The presence of the worms and their eggs produces injury to the lung tissues and walls of the bronchioles. Since, except in rare cases, only a few parasites are present in the lungs of the human host these injuries usually produce a long-standing chronic disease, characterized by a cough, vague pains in the chest, and a more or less severe hemoptysis. The young worms reach the lungs by migrating through the peritoneal cavity and penetrating the diaphragm, and can in some cases penetrate into various organs of the body where occasionally they reach sexual maturity. When present in large numbers outside the lungs they can produce severe lesions and a generalized paragonimiasis. Fortunately, this condition appears to be rare.

*Paragonimus westermani* has a widespread distribution in the Far East. Its most important endemic area appears to be southern Korea where it is a real public

health problem. It is also of considerable significance in the production of disease in certain parts of Formosa, especially among the aboriginal tribes, and in central China (Chekiang province). It also is rather widely distributed in Japan and the Philippines, but with low incidence.

A very closely related species, *P. kellicotti*, has an extensive distribution in the United States and Canada in dogs, cats, and pigs, and in certain wild mammals of which the mink is the most common. The encysted stages of this species occur only in the heart of the crayfish which serve as second intermediate hosts. It seems probable that man in this country could serve as a host of *P. kellicotti* but is protected by this peculiar location of the infective stage in a host that is not frequently eaten. Reservoir hosts appear to be more important than man in infecting the intermediate hosts of *Paragonimus*. There is no satisfactory treatment, so that the only feasible control measures appear to be to try to prevent the eating of raw or insufficiently cooked crabs or crayfish.

**Blood Flukes.** Schistosomiasis, the disease produced in man by the blood flukes, *Schistosoma haematobium*, *S. mansoni* and *S. japonicum*, is one of the most widespread and serious of all the diseases produced by animal parasites. It seems to be spreading in various parts of the world. It has recently been discovered that the larval stages of two of the three schistosomes of man can complete their development in snails in the United States, but there is no evidence that any of the three human schistosomes has ever become established in this country.

The schistosomes infect the final host by penetration of the cercariae through the skin. From the skin they make their way to the vessels of the hepatic portal system in the liver where they grow to sexual maturity in about a month. The course of migration to the liver appears to be by the blood stream. After reaching sexual maturity, the males and females copulate and migrate along the mesenteric veins to the smaller vessels where the females lay their eggs. The eggs work their way out through the wall of the intestine or urinary bladder (*S. haematobium*) and are passed in the feces or urine.

In infections with the schistosomes there is an early phase of fever and urticaria which appears to be an allergic reaction to the toxic products given off by the worms during their migrations and growth. Later injuries are related chiefly to the passage of the eggs through the wall of the intestine or bladder in their escape from the host, and to the host reaction in encapsulation of the large numbers of eggs that are retained in various tissues. While a considerable proportion of the people infected with the schistosomes show only minor symptoms on account of the small numbers of worms present, in most of the endemic areas there are large numbers of severe cases and frequent deaths.

*S. haematobium* has its worst endemic areas in the delta and valley of the Nile where a large proportion of the population is infected. It has a widespread distribution with varying incidence throughout most of Africa (Faust, 1949). It is an important parasite in Madagascar, and also occurs in Arabia, Israel, Iraq, and Iran. Recently a rapidly spreading endemic area has been uncovered in northern Syria near the Turkish border. Stoll (1947) estimated the number of cases of schistosomiasis haematobia in the world at almost 40,000,000. Because of the migration of the adult worms to the blood vessels near the urinary bladder and the lesions produced by the eggs in the wall of the bladder and nearby tissues, the pathology

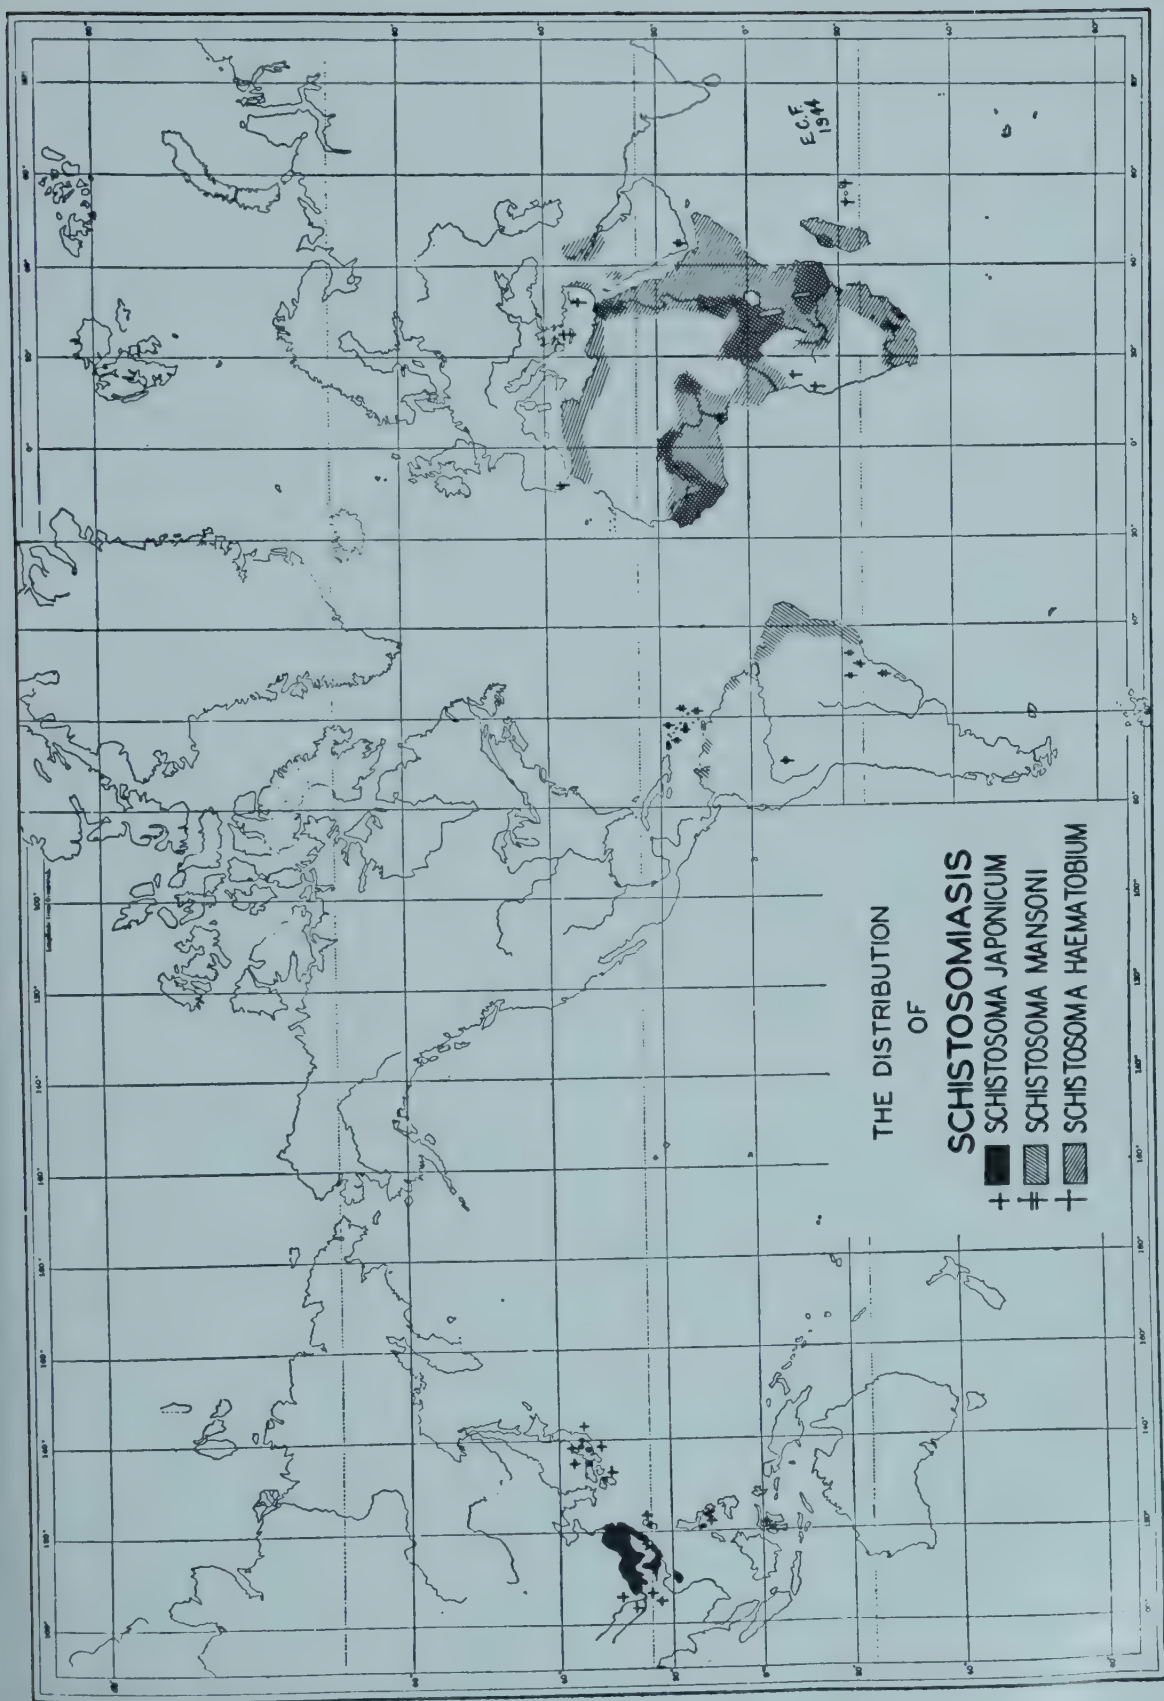

Fig. 9-1. Map showing the distribution of the human schistosomes.

From Faust, E. C., Human Helminthology. Courtesy of Lea & Febiger.

produced by *S. haematobium* centers in the urinogenital system, and the disease is frequently called vesical schistosomiasis. The lungs are frequently involved because eggs and even worms are carried to them from the vesical plexus. Except for a species of monkey in certain parts of Africa, there appear to be no significant reservoir hosts for this parasite. The typical intermediate hosts are nonoperculate snails of the genera *Bulinus* and *Physopsis* which live on vegetation in small bodies of water.

*S. mansoni* has a wider distribution than *S. haematobium* since it is found in the Western Hemisphere where it was apparently carried by slaves brought over from West Africa. In Africa, its most concentrated endemic area is the delta of the Nile. It is also widely prevalent in tropical East Africa, in the Congo Valley, and in West Africa between the Sahara Desert and the north coast of the Gulf of Guinea (see Faust, 1949, Fig. 31). In the Western Hemisphere, *S. mansoni* is a particularly important health problem in Brazil, especially in the northeastern part, where it appears to be spreading. A recent estimate gave nearly 6,000,000 people infected in this country (Stoll, 1947). This parasite is also present in Venezuela, Dutch Guiana, and in several of the West Indian Islands including Puerto Rico.

*S. mansoni* frequently has been introduced into the United States especially by Puerto Ricans, but there appear to be no authentic records of indigenous cases. Although several species of mammals have been shown to be susceptible to infection with this parasite, only monkeys have been suggested as possible reservoir hosts. The intermediate hosts are several species of planorbids. Recently, a species of *Tropicorbis* from Louisiana has been shown to be susceptible to infection.

Since the adult worms of *S. mansoni* tend to migrate to the wall of the large intestine, the lesions are chiefly in the rectum. The liver is very frequently involved on account of eggs that are swept back into it from the mesenteric veins.

*Schistosoma japonicum* is limited to the Orient (see Faust, 1949, Fig. 42). In China a vast extent of territory with a very large population including most of the Yangtze Valley is included in the areas where schistosomiasis japonica is known to be endemic. The second most important endemic areas are on several islands of the Philippines. Five small endemic areas are present in Japan and one each in Formosa and the Celebes. Stoll's (1947) estimate of the number of people in the world infected with this parasite is 46,000,000. The disease produced by *S. japonicum* is, in general, the most serious produced by the human schistosomes. Extensive intestinal lesions are present with a severe pseudodysentery and the liver involvement is very serious. This parasite differs from the other two human schistosomes in the importance of reservoir hosts. In China and Japan the use of human excrement as fertilizer is the most important factor in infecting the snail intermediate hosts. However, throughout the endemic areas infections in dogs, cats, pigs, cattle, water buffaloes, and even rats contribute to its spread. The intermediate hosts of *S. japonicum* are several species of small operculate snails, of the genus *Oncomelania*. They live in small irrigation ditches and other shallow bodies of water, and have a very considerable resistance to desiccation.

The spread of the human schistosomes, except in the few areas where reservoir hosts are important, depends primarily on close relations between the human host and bodies of water where the snail intermediate hosts find suitable habitats. The snails are infected from eggs passed into the water in feces or urine, and man derives his infection from contact with bodies of water in which the infected snails live. When

ever these relations are more or less accidental the incidence of infection is low, and the disease is mild. Agricultural practices in relation to irrigation have been very important in the spread of these parasites. In Egypt, where *S. haematobium* and *S. mansoni* are so prevalent and the diseases they produce are so severe, the system of perennial irrigation is responsible. The extensive network of canals which reaches to every field has enormously increased the habitats available to their snail intermediate hosts. Religious practices encourage urination and defecation in and near these canals. Their proximity to the houses where the people live and the methods used by the farmers in irrigating and tending the fields bring the people into constant contact with the infested water. These relations have led to the constant infection and reinfection of the population and have produced the most concentrated endemic center of schistosomiasis in the world.

In China and Japan it is the wet cultivation of rice that has made schistosomiasis so prevalent. The snails live in enormous numbers in the canals leading up to the rice fields, and are frequently present along the edges of the fields. The use of human excrement as fertilizer insures the infection of the snails, and the work in the canals and in the fields insures long and repeated exposure to infection. While there are many other sources of infection, it is among the people who raise rice that this disease is most prevalent and severe (Faust and Meleney, 1924). In some of the other endemic areas also, as in Puerto Rico, Venezuela, and parts of Brazil, irrigation canals are important sources of infection.

In recent years, the importance of the control of schistosomiasis has attracted more and more attention. Certainly, the widespread distribution and the severity of this disease, the fact that it seems to be spreading in certain areas such as the Near East and Brazil, and the inadequacy of control measures make it a very important world problem. Recently, the World Health Organization has placed investigations on the control of schistosomiasis among its most important problems. A variety of methods of attack has been suggested. Mass treatment with antimonial drugs has been tried in Egypt, but with little success. In Egypt and elsewhere where miscellaneous pollution of the water with urine and feces produces the infection of the snails, improvement of sanitation is important as a control measure. Perhaps most promising is the attempt to reduce the snail population. In Egypt, this is being done by the clearing of vegetation from the canals and in some cases by killing the snails with copper sulphate. The use of chemicals in killing the snail intermediate hosts seems to be the most promising method of control, and a great deal of work is being carried out at the present time in attempts to find new molluscicides that are adapted for this purpose.

**Schistosome Dermatitis.** A number of nonhuman schistosome cercariae are able to penetrate the skin of man and produce a dermatitis (for a comprehensive review of this subject see Cort, 1950). The most important of these dermatitis-producing cercariae are duck parasites belonging to the genus *Trichobilharzia*. It has been shown recently that this dermatitis is a sensitization phenomenon, since initial infections produce only very minute macular lesions. In individuals sensitized by repeated infections the penetration of the cercariae produces in about 10 to 15 hours discrete papules 3 to 5 mm. in diameter. The development of the papules is accompanied by an intense itching. In heavy exposures the papules may become confluent and the whole area of penetration may become swollen and edematous. On the second or

third day vesicles form on the papules which are often ruptured by rubbing or scratching. The papules usually disappear in about a week after infection.

In many places the snails that harbor the dermatitis-producing cercariae live in swamps, muddy ponds or small ditches. Under such conditions human infection occurs only infrequently. When such snails live on or near beaches that are used for bathing, large numbers of people may be infected with serious results. Under such conditions "swimmer's itch" may render whole beaches unsuitable for bathing and cause great inconvenience to summer resorters and considerable loss to resort owners. This dermatitis has a widespread distribution in the lake region of the north central United States and Canada. It has also been reported in a few places in Europe and in New Zealand. In certain parts of Malaya and Japan it is caused by cercariae from snails that live in or near rice fields. Here it becomes an occupational disease of rice farmers.

Successful control of schistosome dermatitis has been achieved on a number of infested beaches by chemical treatment to kill the infected snails (Cort, 1950). In northern Michigan its prevalence has been greatly reduced in the past 10 years. A mixture of copper sulphate (snow or finely granulated crystals) plus 10 per cent of fresh hydrated lime is used. This mixture is stirred into water (about 50 pounds to 50 gallons) and is distributed from a small rowboat by trailing rubber tubes directly on the sandy bottom where the snails live. Unless the snails are too widely scattered or live in deep water, a single treatment will usually kill most of them, and, if carefully applied, will frequently prevent the recurrence of the dermatitis for a period of three years. Beaches should only be treated when the water is calm, so that the chemical will not be dispersed before it reaches the snails.

#### SNAKE BITE POISONING

##### (Envenomation)

Poisoning of man and domestic animals by snake bites is a biological accident, sometimes fatal, which occurs because certain reptilian species are equipped with a mechanism for capturing, killing and digesting their prey of small animals, which may be converted into a means of attack upon their predatory enemies. The frequency of this accident is determined by the number and aggressiveness of venomous species in a region relative to the human population living or working in a primitive ecology. Swaroop and Grab (1954) reviewed the reported mortality for this cause on an international basis. Though these data are relatively crude and

unsatisfactory, the highest rates are in tropical and semitropical countries (India, Burma, Thailand, Ceylon) and the lowest in the cooler climates (Finland, Norway, Sweden, Canada). The authors estimate that world-wide deaths due to snake bites are between 30,000 and 40,000 annually. Thanks to St. Patrick there are none in Ireland. Every state in the United States has at least one poisonous species of snake within its boundaries. Apparently the highest mortality rates are registered by Arizona, New Mexico, Texas and Florida.

**Venomous Snakes.** Venomous land snakes belong to two families, the Colubridae (colubrine) and the Viperidae (viperine). The more important species classified as potentially dangerous are the following:

In the Old World: the cobra (*Naja naja*), the king cobra (*Naja bungarus*), the common krait (*Bungarus candidus*), the Egyptian asp (*Naja haje*), the brown snake of Australia (*Diemenia textilis*), the Australian black snake (*Pseudechis porphyriacus*) and the death-adder (*Acanthopis antarcticus*), all of which are colubrine. Among the viperine are the daboia (*Vipera russellii*), the habu (*Trimeresurus flavoriridis*), the puff-adder (*Bitis arietans*), etc.

In the New World: the fer-de-lance (*Bothrops atrox*), the urutu or cross viper (*Bothrops alternata*), the surucucu or bushmaster (*Lachesis muta*), the neotropical cascavel (*Crotalus terrificus*), and the various species of rattlesnakes of the United States and Mexico, especially the western diamond-back rattler (*Crotalus atrox*), the eastern diamond-back rattler (*Crotalus adamanteus*), the red rattler (*Crotalus exsul*), and others, the cotton-mouth moccasin (*Agkistrodon piscivorus*) and the copperhead (*Agkistrodon mokasen*), all of which are viperine; and among the colubrine, the various elapine snakes (genus *Micrurus*).

**Venom.** In snakes, the venom glands are actually specialized salivary organs, and inoculation is effected by canalized or grooved teeth (fangs). The venom not only tends to immobilize the prey but also aids subsequent digestion of the animal tissues. It is a complex, chiefly of proteins, varying in composition from species to species. What is known about the biochemistry and mode of action of snake venoms has been summarized by Porges (1953). In general, their destructive action is due to their content of powerful digestive proteolytic enzymes—phosphatidases, hyaluronidase, opio-oxidases, lecithins—and to their paralyzing action.

**Envenomation.** The fangs in normal position are folded against the roof of the mouth. When the snake strikes they are thrown forward for the bite and the ejection of venom. Fangs are shed periodically and replaced. Venomous snakes in the United States can strike with accuracy at a distance of one half the length of the body. The amount and virulence of the venom injected varies with the species and size of the snake, the condition of the venom glands (whether full, partially depleted, or evacuated by reason of recent feeding), character and location of the bite and other factors.

After crotaline (pit viper) bites, burning pain develops at site of the injury within 5 minutes, and in 10 minutes distinct swelling develops which increases and advances to the surrounding tissues. In a serious bite on the hand, the entire arm will become extremely swollen in the first hour. The skin of the area becomes dark and purplish and bloody fluid oozes from the wound. The patient may become weak and dizzy, perspires profusely, is nauseated and sometimes vomits blood-stained material. Subcutaneous and internal hemorrhages may occur, with bleeding from

the nose, bladder and intestines. The pulse may become weak, pupils dilated and respiration difficult. Later, there may be loss of vision, paralysis, unconsciousness, coma and complete collapse. On the other hand, the venom of colubrine snakes is principally neurotoxic. Local reaction around the site of the bite is frequently insignificant. Involvement of the central nervous system is rapidly evident, with difficult articulation, nausea, vomiting and paralysis of respiration and a fatal issue within a few moments. All gradations in symptomatology occur between these two extremes.

Treatment is directed toward the accomplishment of two objectives. The first is to remove or delay absorption of the venom that is locally deposited in tissues adjacent to the bite. The second is to neutralize as far as possible the local and general effect of venom by injections of antivenin. In order to accomplish the first of these objectives, if the bite is on a limb, it is generally advised (though there is some difference of opinion, Jackson and Harrison, 1928) that a tourniquet be applied about two inches above the bite until the second measure can be undertaken. The tourniquet should not be applied tightly enough to arrest arterial circulation but only to restrict the flow in veins and lymphatic vessels. The area of the skin about the site of the bite is cleansed for surgical procedure. With a sharp blade a number of punctures or small cuts are made about the point where the fangs entered the skin. Suction is applied by mouth, cupping glass or breast pump. There is no danger from swallowed venom. Suction should continue for 15 to 20 minutes in each hour. In the intervals between suction periods, cover the wounds with sterile gauze pads saturated with sterile hypertonic salt solution. This is continued for 10 to 15 hours.

**Antivenin.** Sera containing protective substances (antivenins) against regional poisonous snakes are commercially available in many countries. For North America they are obtained from the blood of horses which have been given repeated injections of a mixture of crotaline (pit viper) venoms. Refined and dried by vacuum dehydration from the frozen state, this polyvalent antivenin may remain potent for five years. It is readily and fully soluble on addition of distilled water and may be safely and conveniently carried in the sealed vial in pocket or pack at temperatures encountered in the open. It is tested for sterility and potency and is standardized by its ability to neutralize the toxic action of a standard venom, as shown by the intravenous injection into mice. It should be administered to the snake bite victim as early as possible. Full directions for dosage and technic of injection are given in each package.\*

The patient should remain quiet. Contrary to popular opinion alcoholic drinks are of no value and may be detrimental through hastening absorption. Do not attempt to cauterize the wound with strong acids or give local injections of potassium permanganate or other oxidizing agent.

## Section Two

# NUTRITION AND DEFICIENCY DISEASES

WILLIAM H. SEBRELL, JR., M.D.

## 10

### GENERAL CONSIDERATIONS OF FOOD ELEMENTS

Good nutrition is essential for good health. Nutrition directly affects growth, development, reproduction, well-being, and the physical and mental condition of the individual. Health depends upon nutrition more than on any other single factor in hygiene.

The total number of essential nutrients required by man is still unknown since new ones are still being discovered and old ones re-evaluated, and there is suggestive evidence that others as yet unidentified also exist. Furthermore, the role of the obviously complex hormone control factors as well as alterations in enzyme systems still need elucidation. In spite of the above complexities, there is sufficient knowledge to prescribe an entirely adequate diet for man and to evaluate the effect of malnutrition on health.

The following are known nutrients required.

**Energy.** The body requires a certain amount of energy as one of its basic needs in order to sustain life. This energy is obtained by the breakdown of foods to simpler chemical substances in the process of digestion and metabolism. The unit of measurement used for this energy is the calorie. Fuel value is a term denoting the total number of calories derived from one gram of any given food if it is completely burned. Approximate fuel values used in dietary computations are four calories per gram for either protein or carbohydrate and nine calories per gram for fat. In calculating energy requirement, it is necessary to determine first the energy required for basal metabolism. This is the energy necessary to sustain the fasting individual at rest. It is related to the surface area of the body and is obtained for any given age, sex, and weight by reference to a nomogram. The basal requirement for an adult is about one calorie per hour for every kilogram of body weight. There is added to the basal requirement a factor depending on the physical exertion of the individual. This can be related to food required from tables of the caloric value of food. The lowest calorie allowance for very sedentary individuals should be about 1.2 times the basal metabolism as ordinarily measured. The normal recommended calorie allowance for the "standard" man aged 25 years, living in a temperate climate, weighing 65 kg. and engaging in moderate physical activity is 3,200 calories per day. The recommended allowance for a woman weighing 55 kg. under similar conditions is 2,300 calories per day. The individual calorie need is determined by a number of factors such as age, sex, body size, climate and activity, and the calorie allowance must be adjusted to meet the individual's needs as indicated by his weight, his change in weight and his clinical condition. Figures for various ages are given in Table 12-1, page 613. Children need more calories per pound of body weight

than adults because of the extra needs for growth. Old people need less than young adults.

**Proteins and Amino Acids.** Although proteins are the principal source of nitrogen in the diet, their primary importance is that of supplying essential amino acids which cannot be synthesized in the body. Proteins from various foods contain varying combinations of various amino acids. Proteins are, therefore, said to be of high or low biological value according to the amount of nitrogen retained, which is in turn dependent on the amino acids furnished by the food. As a rule, proteins from animal sources such as meat, milk, and eggs have a higher biological value than proteins from cereal and vegetable sources. There are 22 known alpha amino acids in food proteins. Eight of these have been shown to be essential for the maintenance of nitrogen equilibrium in man. Rose recommends daily intakes of these at about twice the highest observed minimum requirements for maintenance of nitrogen equilibrium in young male adults. The amounts recommended are l-isoleucine 1.4 gm., l-leucine 2.2 gm., l-lysine 1.6 gm., l-methionine 2.2 gm., l-phenylalanine 2.2 gm., l-threonine 1.0 gm., l-tryptophan 0.5 gm. and l-valine 1.6 gm. These amounts although recommended are not necessarily the optimum amounts. Rose's data also indicate that 80 to 85 per cent of the methionine requirement may be met by cystine and 70 to 75 per cent of the phenylalanine requirement may be replaced by tyrosine.

As a practical means of calculating a desirable protein intake, a normal adult should receive about 1 gm. of protein per kg. of body weight per day. This should be obtained from a variety of foods, some of animal origin. If a more exact calculation is desired, it must be made in terms of quantities of individual amino acids. Under ordinary conditions in this country, this is not necessary.

**Carbohydrates.** Although the body obtains energy from protein, fat, and carbohydrate, the carbohydrates are the most efficient source of fuel for muscular exercise and they constitute more than one half of the usual diet. Carbohydrate foods contain digestible carbohydrates, such as glucose, sucrose, starches, maltose, and lactose; and indigestible carbohydrates, such as pectins and plant fibers which furnish bulk to the intestinal contents as digestion proceeds. The starchy or high-carbohydrate foods are the tubers, such as potatoes; fruits and cereals; and the highly purified sugars, such as sucrose (cane or beet sugar), glucose, corn starch, syrup, and hard candy. These highly purified carbohydrates are almost completely lacking in vitamins, minerals, and all other nutritional elements except energy value. They also tend to satisfy the appetite. For these reasons they tend indirectly to create malnutrition by reducing the intake of foods of higher nutritive value. Instead of taking them in excessive amounts, they should be utilized at the end of the meal after the requirement for other nutrients has been met and when there is need to further increase the energy value of the diet.

The cereal grains such as wheat, corn, and rice form the basis of food supply of most of the people of the world. They are produced in enormous quantities and usually are the most economical source of food energy. In most areas, these cereals are refined and milled for human use in order to improve their storage qualities and to widen their range of usefulness. The outer parts of the grain contain much of the mineral and vitamin value and constitute an important source of feeds for livestock. The refined product, as a flour or meal, contains protein as well as carbohydrate

At various times governments have required the use of lightly milled products in order to improve nutritive value. Such efforts have failed so far to outweigh the desire for the highly milled product when the requirement has been removed. Another method of improving the nutritive value of these highly important foods was introduced in the United States in 1941 under the name "enrichment." This term applies to white wheat flour, white bread, and corn meal to which certain vitamins and minerals are added in order to make these products more effective in the prevention of certain deficiency diseases. This change has made a significant increase in the vitamin and mineral level of many American diets.

**Fats and Oils.** These are the most concentrated sources of energy in the diet. Since a given weight of fat furnishes more than twice the calories than the same amount of carbohydrate or protein, it is most important to reduce the fat content of the diet in treating obesity. The most important sources of fat in the diet are butter, lard, oleomargarine, fish oil, and a large number of vegetable oils such as olive oil, corn oil, and cottonseed oil. Highly refined fats such as lard and vegetable oil products, like refined sugars, have little or no vitamin or mineral value and contribute practically nothing but energy to the body. Other fats such as butter, cream, vitamin fortified margarine, and fish oil contain the fat soluble vitamins A, D, E, and K.

The fats have other nutritional importance in their "satiety" value. It has been observed that individuals on a low fat diet crave fat and suffer discomfort because of a lack of fat. In spite of these observations, it has not yet been possible to determine the human requirement for fat on a physiological basis. Estimates of need are based very largely on surveys of dietary habits. A diet of which 20 to 25 per cent of the total calories is supplied by fat is the general recommendation, with the quantity increased to 30 to 35 per cent for individuals on a very high calorie intake in order to reduce the quantity of food to be consumed.

The fats also contain unsaturated fatty acids such as linoleic, linolenic, and arachidonic acids. While it has been shown that these are required by certain experimental animals, the human requirement, if any, has not been determined. Since they occur in natural fats, they are not likely to constitute a human deficiency problem.

Fats are readily deposited in the body and in addition to serving an insulating purpose, they are the most important source of stored energy in the body. Fat occurs in all tissue and is an essential in cellular function. The phospholipids, of which lecithin, cephalin, and sphingomyelin are the principal types, are formed of fat, phosphoric acid, and a nitrogenous base. These phospholipids play important roles in metabolism and are widely distributed throughout the body.

**Inorganic Substances.** This term refers to the minerals or the contents of the ash from the body, whether present in inorganic or organic combinations. The term minerals or mineral elements is usually used to identify these substances. On the basis of quantity, the seven substances which are most important and which make up about three quarters of the ash are calcium, phosphorus, sodium, potassium, magnesium, sulphur, and chlorine. However, the quantity is no indication of the physiological importance of minerals and a number of other minerals which are present only in small amounts, and therefore called "trace elements," are known to be essential. The most important of this group of substances are iron, copper, cobalt, iodine, fluorine, manganese, and zinc. There are a number of additional minerals

of varying physiological importance such as selenium, aluminum, boron, beryllium, etc. The essential mineral elements are concerned in every chemical and physical reaction in the body. They are just as vital as the vitamins. The body needs a small but continuing intake of the elements necessary for its structure and function. If metabolic needs are not met, a deficiency ensues, producing symptoms which vary with the mineral element involved and the severity of the deficiency.

**Calcium.** Although about 99 per cent of the calcium in the body is in the bones and teeth, this element has numerous other important functions in the body. It serves as a regulator of heart muscle activity, it is essential for proper blood coagulation, for normal functioning of the nervous system, and it participates in many enzyme reactions. Thus, in addition to being needed in large amounts, it is one of the most important mineral elements and is the one which people in the United States are most likely to fail to obtain in optimum amounts. The quantity recommended for normal adults is 800 mg. and for young children is 1 gm. per day (the amount contained in about one quart of milk if this were the sole source of calcium in the diet). Adolescents, as well as pregnant and lactating women, should receive more.

The condition produced by calcium deficiency depends on the amount of vitamin D and phosphorus present, the activity of the parathyroids, and the age of the individual. Rickets, osteomalacia, osteoporosis, or tetany may occur.

Milk, cheese, and various vegetables such as turnip greens, kale, and soybeans are good dietary sources of calcium. However, a simple diet calculation of calcium does not give a true picture of whether calcium needs are being met. In some foods calcium is so tightly bound chemically, such as in the oxalate of some vegetables, that it is unavailable. Furthermore, the presence of some substances such as the phytate found in whole wheat or lightly milled flour may actually combine with and withdraw calcium from the body. Since most of the calcium excretion is by way of the intestinal tract, its rate of absorption and factors controlling absorption through the intestinal wall play a role in the calcium actually available to and retained by the body. In view of these numerous and complex factors, it is good policy to provide a large margin of safety in meeting calculated calcium needs.

**Phosphorus.** This element is interrelated with calcium and vitamin D, since the bones consist of compounds of calcium and phosphorus. It also is essential in the metabolism of protein, fat, and carbohydrate, and is found in all cells and fluids of the body. It is a constituent of many enzymes and forms a part of the molecule of the phospholipids.

Because of the interactions between calcium, phosphorus, and vitamin D, the lesions produced by phosphorus deficiency depend to some extent on the quantities of calcium and vitamin D present. Phosphorus deficiency may result in rickets or osteomalacia.

Good dietary sources of phosphorus are beans, meats, soybeans, and whole grain cereals. The allowance of phosphorus for children should at least equal the calcium. In the case of adults, the phosphorus should be about one and one-half times the calcium. As a general rule, if the calcium and protein needs are met through usual foods, the phosphorus will be sufficient since foods richest in calcium and protein are usually the best sources of phosphorus.

**Sodium.** This element serves throughout the body, and in metabolic reactions, largely as sodium chloride and sodium bicarbonate to control equilibrium, maintain

water balance, and control osmotic pressure. It is the most important cation in the extracellular fluid. Low sodium diets are useful in the treatment of hypertension. High sodium diets are required in adrenal insufficiency.

Some foods high in sodium are rye and wheat bread, ordinary salted butter, cheeses, and margarine. Since sodium chloride is used widely in cooking and appears on most tables, the requirement for sodium needs little consideration in diet planning. The average intake of salt is about 7 to 15 gm. daily. With excessive sweating 20 to 30 gm. daily may be taken.

Sodium deficiency results in loss of appetite, fatigue, nausea, and severe muscular cramps.

**Potassium.** This element must be considered in relation to sodium. A proper balance must be maintained between the two elements. Potassium is the most important cation of the intracellular fluid. The excitability of the nervous system is partly dependent on the balance between sodium and potassium. A disturbance of this balance results in alterations in water and ionic balance so that a deficiency in either element may cause important symptoms. From a dietary viewpoint a normal food supply will adequately meet the potassium needs so that it is not necessary to calculate the intake.

**Magnesium.** This element is found in the bones as well as in the soft tissues and fluids of the body. It is an antagonist to calcium to some extent, and enters into some cellular enzyme reactions. The human requirement for magnesium is small and is met by the quantity found in foods in an average diet. Some food sources of magnesium are nuts, soybeans, and cereal grains.

**Sulphur.** This element is found in insulin, glutathione, and the vitamins thiamine and biotin. It is also a constituent of the amino acids methionine and cystine. Since methionine is one of the essential amino acids, sulphur is related to protein metabolism. Inorganic sulphur cannot replace the sulphur of methionine and cystine. Protein of good biological quality in adequate amounts will meet the sulphur needs.

**Chlorine.** A large part of the chlorine in the body is found as sodium chloride in all the body fluids. The blood chlorides are important in regulating osmotic pressure and in maintaining the acid-base balance. The free hydrochloric acid of the gastric juice is essential in proper gastric digestion. The chlorides are excreted through the sweat and in large amounts in the urine.

Average diets usually contain enough sodium, potassium, and chlorine, and in the normal individual it is not necessary to make any special diet calculation for chlorine.

**Iron.** The principal functions of this element in the body are in the transportation of oxygen through its role in the formation of hemoglobin and in certain cellular enzymes such as cytochrome.

Since practically no iron is excreted from the body in the urine and feces under normal conditions, the actual daily requirement for iron is probably quite small unless loss of hemoglobin is occurring. Iron is found in the muscles and is stored to some extent in all the organs. Iron is not used up in the body, and since very little is excreted, it is used repeatedly.

Iron deficiency may result from a combination of inadequate intake and excessive loss, such as from hemorrhoids or during menstruation, or from increased demand such as growth or pregnancy.

This results in a microcytic hypochromic anemia, and in chronic cases changes in the mucosa of the lips and mouth.

The recommended daily allowance of iron for the normal adult is 12 mg. However, the absorption of iron is partly controlled by the need; therefore, the normal adult male probably absorbs very little. Good dietary sources of iron are liver, meats, beans, peas, soybeans, whole wheat flour, enriched white flour, and eggs. Since milk is a poor source of iron, infants who do not get an additional supply of iron may develop anemia around the end of the second year of life.

The iron content of a food cannot be used as a measure of the amount of iron available. The absorption of iron into the body from food depends upon the form in which the iron is present, since some organic iron salts may be unavailable for absorption; on the presence of ascorbic acid, which enhances the absorption of food iron; and on the metabolism of the intestinal mucosa.

**Copper.** Although hemoglobin does not contain copper, a trace of this element is necessary in hemoglobin formation. It is also needed in cellular respiration in the oxidases. The recommended allowance of copper for an adult is 1 to 2 mg. a day or about one-tenth the allowance of iron. Since salts of iron and many foods contain traces of copper, it is not necessary to give this element any attention in the usual diet planning.

**Cobalt.** It has been known for some time that cobalt deficiency produced an anemia in cattle and sheep and that the administration of cobalt to experimental animals would produce a polycythemia. However, the importance of traces of this element to man was not appreciated until it was shown that vitamin B<sub>12</sub> contains cobalt and that vitamin B<sub>12</sub> is effective in producing hematopoiesis in cases of pernicious anemia. Cobalt is found in organs such as pancreas, liver, and spleen. The human significance and requirement for cobalt are not known. Many vegetables contain traces of cobalt.

**Iodine.** Although this element is distributed throughout the body, it is most highly concentrated in the thyroid gland where it is combined with tyrosine to produce thyroxine, which regulates the body metabolism. Iodine is excreted in urine, sweat, and milk, and, therefore, there is a definite metabolic requirement for iodine. This requirement must be enough to maintain metabolic activity, to meet the basal daily requirement, and to maintain storage or provide some reserve. The requirement for an adult is about 0.15 to 0.3 mg. daily. This need is most easily met by the regular use of iodized salt.

A deficiency in iodine may be produced by increased demand, insufficient intake, or interference with absorption. The normal function of the thyroid gland and the formation of adequate amounts of thyroxine depend on adequate iodine. Abnormal thyroid function results in serious disturbances of growth, development, and metabolism.

The observation that certain plants contain toxic goitrogenic substances further complicates the iodine requirement. However, it has been amply demonstrated that the regular consumption of iodized salt will prevent endemic goiter, and the experimental evidence indicates that iodine deficiency is involved.

**Fluorine.** This element is found in small amounts in animal and plant tissues, and it has been found that the enamel of good teeth contains more fluorine than the enamel of carious teeth. Fluorine in the drinking water at a level of about one

part per million will decrease the incidence of dental caries. It has also been shown that in areas where the drinking water naturally contains about this level of fluorine, there is less caries than in areas where the drinking water is free of fluorine.

Fluorine in greater amounts than this (1.5 to 3.0 p.p.m.) causes the teeth to show brown stain or mottled enamel. These changes are observed only in those individuals who receive this water at the time the teeth are developing. The topical application of fluorine has also shown some benefit in preventing dental caries.

These observations have led to the recommendation that cities give consideration to the addition of fluorine to water supplies that are naturally free of it as a public health measure in the prevention of dental caries.

It should be noted that fluorine is a very toxic substance and the amounts used are very small.

**Manganese.** It has been demonstrated that manganese is an essential element for experimental animals, and that it is important in many enzyme systems. However, the human requirement, if any, is not known and there is no evidence of symptoms of a human deficiency of manganese. It occurs in traces in many foods.

## VITAMINS

About the beginning of the present century, it was recognized that essential nutrient factors were present in foods in addition to fat, protein, and carbohydrates, and in 1911 Funk coined the word *vitamine* which was later changed to *vitamin*. In 1913, McCollum and Davis demonstrated an essential nutrient in certain fats which was designated "fat-soluble A." Later, Drummond proposed that the anti-scorbutic vitamin be classified as "water-soluble C." From these diverse sources the present unwieldy alphabetical nomenclature of the vitamins naturally developed as new ones were discovered and classed as water soluble or fat soluble, although they bear no chemical relationship and most of them may be synthetically prepared and are completely identified and named according to chemical structure.

In spite of the vast body of knowledge which has been so rapidly accumulated about the vitamins, there is still no completely adequate definition. In general, they are organic substances which must be obtained either preformed or as a provitamin. They are required in small amounts; they do not furnish energy, but are absolutely essential for normal metabolic processes, and an insufficient supply results in a specific deficiency disease or metabolic abnormality.

**The Fat Soluble Vitamins.** *Vitamin A* chemically is a long chain alcohol having the empirical formula  $C_{20}H_{29}OH$ . The vitamin is known to exist in two forms: vitamin  $A_1$ , found in salt water fish and mammals; vitamin  $A_2$ , found in fresh water fish. Although there is no difference in biological activity, since vitamin  $A_1$  is the form found in mammalian liver, this is the one that is of particular interest to man.

Vitamin A may be obtained either as the vitamin or as one of the yellow or red plant pigments known as carotenoids from which all vitamin A is formed in the animal body and stored in the liver. These plant pigments are known as provitamin A. B-carotene is probably the best known of these pigments, since each molecule theoretically yields two molecules of vitamin A. In the animal body many factors influence the absorption and conversion of carotene to vitamin A. In calcu-

lating the vitamin A requirement, the carotene in plant sources should be counted as not more than half the value of vitamin A.

Vitamin A is soluble in fats, oils, and most organic solvents. It is insoluble in water and is stable to heat, but is easily oxidized. The vitamin A esters are more stable than the free vitamin, and oil solutions are relatively stable.

Vitamin A is stored mainly in the liver and may be depleted in various liver diseases. The absorption of carotene is interfered with by the presence of mineral oil in the intestinal tract. Its absorption also requires the presence of bile salts.

Vitamin A is measured in terms of international units (I.U.) which are equivalent to U.S.P. units. One international unit of vitamin A is equivalent to 0.344 micrograms of vitamin A<sub>1</sub> acetate or 0.300 micrograms of vitamin A<sub>1</sub> alcohol. The unit for the provitamin is 0.6 micrograms of B-Carotene.

The richest usual sources of preformed vitamin A are liver and fish liver oils. Swordfish liver oil may contain as much as 500 times as much vitamin A per unit of weight as the usual cod liver oil.

The green leafy and yellow vegetables are the chief sources of carotene. Examples are carrots, sweet potatoes, spinach, kale, and collards. Butter and cream contain variable amounts of vitamin A depending on the vitamin A and carotene content of the food of the dairy herd. Margarine is or should be fortified with vitamin A to the level of at least 10,000 I.U. per pound.

Only two of the several substances that have *vitamin D* activity are of practical importance. These are vitamin D<sub>2</sub> (calciferol or viosterol, which is formed by the irradiation of ergosterol) and vitamin D<sub>3</sub> formed by the irradiation of 7-dehydrocholesterol. The latter is the active form which occurs in animal fats and is produced in the skin on exposure to ultraviolet irradiation.

The D vitamins belong to the chemical group of sterols. They are soluble in fats, oils, and organic solvents.

Since foods contain very little vitamin D, it seems quite likely that exposure of the skin to the direct rays of the sun supplies much of the normal adult's vitamin D requirement. Infants and rapidly growing children should be assured of an adequate vitamin D supply either through the regular use of vitamin D milk, a fish liver oil, or one of the many concentrated vitamin D preparations available. The recommended allowance for normal children is 400 I.U. per day. The International Unit is equivalent to the U.S.P. unit (1 unit is the vitamin D activity of 0.025 micrograms of crystalline vitamin D<sub>3</sub>).

Excessively large doses of vitamin D preparations may produce toxic symptoms. These include gastro-intestinal disturbances and an increased blood calcium. If continued there may be calcium deposits in the tissues and serious damage or death.

The most important compounds which exhibit *vitamin E* activity are the tocopherols. Alpha-tocopherol has the highest biological activity. The tocopherols are liquids at room temperature, soluble in fats, oils, and organic solvents, and insoluble in water. They resist heat, but are easily oxidized.

In spite of a large amount of evidence which demonstrates the great importance of vitamin E to successful reproduction in experimental animals and its value as an antioxidant, its role in human nutrition has not been established. It has been used therapeutically in several human conditions such as habitual abortion, menstrual disorders, sterility, muscular dystrophy and heart disease, with inconclusive results.

The tocopherols occur in greatest abundance in the vegetable oils such as wheat germ oil, corn oil, soybean oil, cottonseed oil, etc.

The International Unit and the U.S.P. Unit of vitamin E are equivalent. One unit is the activity of 0.1 gm. of standard solution containing 1.0 mg. of synthetic alpha tocopherol acetate.

Several substances are known to have *vitamin K* activity. The most important are vitamin K<sub>1</sub> which occurs in the green leaves of plants; vitamin K<sub>2</sub> which has been obtained from putrefying fish meal; and menadione which is a synthetic vitamin K of greater activity than the natural vitamin K<sub>1</sub>. These substances chemically are naphthoquinones. They are fat soluble and stable to heat, but lose activity in the presence of alkali, strong acids, or on exposure to light.

Since vitamin K is abundantly distributed among the leafy vegetables, and is also synthesized in the intestinal tract, any good diet appears to meet the normal vitamin K requirement.

Bile salts are necessary for the absorption of vitamin K and deficiency may result from faulty absorption if bile salts are not present in the intestinal tract as in obstructive jaundice. Vitamin K deficiency also may occur when lipid absorption from the intestinal tract is impaired in conditions such as sprue and pancreatic disease. Vitamin K deficiency results in hypoprothrombinemia and defective blood clotting. This is especially important in hemorrhagic disease of the newborn. Vitamin K preparations are also used to reverse the prolonged clotting time induced by the therapeutic use of dicumarol.

The three most important *unsaturated fatty acids* are linoleic acid (C<sub>18</sub>H<sub>32</sub>O<sub>2</sub>), linolenic acid (C<sub>18</sub>H<sub>30</sub>O<sub>2</sub>), and arachidonic acid (C<sub>20</sub>H<sub>32</sub>O<sub>2</sub>). These substances are included in the vitamins because the early literature uses the term "vitamin F" to designate them. This has now been discarded. The unsaturated fatty acids are required by experimental animals in small amounts, but the human need, if any, is not known. They occur naturally in various fats. Linoleic and linolenic acids are found in vegetable fats and seed oils. Arachidonic acid occurs in animal fats.

**The Water-Soluble Vitamins.** *Thiamine* (vitamin B<sub>1</sub>) contains both a thiazole and a pyrimidine ring which are easily split by sulphite. As thiamine hydrochloride it is a white, crystalline, water-soluble compound with a yeasty odor. It will not stand autoclaving in neutral or alkaline solutions, but is more stable to dry heat or in acid solutions. It is soluble in water and alcohol.

The metabolically active form of thiamine is the pyrophosphate ester cocarboxylase which is a coenzyme in carbohydrate metabolism and is essential for the complete, normal metabolism of carbohydrate. In thiamine deficiency, therefore, carbohydrate metabolism is impaired and pyruvic acid accumulates. The clinical condition produced is beriberi. Thiamine is found in small amounts in a wide variety of foods. Good dietary sources are pork, legumes, nuts, whole grain or enriched flour, and oatmeal. However, the quantity of thiamine needed usually must be met from a variety of sources since no single food is likely to contain enough to make it a major source in the diet. Furthermore, the heat lability of thiamine and its water solubility may result in large cooking losses unless care is used in preparation.

The recommended daily allowance of thiamine for an adult is 1 to 1.6 mg. per day. An international unit for thiamine is no longer necessary and quantity is usually

expressed in terms of weight of pure thiamine. The old international unit is still sometimes used. This is the activity of 3 micrograms of thiamine hydrochloride.

*Riboflavin* (vitamin B<sub>2</sub>) chemically consists of an isoxanthine nucleus to which is attached a molecule of the five carbon sugar ribose. In its active metabolic form it is phosphorylated and combined with a protein to form the flavoproteins which form a part of several important enzyme systems.

Riboflavin is an orange yellow crystalline compound which forms a greenish yellow fluorescent solution in water. It is sparingly soluble in water and stable to heat. It is easily destroyed by exposure to light.

Since riboflavin is probably a constituent of every living cell, it is widely distributed in both plant and animal foods. The best dietary sources are liver, leafy vegetables, cheese, eggs, and milk. The recommended daily allowance of riboflavin for an adult is 1.4 to 1.6 mg.

*Niacin* (nicotinic acid; pellagra-preventive factor) is a pyridine derivative. It is a white crystalline compound which is soluble in water and alcohol. It is very stable and is not destroyed by autoclaving. The amide is the metabolically active form and forms part of the molecule of coenzymes I and II which play important roles in cellular respiration.

The recommended daily allowance of niacin for the normal adult is 10 to 16 mg. The requirement for niacin is conditioned by the amount of the amino acid, tryptophane, in the diet, since tryptophane may be converted in the body to niacin.

Good food sources of niacin are liver, lean meats, poultry, fish, peanuts, and dried yeast.

*Vitamin B<sub>6</sub>* is the name adopted for a group of three closely related substances—pyridoxine, pyridoxal and pyridoxamine. All three are equally effective in animals but differ in their growth stimulating effect on certain bacteria. Pyridoxine is formed in plants and pyridoxal and pyridoxamine in animals. The active metabolic form of vitamin B<sub>6</sub> is pyridoxal 5-phosphoric acid. This is the coenzyme for a large number of reactions in the transamination and decarboxylation of amino acids, especially in the reactions of the degradation of tryptophan. Vitamin B<sub>6</sub> also participates in the conversion of protein to fat and in the formation of highly unsaturated fatty acids.

The recommended intake of vitamin B<sub>6</sub> is from 1 to 2 mg. daily.

Vitamin B<sub>6</sub> deficiency in infants may upset cerebral metabolism and produce convulsive seizures.

Good food sources are liver, wheat germ, yeast and legumes.

*Pantothenic acid* (filtrate factor) is a chemical derivative of beta-alanine. As the calcium salt it is a white crystalline compound. It is soluble in water and stable to heat and oxidation. Pantothenic acid is very widely distributed in nature and is found in many tissues. In experimental rats, a deficiency results in necrosis of the adrenals; neuropathology has been observed in swine, and sudden collapse in dogs. As a part of coenzymes it participates in many metabolic reactions and appears to be an essential metabolite for all animals. A syndrome of "burning" feet in man has been attributed to pantothenic acid deficiency. Nevertheless, the human requirement, if any, is unknown.

Good food sources of pantothenic acid are liver, lean meats, salmon, soybeans, peanuts, bran, and broccoli.

*Ascorbic acid* (vitamin C) occurs as a white, crystalline compound which is readily soluble in water. It is the least stable of the vitamins and is rapidly destroyed by oxidation, especially in neutral or alkaline solution. Destruction is catalyzed by the presence of copper which accounts for the absence of vitamin C from pasteurized milk. Since milk is naturally a poor source of vitamin C, this is of no practical significance.

It occurs both as the free acid and in the oxidized form, dehydro-ascorbic acid. Both forms are physiologically active.

Ascorbic acid is a constituent of all cells. The only practical experimental animals for demonstrating ascorbic acid deficiency are monkeys and guinea pigs, since other animals are able to synthesize the vitamin. In plants it is found most abundantly in the rapidly growing portions of the plants, and synthesis takes place in relation to exposure to sunlight. The concentration is highest at the end of a sunny day. Fruits and vegetables lose their vitamin C rapidly unless refrigerated.

Physiologically, vitamin C is necessary in the organism for proper bone and tooth formation, it is related to amino acid metabolism, and is required for normal collagen formation in wound healing. The amount in the adrenal gland is under hormone control and it may play a role in erythropoiesis. A deficiency of ascorbic acid results in scurvy.

The daily recommended allowance of ascorbic acid for the normal adult is 70 to 75 mg. Good dietary sources are the citrus fruits, tomatoes, cabbage; green leafy vegetables such as kale, broccoli, and turnip greens; and other fruits such as strawberries and cantaloupes.

*Inositol* is a very stable, crystalline compound belonging to the cyclohexanes. It is widely distributed in plants as a complex inositol phosphoric acid compound called phytin. It has been shown to be required by some animals. It is not known to be of any significance in human nutrition.

*Biotin* was for a while designated as vitamin H. It is a cyclic derivative of urea, slightly soluble in water and stable to heat and acids. In experimental animals other than the chicken, raw egg white will produce the skin lesions of biotin deficiency. This is due to the presence of the protein avidin in raw egg white with which biotin combines to become unavailable and is excreted in the feces. Biotin deficiency may also be produced by the administration of an antimetabolite or by destruction of the intestinal flora.

Although humans may require biotin, it seems unlikely that biotin deficiency will naturally occur since biotin is supplied both in the food and by intestinal bacterial synthesis.

*Folic acid* (folacin; vitamin M or vitamin B<sub>9</sub>) is pteroylglutamic acid. It exists as the triglutamate or as the heptaglutamate which is the conjugated form in yeast. It occurs as bright yellow crystals which are slightly soluble in water. Solutions deteriorate on exposure to light.

In experimental animals, a deficiency in folic acid results in anemia and granulocytopenia. The human requirement has not been established. Folic acid is effective in producing a hematologic response in macrocytic anemias but the central nervous system lesions of pernicious anemia do not respond to folic acid. Vitamin B<sub>12</sub> is necessary for a complete response.

Folic acid is widely distributed in nature. Good dietary sources are liver and green leafy vegetables.

*Vitamin B<sub>12</sub>* is a bright-red crystalline compound of high molecular weight containing cobalt. It is heat stable and was originally isolated from liver. It is produced by some micro-organisms. In experimental animals it has been shown to have "animal protein factor" activity through its growth-stimulating effects on animals on vegetable protein diets. Studies on its possible growth stimulating effect on children are inconclusive.

In humans it is very effective in treating pernicious anemia and some other macrocytic anemias. One microgram is equivalent to one unit of anti-pernicious anemia activity in liver.

The human requirement is unknown.

*Choline* is a quaternary ammonium compound usually available as choline chloride which is a very hygroscopic crystalline substance with a disagreeable taste. It is stable to acid and unstable to alkali. It occurs as a part of the phospholipid lecithin.

The principal function of choline appears to be as a source of labile methyl groups. Therefore, the need for choline is related to the amount of the amino acid methionine available.

An acute deficiency of choline in experimental animals results in hemorrhage and necrosis of the kidneys. Under controlled conditions an episode of choline deficiency may be followed at a later time by hypertension. Choline deficiency results also in fatty and cirrhotic livers. It is being tried in the control of human liver cirrhosis.

The human requirement for choline has not been determined.

Good dietary sources of choline are liver, egg yolk, meats, soybeans, wheat, and oatmeal.

**OTHER WATER-SOLUBLE VITAMINS.** There are a few substances of relatively minor importance in addition to the above which are sometimes included in this classification, such as para-aminobenzoic acid, vitamin P, adenylic acid, and possibly other less well recognized substances. These are of such questionable value to man they do not warrant discussion in this chapter.

**Antivitamins.** There is a growing recognition of the possible importance of a group of chemical substances which have an antagonistic action to specific vitamins. These substances are closely related chemically to the vitamins and appear to be capable of displacing the vitamin in metabolic reactions. These substances were largely of experimental importance in studying vitamin action until one of the antagonists of folic acid was shown to have a beneficial effect in leukemia. This suggests that other antivitamins may have some practical value. Examples of vitamins and antagonists are:

VITAMIN	ANTAGONIST
Thiamine	Pyriethamine
Riboflavin	Isoriboflavin
Pyridoxine	Desoxypyridoxine
Pantothenic acid	Methylpantothenic acid
Biotin	Desthiobiotin
Folic acid	Methyl folic acid
Vitamin K	Dicumerol

**Water.** Although not usually included in dietary essentials, water is so important to the nutritional well-being of the individual that it must not be neglected in dietary calculations. In normal individuals the sensation of thirst is usually a guide. Water should not be restricted unless there are medical indications for this. A usual allowance of water for adults is 2.5 liters daily. Much of this is obtained in foods. Under unusual conditions of heat, work, and sweat, requirements may go very high—up to 13 liters daily.

# 11

## MALNUTRITION

Malnutrition is a very broad term meaning any one of many manifestations of any type of disorder in the nutritional state of the individual. Thus, obesity as well as starvation is a form of malnutrition. Malnutrition presents itself in a varied series of disease conditions according to the specific nutrient involved. It is most frequently seen as a complex clinical syndrome presenting a confusing mixture of symptoms due to a simultaneous deficiency in several specific nutrients. Nevertheless, the symptoms of the various deficiencies are sufficiently well defined for specific diagnosis to be made.

It is frequently assumed that the only cause of malnutrition is a failure to consume an adequate diet because of unavailability of food. This unwarranted assumption may be the cause of missing the diagnosis in many cases of malnutrition. Although economic factors, famine, ignorance, bad dietary habits, and similar causes may lead to widespread malnutrition in large population groups, there are many other causes that must be taken into consideration which result in serious malnutrition in the presence of an apparently adequate food supply. Thus, such apparently simple things as lack of teeth, food allergies, mental conditions, and alcoholism may all result in failure to eat available food and produce malnutrition. The presence of other disease is a most important factor in producing malnutrition, and many of the most serious cases seen in this country occur as complications of other diseases. Such diseases as hyperthyroidism may increase the need for nutrients. Diseases of the intestinal tract producing diarrhea, nausea, anorexia, achlorhydria, or other changes such as occur in tuberculosis, malignancy, liver and gallbladder disease, pregnancy, etc., may interfere with absorption or utilization, or result in increased excretion and thus produce malnutrition.

The most important forms of malnutrition are as follows:

1. **Underweight and Starvation.** In its extreme form, this is the most obvious form of malnutrition and results from a continued calorie deficiency. With a deficient energy intake, the body must utilize its own fat and other tissues, producing loss of weight and, in children, stunted growth and development. In serious starvation there is a reduction in metabolic rate, a slowed and weak pulse, a lowered blood pressure, loss of body fat and wastage of muscle, decreased muscle tone, loss of skin elasticity, mental dullness, and easy fatigue. In many famine situations diarrhea is common, but the cause is not clear. In extreme starvation edema appears in the dependent portions of the body and increases as the starvation proceeds until the body is severely waterlogged and body weight determinations are useless. Death frequently occurs from heart failure even after remedial feeding has been started.

The possible importance of mild degrees of emaciation, especially in children and as complications of diseases, has not been determined and may be difficult to detect. Tables of age, height and weight are not very helpful in assessing the individual, although they may be very useful statistically. This is because of the variations which occur in the size of the bones and in the relation between weight of organs and musculature in relation to weight of body fat. If the subcutaneous fat is gone and the skin is thin and lacking in elasticity, an early stage of underweight should be suspected and further evidence sought. In this connection accurate information on the previous body weight is important since a rapid loss of a considerable amount of weight (in the absence of a clearing edema) constitutes a more serious clinical situation than a very slow loss. In cases of starvation the symptoms of specific deficiencies in vitamins and minerals are likely to be minimal.

Children usually make good recoveries from partial starvation and recover their lost weight. Adults recover very slowly and complete recovery is a matter of months. Mental changes are variable. In extreme starvation, care must be used in early feeding and milk, if available, is well tolerated. Overfeeding may cause death and intravenous injections may result in pulmonary edema or death from heart failure.

**2. Obesity and Overweight.** In the final analysis this may be as serious a form of malnutrition as starvation. The true medical importance of obesity is just being appreciated. In this country it is perhaps the most prevalent form of malnutrition. Its importance bears a direct relation to age. The older the individual, the more important that he not be loaded with an excess of fatty tissue.

The basic cause of obesity is the reverse of the cause of starvation. It is the continued intake of food in excess of that needed to meet the energy requirements of the body. The reasons why individuals eat more food than they require are very complex and appear to be deeply involved in dietary habits perhaps established in youth, to mental and emotional problems involved in frustrations and emotional relief obtained from the sense of gratification supplied by an overly full stomach, and various other factors.

The diagnosis of obesity requires more than a casual glance at the patient. Various postural abnormalities and certain diseases may give the patient an appearance resembling obesity superficially when the patient may actually be emaciated. It should be determined that the patient is actually carrying an excess of adipose tissue.

The prevention of obesity is much easier than its treatment. It requires an appreciation of the importance of the condition, frequent accurate determinations of body weight and restraint in food consumption if fat is accumulating. It involves educating the public to realize that overeating may be as bad as undereating.

The only treatment for obesity of any consequence is to reduce the caloric intake enough to create an energy deficit. The rate of loss of weight is controlled by the amount of the energy deficit. Although this sounds simple, it is very difficult to achieve success unless the patient has a real urge to reduce and to stay thin. This means that basically the underlying emotional factors which created the obesity must be corrected or overcome by a greater urge such as a fear of early death. Exercise and medication are merely useful adjuncts of limited value.

**3. Protein Deficiency.** Protein deficiency may be either acute or chronic. An acute deficiency may result from a severe hemorrhage, an extensive burn or severe

injury, or large exudation or transudation of body fluid. In acute severe protein loss, there is shock and there may be circulatory collapse. Chronic protein deficiency follows a period of negative nitrogen balance which may be caused by inadequate protein intake; or by some condition creating increased protein catabolism; or by interfering with absorption or utilization such as intestinal obstruction, chronic diarrhea, liver disease, steatorrhea, etc. In most instances, the clinical picture is one which also involves starvation. There is anorexia, secondary anemia, weight loss, and weakness. The skin loses elasticity, wounds do not heal well, ulcers appear, diarrhea is common. The plasma protein level is lowered. In the severe stages edema appears in dependent portions of the body and is at first transient, later increasing until it may involve the entire body. This is accompanied by severe muscle wastage. Prevention and treatment involve supplying adequate protein of good quality. In treatment the same precautions must be observed as in starvation. Intravenous feeding is dangerous in severe cases. Protein hydrolysates, milk, transfusions, amino acid mixtures, etc., may be used freely to supply the necessary protein with due caution about overfeeding severe cases.

4. **Vitamin A Deficiency (Xerophthalmia).** This vitamin has several important functions in the body and a deficiency produces symptoms related to these disturbed functions. Vitamin A is necessary for normal bone growth. Since it is a component of the visual purple of the retina, it is essential to normal vision. It is also essential for the normal functioning of glandular and epithelial tissue. In vitamin A deficiency, secreting epithelium tends to keratinize and cease functioning, resulting in a wide variety of symptoms.

In humans one of the common symptoms of vitamin A deficiency is hemeralopia or night blindness. This is an interference with vision in dim light related in all probability to interference with formation of the visual purple of the rods of the retina.

Skin changes consist of a follicular hyperkeratosis which may appear first on the extensor surfaces of the thighs and the lateral surface of the forearms. The face, back, and chest may be involved also. Comedones and small pustules may occur. Eye lesions result from changes in the lacrimal gland which cause drying and thickening of the conjunctiva: Bitot's spots, followed by swelling and redness of the eyelids; photophobia; secondary infections; ulcers and panophthalmia with blindness. In very serious cases the interference with normal epithelial function may result in bronchopneumonia, middle ear and kidney infections. Prevention consists of including in the diet foods containing vitamin A or carotene in the needed amounts. The essential in treatment is the administration of large doses (25,000 to 100,000 I.U.) of vitamin A daily to adults, accompanied by dietary correction. If complicating disease is contributing to the deficiency, it must be corrected.

5. **Rickets (Vitamin D Deficiency).** Rickets is a chronic nutritional disorder of the young, characterized by changes in the bones. Rickets is characterized by an alteration in the structure and growth of bones, which become enlarged at the extremities and so soft that they bend under the weight of the body. It occurs during the first two years of life, when growth is rapid. The symptoms develop gradually, and when well advanced the disease is characterized by restlessness and night sweating, delayed dentition, softening of the skull bones, and flabby muscles. Rickets is responsible for bowed legs, knock knees, flatfeet, and saber legs, and is associated

with the rickety rosary, pigeon breast, square head, and pot belly, a strange medley that finds its most exaggerated expression in misshapen dwarfs.

Rickets constitutes one of the important diseases of infancy on account of its prevalence, its serious complications and sequelae, and the fact that it is readily preventable. Deformity of the bones of the pelvis produced by rickets in childhood is one of the causes of difficult labor, and may result in fetal or maternal death.

Rickets first manifested itself in Europe in the sixteenth century. The reason is obvious. Populations, particularly in England—a country never noted for its abundance of sunlight—were attracted to city life with its impoverished diet and bad housing. Rickets became so prevalent by 1650 as to call forth Glisson's famous monograph on the subject. It was not until 1885 that Pommer described its pathology.

Rickets occurs mostly in cities. It began in the cities of Europe and later appeared in North America. In India it is found as osteomalacia among the upper classes, due to "purdah," or the custom of keeping women with their children permanently in darkened houses; the lower classes, even with a restricted diet, are spared because they live so much in the sun. It is not infrequent in northern Africa, for example in Algiers, as well as in northern China. In Japan it is very common.

The poor suffer most, although the children of the well-to-do are not spared. Rickets is much more prevalent than is indicated by the meager figures found in vital statistics. It does not appear in the mortality tables because it is seldom a direct cause of death.

Rickets begins to increase in the fall, becomes more marked in the winter, and reaches its peak in March; it then declines steadily, and new cases rarely develop after June. Rickets is most frequent during the second half of the first year of life or the first half of the second year. It often occurs earlier, but is not congenital. Premature infants are notably predisposed to rickets, probably on account of their exceptionally rapid rate of growth. To a less extent this is true of twins.

In the temperate zones, rickets is more frequent among colored and dark-skinned races than white on account of the pigment armor against the effect of sunshine. As is well known, Italian and Negro babies in our large cities are especially prone to develop this disorder.

The earliest symptoms are restlessness, irritability, and head sweating—signs which are suggestive rather than indicative. Soon thereafter, enlargement of the costochondral junctions (the rachitic rosary) develops. The head becomes somewhat square in shape, the fontanel is too widely open, the areas of softness may be felt along the lower part of the occipitoparietal suture. The epiphyses at the wrist may be enlarged and radiographs disclose changes in the ulna typical of rickets. There is a decrease in serum phosphorus and an increase in alkaline phosphatase. All these signs are not present in every case. Radiographic changes in the ends of the long bones are characteristic but do not appear early. The rachitic process must have been developed for some months before the lesions can be demonstrated by the roentgen ray.

The well-developed or advanced case presents a picture which is evident at a glance. The head is square, the thorax deformed, showing two lateral rows of visibly enlarged costochondral junctions and a groove traversing its lower part (Harrison's groove). The abdomen is large and protuberant—the well-known "pot belly"; con-

stipation rather than diarrhea is the rule. The legs are bowed or knock-kneed and the ligaments lax. The infant may no longer be well-nourished, for the extreme cases are associated with retardation in growth and weight.

The majority of cases are mild; so mild indeed that many pass unrecognized and leave no local deformity or systemic disturbance. Recovery comes about spontaneously as the result of the fortuitous advent of spring or summer, or the decrease in rate of growth. Bowed legs, beading of the ribs, and enlarged epiphyses gradually disappear and the bones regain their normal contour in most cases. However, these signs may persist, as well as the square head, the deformed chest, the scoliosis, kyphosis, flatfoot, etc.

The cause of rickets is a deficiency in vitamin D brought about by failure to expose the skin to the ultraviolet rays of the sun. Under modern conditions in temperate climates this is usually not practicable in the wintertime and a dietary source of vitamin D is necessary if rickets is to be prevented. The full-term infant should receive 800 I.U. daily of vitamin D during the first year of life; during the second year, 400 I.U. daily. Premature infants require larger amounts. In treatment, 4,000 to 5,000 I.U. daily may be used for as long as 5 to 6 weeks. Some cases of refractory rickets may require much larger dosage.

One of the most useful forms of vitamin D in preventive medicine is vitamin D milk, which is now available in most cities in this country, and contains 400 I.U. of vitamin D per quart. This is available either as fresh, dried, or evaporated milk and offers a simple, practical, and economical method of ensuring a regular intake of vitamin D, which can be supplemented by medicinal preparations of higher potency when indicated.

Osteomalacia is the adult counterpart of rickets in infants.

**6. Hemorrhagic Disease of the Newborn (Vitamin K Deficiency).** Since vitamin K is usually supplied from synthesis by intestinal bacteria as well as from the diet, there is little evidence of vitamin K deficiency in adults except in conditions where there is interference with lipid absorption such as chronic ulcerative colitis, steatorrhea, etc. Normal absorption requires the presence of bile salts in the intestinal tract and, therefore, obstructive jaundice may produce vitamin K deficiency. The essential difficulty in vitamin K deficiency is a hypoprothrombinemia, which prevents normal blood clotting. The lack of bacterial synthesis of vitamin K in the intestinal tract of the newborn infant probably explains the hypoprothrombinemia usually seen. In an occasional infant this results in hemorrhages during the first week of life called "hemorrhagic disease of the newborn." The condition may be prevented by parenteral administration of 1 mg. of a vitamin K preparation to the mother during the last week of pregnancy or just before delivery or to the infant at birth.

Treatment consists of giving a vitamin K preparation if there is a prolonged prothrombin time and a hemorrhagic tendency.

**7. Beriberi (Thiamine Deficiency).** The clinical descriptions of severe beriberi in the older literature probably include symptomatology from multiple deficiencies, although the most prominent findings were the result of thiamine deficiency. The underlying defect in thiamine deficiency is a deranged carbohydrate metabolism. Thiamine is essential for the formation of cocarboxylase. If there is insufficient cocarboxylase, the carbohydrate intermediate pyruvic acid begins to accumulate in abnormal amounts in the system and other metabolic derangements also probably

occur. This derangement in carbohydrate metabolism appears then to lead to a variety of symptoms depending on the severity of the deprivation of thiamine and the acuteness of withdrawal.

Just as in the other deficiencies, thiamine deficiency may occur either as a result of insufficient intake or from factors in the body influencing absorption, destruction, utilization, or excretion. Since thiamine is necessary for normal carbohydrate metabolism, the administration of glucose parenterally in large amounts should be accompanied by administration of thiamine or deficiency symptoms may be precipitated in a thiamine-depleted individual. A diet high in refined sugar and starch requires the presence of adequate thiamine. A diet high in fat requires less thiamine.

The symptoms of thiamine deficiency may be classified as neurological, cardiac, and gastro-intestinal.

The earliest symptoms of thiamine deficiency are referable to the central nervous system. The symptoms are those of neurasthenia, loss of attention, irritability, vague fears, emotional disturbances, etc. This is followed by a peripheral polyneuritis beginning as a hyperesthesia and paresthesia of the extremities, especially the toes and feet, which may become quite severe. There is tenderness and weakness of the calf muscles, and the patient has difficulty in rising from a squatting position. Loss of the ankle jerk reflex and loss of vibratory sense over the great toe and malleoli may appear early. In severe cases the condition progresses to wrist or ankle drop with muscular atrophy and serious disturbance in walking.

The cardiac symptoms in the early stages are those of tachycardia, shortness of breath, heart consciousness and dizziness, and irregularities in the heart beat. The heart rate may be slowed. The electrocardiogram usually shows a decrease in amplitude or an absence of the T-wave. In more advanced cases, edema of the extremities appears which becomes extensive with serous effusions and signs of congestive heart failure, accompanied by right-sided dilatation of the heart and enlargement of the liver. This serious stage of the disease may lead to sudden circulatory collapse and death. Patients with beriberi should be kept in bed in order to avoid an unexpected circulatory failure and death.

The gastro-intestinal symptoms are less important than the neurological and cardiac. They consist of loss of appetite, indigestion, constipation, and occasionally vomiting. The x-ray shows atony and dilation of the bowel.

Infantile beriberi is a serious condition and in some areas is a leading cause of infant mortality. It may occur in a nursing infant if the mother is depleted of thiamine. The mother may be free of gross clinical symptoms of beriberi.

The prevention of thiamine deficiency is theoretically simple, but practically difficult. Beriberi is most prevalent in those areas of the world where rice is the staple cereal, although it is now known to occur widely in mild form in many other areas where refined carbohydrate foods constitute a considerable item of the diet. It is well known that if brown, unpolished rice is substituted for polished rice beriberi will be prevented due to the thiamine content of the outer layers of the rice. In areas of the world where other cereals predominate, the whole cereal supplies more thiamine than the refined product since as a general rule the thiamine in the cereals is concentrated in the germ and the outer coatings of the crude grain. However, in spite of vigorous efforts to substitute the brown rice for white rice this has never succeeded for a variety of reasons, among them poorer keeping qualities which

interfere seriously with storage and a social factor in addition to taste preference. These difficulties led to efforts to popularize and extend the use of parboiled rice which is a satisfactory product and has met with some limited success. A new development which offers considerable promise is the work of Salcedo in the Philippines, who has shown it is practical to add thiamine to white rice and that this "enriched rice" is acceptable and most effective in controlling beriberi. This "enrichment" of white rice is now required by law in the Philippines. This is an extension to rice of the procedure used in the United States for "enriching" white flour and corn meal in order to improve their thiamine content without altering the desirable features of the refined product. Other methods of reducing the prevalence of beriberi consist of education and attempts to include in the diets foods containing thiamine.

The treatment of beriberi requires the administration of thiamine in doses of 10 to 50 mg. daily by mouth or parenterally, depending on the severity of the case. It should be used with care intravenously since a few deaths, apparently of an anaphylactic type, have been reported.

8. **Ariboflavinosis (Riboflavin Deficiency).** Riboflavin is a constituent of several enzyme systems and occurs probably in all the cells of the body. It functions in the metabolism of both carbohydrates and proteins. The mechanism by which the deficiency symptoms are produced is unknown. The symptoms may be classified as ocular, oral, and dermal.

The ocular symptoms are essentially those of an interstitial keratitis. There is photophobia, lacrimation, and injection of the vessels of the cornea with a complaint of a gritty feeling of the eyes. A mild photophobia may be an early symptom. In severe stages the patient cannot stand light at all because of the pain and the condition may superficially resemble a severe conjunctivitis. There is a circumcorneal injection of the vessels and slit lamp examination reveals extension of numerous capillaries from the limbic plexus into the cornea. Corneal opacities appear and may become dense with almost total blindness. Such opacities, if recent, show remarkable improvement on riboflavin therapy.

The oral lesions consist principally of changes in the lips. The mucosa of the lips becomes denuded, shiny, reddened, and scaly, resembling a "chapped lip." In addition, a macerated area appears in each angle of the mouth, followed by the development of a small transverse fissure which tends to extend onto the face rather than into the mouth. These fissures have been designated "angular stomatitis" and the entire lip lesion has been called "cheilosis." In some cases the tongue takes on a magenta hue.

The dermal lesions are seborrheic in nature and usually appear as greasy flakes over an erythematous base and are seen in the various folds of the body, especially the nasolabial folds, the canthi, behind the ears, the axillae, and groin. They may become secondarily infected and involve considerable areas of the body. In many cases filiform excrescences appear and project from the sebaceous follicles across the nose and cheeks, especially producing what has been called "shark-skin."

The riboflavin requirement is usually met from a number of food sources. Prevention is accomplished by supplying riboflavin-containing foods. In the United States, the use of riboflavin to "enrich" white flour makes a significant and cheap source. Milk and green leafy or yellow vegetables are other important sources.

Treatment requires the administration of 15 to 20 mg. of riboflavin daily in divided doses.

9. **Pellagra (Niacin Deficiency).** Although this disease is basically due to a deficiency in niacinamide, its occurrence is also controlled by the amount of tryptophane in the diet since the quantity of this amino acid that is present affects the need for niacinamide. This has led to much confusion in attempts to relate diet composition to the occurrence of pellagra.

As in beriberi, the older clinical literature gives a description of the symptoms of pellagra which in the light of present knowledge was a multiple deficiency state. The neurological symptoms were probably due to thiamine deficiency and the condition called "pellagra sine pellagra" appears to have been riboflavin deficiency. It should always be kept in mind that the clinical picture in deficiency disease is most likely to be a multiple deficiency state. It seems desirable to use the designation "pellagra" for the clinical syndrome produced as a result of niacin deficiency, although in practice it is recognized that the case may have symptoms of other deficiencies simultaneously.

Outbreaks of pellagra resembling epidemics occur in localities with restricted food conditions; sporadic cases may crop out anywhere and have a world-wide distribution. A marked feature in the United States is the high prevalence in late spring and early summer, following the limited winter diet. Under unfavorable dietary and economic conditions in endemic localities, pellagra recurs year after year, giving a false impression of chronicity. *Black tongue*, a disease in dogs, resembles pellagra pathologically, and is due to dietary defects similar to those which cause the disease in man.

The digestive symptoms of pellagra are dyspeptic disturbances and later stomatitis. Nervous manifestations begin with weakness, vertigo, and insomnia. About 2 per cent of pellagrins develop mental disturbances requiring institutional care. The skin eruption is the most characteristic sign. It begins as an erythema, usually bilateral and symmetrical, affecting especially the backs of the hands and forearms, the face and neck, feet and genitalia. The symptoms vary greatly in severity. Fully developed cases present a characteristic picture.

Sporadic or endemic pellagra has now been reported from nearly all parts of the civilized world. In Europe, the disease has long prevailed in Portugal, Spain, Italy, and Rumania, while the northern countries have been slightly if at all affected. Pellagra also is unevenly distributed in America. It has prevailed especially in the southern part of the United States and some of the West Indies, while Canada, Mexico, and South America have remained well-nigh free. The areas of the world most affected are the northern part of Italy, Rumania, lower Egypt, Yugoslavia and in the United States the regions south of the Ohio and Potomac Rivers.

Endemic areas have widely contrasting conditions of climate and soil. In the United States, the prevalence is in the late spring and early summer. There is no special race susceptible. In some localities the white and in others the colored pellagrins predominate.

The disease may develop at any age, but is rarely seen during the first year of life. It attacks both sexes about equally during childhood and adolescence, but many more cases are seen in adult women than in men.

Sporadic cases may occur anywhere at any time, even in well-to-do families.

These are due to eccentricities of diet, food fads, gastro-intestinal diseases, chronic alcoholism, deranged mentality, or other conditions which cause the diet to become one-sided, restricted, monotonous, and faulty in one or more respects.

In Europe, the disease attacks almost exclusively the peasant farm laborer. In the endemic area in the United States, it also has a marked rural distribution but is not restricted to the agricultural population. Indeed, with us, pellagra has prevailed extensively in certain types of rural industrial communities, such as cotton mill villages, mining and sawmill camps.

The symptoms of niacin deficiency are glossitis, gastro-intestinal disturbances, and skin lesions. In mild cases the glossitis may be manifested only by reddening of the tongue with loss of papillae. In acute cases there is a severe burning sensation in the mouth. The tongue becomes very bright red and sore and denudation of both tongue and cheeks occurs with pseudomembrane formation and the picture is one of severe acute stomatitis resembling an extensive Vincent's infection of the mouth.

The earliest symptoms of niacin deficiency are loss of weight, weakness, mental depression, and gastro-intestinal distress with gaseous eructations and indigestion. This is followed by diarrhea or alternating diarrhea and constipation, with more distressing indigestion, nausea, and vomiting. Gastric analysis shows an achlorhydria.

The dermal lesions are most characteristic. In old chronic and mild cases the pressure points, such as elbows and knees, show dry, scaly, darkly pigmented areas which may also involve the legs or forearms where the skin assumes a thin, cracked appearance called "pavement epithelium." The acute case begins like a sunburn with an acute erythema. This goes on to desquamation or to bullae formation followed by desquamation. The lesion is fiery red, painful, and usually becomes secondarily infected. It is most frequently bilateral on the extremities or appears across the face or around the neck. The genitalia are frequently involved. The skin lesion has a sharp line of demarcation from the normal skin and becomes heavily pigmented during healing. The pigmentation may persist for a long time after the lesion has completely healed.

Many cases show mental changes characterized by depression, fear, confusion, and impaired memory. These lesions may go on to a major psychosis. Another type of mental change is an encephalopathy with cogwheel rigidities, grasping and sucking reflexes, and disorientation.

Prevention of niacin deficiency requires foods containing either niacin or tryptophane. Thus milk, although low in niacin, is a very useful preventive because of its tryptophane content. Enrichment of corn meal and white flour with niacin has made a widespread valuable contribution to the niacin content of diets in the United States.

In treatment, niacinamide or niacin should be used in daily doses of 150 to 500 mg. by mouth. In cases with encephalopathy larger doses given parenterally are required. Niacinamide is usually preferred to niacin since the latter gives a flushing reaction which is uncomfortable but apparently harmless.

10. **Scurvy (Vitamin C Deficiency).** Scurvy is a typical deficiency disease due to lack of the specific food factor vitamin C. It is a disorder of nutrition, usually brought on by the prolonged lack of fresh food in the ration, and is characterized by debility, anemia, a spongy condition of the gums, and a tendency to hemorrhages. The lesions occur especially in the bones and the blood vessels. The essential pathology is failure to form and maintain intercellular substance.

Scurvy occurs independently of age, sex, and general vitality, if the diet is deficient. It may develop in vigorous adults and even in the aged, but it is especially prevalent in infants because of the monotonous one-sided diet of cow's milk or some proprietary food lacking in the specific vitamin.

Scurvy ordinarily is caused by a lack of fresh fruit and vegetables in the diet. The potato is the mainstay against scurvy during the winter months in some countries. Foods lose their vitamin C on aging; fresh vegetables are superior to those which have been dried or stored for long periods. If foods are protected from oxidation during canning there should be little loss of vitamin C. This is especially true of the acid foods such as tomatoes. In cooking, foods should be protected from exposure to air; soda should not be used; cooking water should not be discarded; cooking time should be as short as possible; foods should not be beaten (such as mashing potatoes) and should be served as soon as possible after preparation if vitamin C is to be retained.

Severe adult scurvy is relatively rare in the United States. It apparently requires several months of severe vitamin C deprivation to produce the severe clinical condition. It is not clear how much lesser degrees of deprivation have to do with the occurrence of chronic gingivitis, pyorrhea, and similar conditions.

Severe adult scurvy begins with weakness, loss of weight, and muscle pains. The gums are swollen and hemorrhage freely and the teeth become loosened. Hemorrhages occur in all parts of the body on the slightest trauma. There may be severe nose bleed, hematuria, and cerebral or retinal hemorrhages. Slight skin trauma results in the appearance of "bruises." Death may occur from heart failure on exertion.

Infantile scurvy presents a different picture and is much more prevalent. It occurs almost exclusively in artificially fed infants and most frequently under one year of age. The symptoms are irritability, anorexia, and loss of weight, with pain on movement or on handling. The child does not voluntarily move the extremities because of pain. Hemorrhages are usually found under the periosteum of the bones which produces swelling which does not involve the joint. Hemorrhages may occur anywhere in the body. Enlargements are usually found at the costochondral junctions resembling rickets. X-ray examination reveals a typical picture with thickening of the epiphyseal line at the ends of the long bones where growth is most rapid.

In prevention, all infants should be given a source of vitamin C from the first month of life. This may be given as one to two ounces of unheated orange juice starting with one teaspoonful daily in the first weeks and rapidly increasing the amount. If this is not tolerated or is unavailable, 25 to 50 mg. of ascorbic acid may be used.

In treatment of infantile scurvy, 300 mg. daily by mouth should produce rapid improvement. The dose may be reduced after the first week. Adults should be given 1 gm. daily for the first week in divided doses, then 500 mg. a day as long as necessary.

**11. Liver Cirrhosis.** There is now much evidence to indicate that portal cirrhosis (Laënnec's cirrhosis) is basically caused by malnutrition, although the condition may be aggravated by alcohol. Experimentally, the condition is produced by a diet deficient in choline or in choline precursors, the most important of which is the amino acid methionine. Choline is a lipotropic agent and, if deficient, fat

accumulates in the liver followed by an increase in connective tissue and a diffusely scarred, nodular liver, with serious interference to liver function. Many cases show symptoms of multiple deficiencies, especially of the vitamin B complex, as complications of the symptoms due to the cirrhosis.

In treatment, the diet should be high in protein (140 gms.) supplemented by daily oral doses of 2 to 5 gm. of either choline or methionine and by dried brewers yeast, one ounce twice daily. The diet should be low in fat and cholesterol, but should meet calorie requirements. The presence of signs of vitamin deficiency may require other specific vitamin treatment.

**12. Macrocytic Anemias.** This group of anemias includes pernicious anemia, the macrocytic anemia of pregnancy, sprue, celiac disease, etc. They appear to be nutritional in origin in the sense that they occur as a result of defective blood formation, either from failure to receive, absorb, or utilize extrinsic factor (vitamin  $B_{12}$ ), or an absence of intrinsic factor which is responsible for the absorption of extrinsic factor. Extrinsic factor (vitamin  $B_{12}$ ) and erythrocyte maturation factor appear to be identical. In pernicious anemia the essential difficulty is a lack of intrinsic factor in the gastric mucosa which interferes with absorption of extrinsic factor from the diet. Lack of extrinsic factor prevents the normal development of the red cell which is stopped at the megaloblast stage.

Nutritional macrocytic anemia is due to a diet deficient in the extrinsic factor (vitamin  $B_{12}$ ), folic acid or both.

In the macrocytic anemias of intestinal diseases such as sprue or celiac disease the defect may be lack of absorption of extrinsic factor (vitamin  $B_{12}$ ).

The role of the pterolyglutamates (folic acid) still needs explanation. It is effective therapeutically in causing regeneration of erythrocytes, and in the macrocytic anemia of pregnancy it is effective (5 to 15 mg. daily) although parenteral liver extracts and vitamin  $B_{12}$  are not effective.

Uncomplicated pernicious anemia should be treated with parenteral administration of 15 to 30 micrograms of vitamin  $B_{12}$  once or twice weekly and recovery followed by a maintenance dose of 15 to 30 micrograms once every two weeks.

**13. Iron Deficiency Anemia.** This is the traditional nutritional hypochromic microcytic anemia resulting from iron deficiency. It must be recognized that there must be blood loss or increased iron demand as in pregnancy so that the body store of iron is depleted for this form of anemia to occur. Its occurrence under simple conditions of low iron intake with no loss must be very rare. However, since chronic blood loss can occur in many insidious ways, the occurrence of iron deficiency anemia is very common.

Symptoms are pallor, weakness, irritability, appetite disturbances, brittle fingernails, fissures at the angles of the mouth, hemic heart murmurs, indigestion, etc. Examination of the blood reveals a greater loss of hemoglobin than of red cells which are small in size and pale.

The prevention is to include adequate iron in the diet and reduce or stop the blood loss. The treatment is administration of iron salts such as ferrous sulphate (0.2 gm. three times a day after meals). This will result in rapid regeneration of hemoglobin. Other defects in dietary habits and other deficiency symptoms should, of course, be corrected.

14. **Kwashiorkor.** This dietary disease of unknown etiology is probably the most important form of malnutrition in the world today on the basis of mortality and prevalence. It is found widely among African natives where it was first recognized by Proctor in 1926 and described in West Africa by Cecily Williams in 1933. The condition is also widespread in India, Malaya, the West Indies and in Central and South America. It occurs primarily in infants and small children on grossly deficient diets low in good quality protein.

The clinical signs are retardation of growth, edema, hypoproteinemia, scaly pigmented skin lesions, depigmentation or dyspigmentation of the hair, anemia, enlarged fatty liver and decreased serum amylase. An atrophic pancreas may be found at autopsy. The mortality is high. The total clinical picture may be an electrolyte imbalance and multiple vitamin deficiency superimposed on an underlying amino acid deficiency and imbalance. The basic cause seems clearly associated with amino acids or good quality protein. The most effective treatment is skim milk to which other dietary essentials are added as indicated and the child's condition permits.

Prevention consists in maintaining a diet with adequate protein of good quality such as milk, meat and fish.

15. **Goiter.** This is a chronic enlargement of the thyroid gland due to a variety of causes. Disorders of the thyroid are most frequent in regions where the iodine content of food and water is low. Factors, however, other than iodine deficiency may cause goiter. As in other deficiency diseases, an iodine deficiency may occur even though the intake appears to be adequate. This can occur from a variety of causes such as an unusually high requirement, failure of adequate absorption, poor utilization, etc. Also in the case of iodine, it is known that the presence of cyanate will lower the iodine content of the thyroid. The excessive use of foods high in cyanate such as cabbage or the use of medicine containing cyanate may result in goiter.

The thyroid regulates the rate of metabolism, controls growth, is necessary for the normal development of the brain, stimulates sexual development at puberty, maintains normal pregnancy, and controls production of an adequate milk supply during nursing.

The thyroid gland, of all the body tissues, has an affinity for iodine. Iodine taken into the body is combined with the amino acid tyrosine in the thyroid to form diiodotyrosine. Two molecules of diiodotyrosine combine to form the hormone thyroxine. This may be used or combined with protein and stored as thyroglobulin. Iodine is absolutely essential for the formation of thyroxine. The thyroid gland normally contains 15 to 20 mg. of iodine.

There are three disease states due to disturbed function of the thyroid gland: (1) hypothyroidism, (2) hyperthyroidism, and (3) simple goiter.

The two important hypothyroid conditions are cretinism and myxedema.

A cretin is a child dwarfed by a lack of sufficient thyroid secretion during fetal life. Myxedema is similar, but less severe, and occurs from thyroid insufficiency at any time after birth. In cretins the mental, physical, and sexual development is greatly retarded. If they live to be adults they retain their childhood body build and may not mature sexually. If untreated, their mentality may be arrested at a low level. They have a low metabolic rate, the skin has a typical thick dry appearance, and

deaf mutism is common. If thyroid extract is given at an early age marked improvement results, but complete recovery does not always occur. Cretinism should be prevented by an adequate supply of iodine for the mother before and during pregnancy.

Myxedema results when the thyroid is destroyed, or degenerates for any reason. There is a loss of vigor, the hair becomes dry and brittle, there is apathy and lethargy, and the skin becomes thickened due to accumulation of a semi-fluid albuminous material. Thyroid extract will completely control the symptoms of myxedema.

Hyperthyroidism is an enlargement of the thyroid gland with increased functional activity. The chief symptoms are rapid heart beat, exophthalmic goiter, tremor and nervousness, high blood pressure, elevation of temperature, and increased rate of metabolism. The symptoms are associated with increased activity of the thyroid gland and the condition is, therefore, also called thyrotoxicosis. Secondary toxic goiter also follows simple goiter as a complication. Usually, hyperthyroidism does not occur until after 15 years of simple goiter. The simple adenomatous goiter becomes a toxic adenomatous goiter for unknown reasons. If simple goiter is avoided by adequate iodine intake we would not have any secondary toxic goiter.

Simple goiter is by far the commonest form of goiter, and occurs in all parts of the world. Goiter areas exist, often separated only from the next area by a change in the watershed, or the supply of salt.

The enlargement which occurs in simple goiter may be accompanied by a mild degree of hypothyroidism, or underactivity. The enlargement represents an effort to manufacture adequate amounts of thyroxine.

Simple goiter begins with a lessening in the amount of iodine in the colloid and an increase in the size and number of the thyroid cells. The first stage is called parenchymatous goiter. When hyperplasia spreads evenly through the whole gland, the resulting goiter is symmetrical and firm. Parenchymatous goiter may go on to a complete exhaustion, or wearing out of the cells; or the increasing process may stop, and the follicles become filled with colloid.

When the latter happens, a colloid goiter results. Colloid goiters are usually symmetrical and somewhat soft. They may be very large, because each of the many additional follicles becomes distended with colloid. The total quantity of iodine in the entire gland may be close to normal, but because of the enlarged size, the ratio of iodine per gram of gland tissue is low.

Another kind of goiter is called an adenomatous or nodular goiter. Either parenchymatous or colloid goiter may gradually change to adenomatous goiter, which is the commonest type of goiter after the age of 30. Asymmetrical, or uneven, bulges or nodules form. They may increase in size from that of cherry stone to plum stone or larger.

Simple goiter is so called because it does not cause any toxic or poisoning symptoms. Its importance from a medical standpoint is due to the fact that nodular or adenomatous goiter may frequently have its origin in a pre-existing colloid goiter, and when this occurs nodular goiter may subsequently become toxic; also, symptoms due to pressure on neighboring structures such as the windpipe may occasionally be bothersome in patients with colloid goiter. From a health standpoint, colloid goiter is completely preventable by taking a small but adequate amount of iodine in the

food regularly. Where iodized salt is used from infancy, simple goiter, with very few exceptions, is avoided.

From ancient times goiter has been known to exist in certain regions. It occurs throughout the world wherever the supply of iodine is inadequate. Iodine is especially lacking in glaciated regions away from the sea. The classic home of simple or endemic goiter is in the Swiss Alps. The disease is prevalent in all of Switzerland, northern France, northern Italy, and the Balkan states. The traditional seat of goiter in England is in Derbyshire ("Derbyshire neck"), while Sussex and Hampshire have also been affected. There are many endemic centers in the Himalayan Mountain regions of eastern and southeastern Asia, the Gilgit district of northern India, and the plateau regions of western China and Mongolia. In South America, it is found in the Andes regions, the most noted section of which is the Peruvian plateau. Goiter also occurs in Africa, Central America and Mexico. In Japan, the malady is infrequent, probably because the people regularly partake of marine plants which are rich in iodine. The early explorers found goiter among the North American Indians. The region of our Great Lakes shows considerable numbers; also sections of the Middle West and parts of the Rocky Mountains, but in the United States and Canada the goiters are usually not large and cretinism is rare. The draft boards of World War I found two endemic goiter areas in the United States, one centering around the Great Lakes region and the other in the Pacific Northwest. However, it is not limited to these areas and may be found in almost any part of this country to some extent. It continues to be a public health problem in the United States.

Because individuals cannot tell whether their natural supply of iodine is adequate, some plan of giving everyone the food equivalent of iodine has been tried in many parts of the globe for many years. The most popular and most practical way has been to add an infinitesimal (0.01 per cent) amount of necessary iodine to table salt.

The name iodized salt came into use more than 25 years ago for table salt containing iodine equivalent in amount to that which would result from adding 0.02 per cent of sodium or potassium iodide to ordinary table salt. About a decade ago it was demonstrated that the addition of small quantities of certain substances would greatly retard the loss of iodine that otherwise occurs in packaged iodized salt. Use of these so-called stabilizers has made it possible to reduce the quantity of iodide from 0.02 to 0.01 per cent of the salt with assurance that the use of such salt will provide an adequate intake of iodine.

The addition of iodide to salt for the prevention of goiter has been impractical in the past in many parts of the world where crude or bulk salt is widely used because of the loss of iodine by vaporization from salt handled in bags or open containers.

Recent studies have shown that the iodate is stable and also effective in the prevention of goiter. It therefore appears that the addition of iodate to salt may be a practical way of preventing goiter in areas where packaging refined salt is not feasible.

The use of iodized salt is the most effective way of combating this important public health problem.

# 12

## NORMAL NUTRITIONAL REQUIREMENTS

Human requirements for the essential nutrients are based on the same physiological considerations the world over and fortunately may be met by an infinite variety of combinations of food and drink. Since the actual requirement of an individual is dependent on physical activity, age, sex, weight, as well as other factors, and would require careful and long study to determine accurately, practical methods of using averages have been devised which serve the very useful purpose of estimating the adequacy of the diets of groups of people. Such information used with a clinical examination and laboratory studies for evidence of malnutrition not only gives an adequate evaluation of the nutritional status but also furnishes the data necessary for planning suitable corrective and preventive measures.

The most complete and valuable table of standards is that prepared by the Food and Nutrition Board of the National Research Council and is given in Table 12-1.

This table is one of recommended allowances. It is not an attempt to set requirements. It is a set of recommended allowances designed to maintain good nutritional status. It is a desirable goal or objective at a level high enough to cover individual variations in the nutritional requirements of normal people.

Although these technical data are essential for accurate calculations and planning, it is necessary to convert the data into meal plans for them to be of practical public health use. This also has been done by the Food and Nutrition Board in three types of menus which suit the usual North American dietary habits. These are:

### MENU 1

#### *Breakfast*

Orange juice  
Cooked cereal—milk  
Eggs  
Toast—butter or fortified margarine  
Beverage

#### *Lunch*

Baked macaroni and tomatoes  
Green beans  
Rolls—butter or fortified margarine  
Fruit in season  
Milk

#### *Dinner*

Broiled chopped steak  
Creamed potatoes—carrots  
Head lettuce—French dressing

Table 12-1. Recommended daily dietary allowances<sup>1</sup> designed for the maintenance of good nutrition of healthy persons in the United States.

(Allowances are considered to apply to persons normally vigorous and living in temperate climate)

1953 Revision, Food and Nutrition Board, National Research Council.

<sup>1</sup> In planning practical diets, the recommended allowances can be attained with a variety of common foods which will also provide other nutrient requirements less well known; the allowance levels are considered to cover individual variations among normal persons as they live in the United States subjected to ordinary environmental stresses.

<sup>2</sup> These calorie recommendations apply to the degree of activity for the "standard" man and woman described on page 585. For the urban "white-collar" worker they are probably excessive. In any case, the calorie allowance must be adjusted to the actual needs of the individual as required to achieve and maintain his desirable weight.

<sup>3</sup> The recommendations for infants pertain to nutrients derived primarily from cow's milk. If the milk from which the protein is derived is human milk or has been treated to render it more digestible, the allowance may be in the range of 2-3 gm. per kg. There should be no question that human milk is a desirable source of nutrients for infants even though it may not provide the levels recommended for certain nutrients.

<sup>4</sup> During the first month of life, desirable allowances for many nutrients are dependent upon maturation of excretory and endocrine functions. Therefore no specific recommendations are given.

## NORMAL NUTRITIONAL REQUIREMENTS

Bread—butter or fortified margarine  
 Apple pie and cheese  
 Beverage

## MENU 2

*Breakfast*

Tomato juice  
 Ready-to-eat cereal—milk  
 Eggs

Hot biscuits  
 Butter or fortified margarine—jelly  
 Beverage

*Lunch*

Baked sweet potato  
 Turnip greens or collards  
 Sliced onions with vinegar  
 Corn bread or muffins  
 Butter or fortified margarine—molasses  
 Beverage

*Dinner*

Fried fish  
 Hominy grits—cole slaw  
 Bread—butter or fortified margarine  
 Stewed prunes or fruit in season  
 Cookies  
 Beverage

## MENU 3

*Breakfast*

Banana on ready-to-eat cereal  
 Milk  
 Toast—butter or fortified margarine  
 Beverage

*Lunch*

Chick pea soup  
 Tortillas  
 Orange  
 Cocoa or chocolate

*Dinner*

Chili rellenos  
 (Stuffed green peppers)  
 Mexican rice  
 Raw vegetable salad  
 (Cabbage, carrot, green pepper, French dressing)  
 Tortillas  
 Fruit gelatin  
 Milk

An even simpler method of using the same basic data for general educational purposes is to furnish the information in terms of food groups which have been called "The Basic Seven" and are as follows:

- Group 1. Leafy green and yellow vegetables, one or more servings.
- Group 2. Citrus fruits, tomatoes, raw cabbage, one or more servings.
- Group 3. Potatoes and other vegetables and fruits, two or more servings.
- Group 4. Milk and milk products: fluid, evaporated, dried milk or cheese. Children, three to four cups of milk; adults, two or more cups.
- Group 5. Meat, poultry, fish, eggs, dried beans, peas: one to two servings.
- Group 6. Bread, flour, cereals, whole grain, enriched, or restored: daily.
- Group 7. Butter or fortified margarine: daily.

In addition to some foods from each of these groups, the appetite and energy needs may be met by any other foods desired.

In addition to the above recommended dietary allowances, there is a table of minimum requirements for certain nutrients which serve as a legal standard for the enforcement of certain provisions of the Food, Drug, and Cosmetic Act. These standards are set at a minimum level and label statements of quantity are given in terms of fractions of a day's requirement referred to these levels. These figures are given in Table 12-2.

Table 12-2. Minimum daily requirements at various ages for certain vitamins and minerals

	Vitamins					Minerals			
	A	B <sub>1</sub>	B <sub>2</sub>	C	D	Ca	P	Fe	I
	I.U.	Mg.	Mg.	Mg.	U.S.P.U.	Gm.	Gm.	Mg.	Mg.
Infants	1,500	0.25	0.5	10	400	—	—	—	—
Children 1-5 yrs.	3,000	0.50	—	20	400	0.75	0.75	7.5	0.1
6-11 yrs.	3,000	0.75	—	20	400	0.75	0.75	10.0	0.1
12 yrs. or over	4,000	1.0	2.0	30	400	0.75	0.75	10.0	0.1
Adults	4,000	1.0	2.0	30	400	0.75	0.75	10.0	0.1
Pregnancy or lactation	—	—	—	—	—	1.50	1.50	15.0	0.1

Under conditions of food rationing or other situations where the liberal allowances cannot be met it may be necessary to use more restricted rations. Such restrictions must be used with care especially over long periods of time. Undue restrictions are certain to result in difficulties. This question has been studied by both the Food and Nutrition Board of the National Research Council of the United States and the Food and Agriculture Organization of the United Nations. Their conclusions may be summarized as follows:

A semi-starvation diet which will result in a reduced capacity to work, apathy, depression, and increased susceptibility to infectious diseases is one calculated to contain 1,700 calories per day for a man or an average intake of 1,450 calories for a North American or European population of a distribution similar to that of the United States.

A reasonably safe emergency subsistence level is 2,200 calories per man per day or an average intake for the population of 1,900 calories. This is the food consumption level needed to prevent the most serious undernutrition.

A temporary maintenance level designed to maintain fairly good health, but not for rapid or complete rehabilitation is 2,560 calories per man per day, or an average

intake for the population of 2,200 calories. At this level of intake attention should be given to the protein which should be an average of about 60 gm. per person daily, at least 10 per cent of which should be animal protein.

Since many population groups in non-European countries are of smaller size, living in warm climates with less energy output, the recommended calorie intakes may be reduced by 15 to 20 per cent and the protein by 10 per cent.

Table 12-3. Nutritive value of 100 grams of selected foods, edible portion

NOTE: Asterisk indicates Army ration component; parentheses, imputed value.

<sup>a</sup> Average values for composition of all cuts in a boned and trimmed carcass of commercial grade generally used for (a) chopped meat, (b) roasting and broiling, (c) stewing and boiling.

<sup>7</sup> Values for fresh items are from the medium fat wholesale cuts considered to be nearest approximations for corresponding retail items.

<sup>8</sup> Lean cuts from medium fat carcass weighted according to civilian supply, 1944. Excludes bacon, lard; salt side; fat back.

Table 12-3 (cont.). Nutritive value of 100 grams of selected foods, edible portion

NOTE: Asterisk indicates Army ration component; parentheses, imputed value.

24 Based on peanuts without skins; when skins are included the thiamine value is higher.

25 118 mg.; may not be available because of presence of oxalic acid.

26 105 mg.; may not be available because of presence of oxalic acid.

27 Based on yellow corn; white corn contains only a trace.

28 Based on pared cucumber; unpared contains about 260 I. U. vitamin A per 100 gm.

29 Green bunching onions contain about 23 mg. ascorbic acid per 100 gm.

30 81 mg.; may not be available because of presence of oxalic acid.

31 If pale varieties only were used, value would be very much lower.

32 Based on green products; bleached products contain only a trace.

33 Drained solids only.

34 90 mg.; may not be available because of presence of oxalic acid.

## NUTRITION IN PREVENTIVE MEDICINE

The first recognition of the public health importance of food in this country was in relation to problems of sanitation and adulteration. The first federal action in this field was the authority given the Public Health Service in 1893 to establish sanitary regulations for common carriers in interstate traffic. The first state laws governing contamination or adulteration of food were passed in 1880 to 1889 in four states. The Federal Food and Drug Act was passed in 1906 and expanded in the Food, Drug and Cosmetic Act of 1938. Milk sanitation standards were first set by the Public Health Service in 1924.

The work of Goldberger and his associates in the Public Health Service on the dietary cause of pellagra in the southern United States demonstrated the public health importance of malnutrition and added a new public health responsibility to the earlier work which had been limited to sanitation and adulteration.

The development of pediatrics and the growing knowledge of the elements of nutrition and their effect on the growth and development of children led to early recognition of the great importance of nutrition to child health and the child hygiene divisions of health departments opened the way for the development of nutrition services in state health departments. Our present knowledge of the tremendous importance of good nutrition in the maintenance of the best degree of health and our extensive knowledge of the numerous nutritive essentials and the element of a good diet require that the present-day health department deal adequately with this new field of preventive medicine.

This problem of adequate nutrition is so different from other health problems that it requires a new approach by the health officer. It is vast in its ramifications, involving as it does such diverse problems as crop production programs, farm machinery and manpower, food distribution and rationing, food preservation, processing and transportation, storage and proper food preparation, as well as nutrition education, and the diagnosis, prevention, and treatment of specific dietary deficiency diseases. It is obvious that such problems cannot be solved by any one agency alone. Close cooperation and intimate relations among a number of agencies, of which one certainly should be the health department, are essential.

Some of the lines along which a state health department nutrition program might operate are as follows:

1. Conduct appraisals of nutritional status. Even small samplings are of value in indicating the need for more comprehensive appraisals. The determination of the prevalence of nutritional diseases is as much a health department function as the determination of the prevalence of infectious diseases. Such appraisal is made preferably by a combination of dietary survey, clinical survey, and laboratory determina-

tions. The dietary survey may be conducted by a variety of methods. The general technic is an inquiry into the food consumed over a given period of time and the calculated nutritive value compared with a standard of intake such as the recommended allowances of the Food and Nutrition Board. The value of such surveys depends on the training of the surveyor and the care with which the data are collected and analyzed. This type of data gives an excellent indication of food habits, trends in consumption and a background for further study of the prevalence of deficiency symptoms. Although valuable in itself, the dietary survey becomes of greater value when combined with a clinical study of the prevalence of symptoms of malnutrition. This requires the services of a physician trained in the recognition of the skin, mouth, tongue, eye, and neurological lesions of mild deficiency states and the value of the clinical study is enhanced if laboratory data can be added.

2. A nutrition appraisal furnishes a sound foundation for a specific nutrition program. From this base the health officer can proceed with confidence to attack the problem in a variety of ways. He can make specific recommendations in regard to school lunch programs and nutrition education in the school. His program of nutrition education and consultative work with individuals, families, and other agencies interested in nutrition work is a most important function. His information service should prepare nutrition and health material related to other nutrition material available in the state. This should be handled as a part of the health education program.

3. An important field of direct service is that of adequate nutrition for inmates of institutions such as prisons, sanatoria, homes for the aged, orphanages and children's camps. The health department nutritionist can do much in this field to obtain adequate nutrition at lower cost and give better protection against food and water-borne diseases.

Other fields of direct service are an industrial nutrition service and the enforcement of regulations dealing with food handling, adulteration and sanitation.

4. A most important nutrition function for the health officer is that of leadership in policy making and program planning. It is essential that there be collaboration between the many public, private, and civic agencies with an interest in nutrition. Many agricultural, welfare, relief, and other agencies have had good nutrition programs for many years. The health officer should help coordinate these activities to secure the best results in the health field.

5. Staff education in nutrition and aid to local health departments require the services of trained nutritionists.

6. Finally, constant study, investigation, and research should always be included to discover better methods, to better the application of existing methods, and constantly to evaluate changing conditions.

## INTERNATIONAL HEALTH AND NUTRITION PROBLEMS

We do not yet know the full extent of malnutrition in the United States nor do we know how much better nutrition might improve our national efficiency and productiveness or reduce our morbidity and mortality statistics.

In planning nutrition programs in relation to health it must be remembered that adequate food production and availability are the basic problems of international

significance. A comprehensive program in the United States requires consideration of the world food situation and nutritional problems in other countries. Three of the United Nations organizations are intimately concerned with nutrition, food, and health. The World Health Organization has malnutrition as one of the great health fields to which it must give attention. A nutrition division of this organization has started work on kwashiorkor and goiter, and of great health significance is the Nutrition Institute of Central America and Panama set up under the Pan-American Sanitary Bureau. This institute has begun an active program not only of research but to furnish training, analyses, advice, and assistance to its member countries in attacking nutritional problems.

Another very important international nutrition service is that of the Food and Agriculture Organization. The principal problems of this organization are those of agricultural production and distribution. However, its nutrition division carries out an important function in the field of nutrition education, and in relating nutrition and health to agricultural improvement, and in the world movement of food.

The third international organization concerned with nutrition is the United Nations Children's Fund (UNICEF). This organization has played a leading role in milk conservation programs and in the distribution of dried skim milk to needy areas in many parts of the world.

Close cooperation is maintained between the nutrition programs of WHO, FAO and UNICEF. One deals with the nature and prevalence of nutritional diseases, the others with the production and distribution of the agricultural products necessary to control these diseases. Through these and other international efforts, the role of nutrition in health gradually is being established on a world-wide scale and we can see the prospect of a new era of better health comparable to the improvement following the development of sanitation.

## MAINTENANCE OF HEALTH AND PREVENTION OF DISABILITY

### 14

#### HISTORICAL DEVELOPMENT OF MATERNAL AND CHILD HEALTH

PAUL A. HARPER, M.D., M.P.H.

Maternal and child health is concerned with the physical, mental, and emotional health of pregnant women and of children. One way of defining this field of work is to say that its primary concern is with the preventive aspects of obstetrics and pediatrics and with their application in public health and child welfare. In addition, agencies in this field have provided medical care for certain chronic diseases and handicapping conditions ordinarily included under the term crippled children. This designation, which originally referred to children with orthopedic defects, has gradually been broadened to include children with cerebral palsy, epilepsy, rheumatic fever, congenital defects such as hare lip, and children with handicaps of hearing, speech and vision. A consideration of the historical development of maternal and child health will show that its responsibility has been a continually changing one and that a static definition is not adequate.

The maternal and child health program as we know it today is a development of the past 50 or 75 years. Interest in this area goes back as far as history will take us, but organized programs of the sort currently operating began in France in the late nineteenth century. At this time there was a world-wide concern over the appalling loss of life in early infancy. The French were particularly alarmed about the effect of their low birth rate on their military power, and the question of measures which might improve this manpower situation was debated in the Chamber of Deputies. The names of three French physicians stand out in the early history of this movement: Pierre Budin, Felix Joseph Variot, and Leon Dufour. Budin, one of the famous obstetricians of Paris in the late nineteenth century, initiated the practice of asking the women whom he had delivered to return with their infants after six or more months for a follow-up visit. He was shocked to find how many of these mothers came back without their infants, stating that the child had died during the months since delivery. As a result of this experience, Budin established his "Consultations de Nourrissons" at the Charité Hospital in Paris in 1892. About this same time Variot and Dufour in and near Paris established the forerunners of our present child health conference. These conferences were primarily concerned with the encouragement of breast feeding and the provision of a safe supply of cow's milk for those children whose mothers were unable to feed them from the breast, and the name of these conferences was, appropriately, "Gouttes de Lait." The success of this type of clinic in the saving of life among infants was so great that similar programs

were undertaken in most of the countries of Europe and in the United States and Canada. Physicians in this country who took an interest in this work included Abraham Jacoby, Thomas Morgan Roche, Henry Koplik, L. Emmett Holt, and others. Nathan Strauss established the first of a series of many infant depots in New York City in 1893. Over the next few decades milk depots and clinics were organized by voluntary groups in most large cities in the country. Comparable movements developed in many countries. For example, Dr. Trubie King organized the Plunkett Society in New Zealand, which utilized a group of especially trained nurses and promoted the use of breast milk or, if this failed, gave instruction in the preparation of a safe mixture of cow's milk and otherwise educated mothers in infant care.

Other groups became active. In 1891, Dr. Henry L. Coit and a group of physicians in New Jersey organized the first certified milk commission which cooperated with a few enthusiastic dairymen to improve the conditions of milk production and so assure a safe milk supply. International congresses of interested persons were held in 1905 and 1907. The American Association for the Study and Prevention of Infant Mortality was organized in 1909, was renamed the American Child Hygiene Association in 1918, and was merged with and assumed the name of the American Child Health Association in 1923. These voluntary organizations were effective instruments for the promotion of health services for children. By 1935 it was felt that activities in the interest of child health had been so firmly established that the stimulation of a volunteer privately financed organization was no longer needed and the Child Health Association disbanded.

Reliable figures on infant mortality were one of the greatest needs during the early part of this century. Only a few cities published such information and lack of accurate birth registration decreased the value of even these limited data. For example, some of our most reliable information on infant death rates at the turn of the century was laboriously collected from nine cities by C.-E. A. Winslow and D. F. Holland and between 1880 and 1890 shows a rate of 200 to 300 per 1,000 estimated population under one year of age. More easily available and reliable information was essential if widespread interest and concerted action was to result. This became a process of mutual stimulation between the individuals responsible for our vital statistics and those concerned with child health. More accurate data made clear the serious nature of the situation and created interest in more people who in turn called for better vital statistics. Since 1917, fairly reliable infant mortality rates have been available in the expanding birth registration area; at that time the rate was about 100 per 1,000 live births. Since 1933 data from all the states have been available.

Most of the early work in maternal and child health was the result of efforts such as have been described by voluntary groups and by individuals. The concept slowly grew that the health of mothers and children was a public responsibility and, as such, deserved special status in official health agencies. New York City was the first large political unit in the United States to establish a Bureau of Child Hygiene, in 1908. Dr. Josephine Baker, as the first head of this bureau, gradually overcame great opposition and pioneered in the building of public health programs for children. In 1914, New York became the first state in the union to establish a division of child hygiene in its state health department. This trend toward acceptance of responsibility in this field by official health agencies at state and local level has been

greatly accelerated by federal aid, as will be described. But it should be emphasized that the primary responsibility still remains at the state and local level.

Federal assistance began with the establishment of the United States Children's Bureau in the Department of Commerce and Labor by an Act of Congress in 1912. It was the first government agency of its kind, and was made responsible to undertake research to promote the welfare of infants and children. It was transferred to the newly created Department of Labor in 1913 and was given additional responsibility for the enforcement of child labor laws. Miss Julia C. Lathrop was the first chief. In 1946, the Bureau was again transferred, this time to the Federal Security Agency. In this move the Bureau retained its health and welfare functions but its responsibilities for child labor were left in the Department of Labor.

In 1921, the Infant and Maternity Act (Sheppard-Towner Act) was passed and for the first time federal funds were made available, on a grant-in-aid basis, to assist the various states in developing maternal and child health programs. This law, as is implied by the term "grant-in-aid," required each state to match part of these federal funds with a contribution of its own and also to establish within the state a responsible agency to receive and administer these funds. This gradually resulted in the setting up of an official division or bureau of maternal and child health in each state. These state bureaus have themselves served to stimulate activities in this field and have also acted as a coordinating agency for the activities of many private organizations. There was great controversy as to the wisdom of the Federal Government engaging in such activities, and the opposition became so strong that the Act was allowed to lapse after eight years. A few states provided the necessary funds to continue these activities, but the general effect of withdrawal of federal aid was a considerable decrease in services.

The Social Security Act of 1935 re-established the policy of grants-in-aid to foster maternal and child health work in the various states, and also provided additional funds for a new field of endeavor, crippled children. Funds and activities under this Act have gradually been expanded. The amount of effort and money put into this program by state, local, and voluntary agencies cannot be accurately estimated, but is large.

During World War II, Congress passed the Emergency Maternity and Infant Care Act, better known as EMIC, which provided tax funds to pay for obstetrical care for wives of service men in the lower four pay grades and for pediatric care for the infants of these women. Under this program over 1,100,000 women and their newborn infants were given obstetrical and newborn care, and about 200,000 infants were given additional care during the first year of life. The administration of this Act became the subject of great controversy. It did not always run smoothly and sometimes there was an unnecessary amount of paper work and inflexibility of policy. However, there is no doubt about the value of this activity in raising standards of care and in providing essential services to these mothers and children while their husbands were in the military services (Eliot, 1947; Sinai and Anderson, 1948).

Much of the activity in this field has been the result of cooperative effort between voluntary and governmental agencies and interested individuals. The number of agencies and individuals who have been and are concerned with work in this field is too great for enumeration. But this account would be incomplete if it failed to

recognize that one of the most potent factors in reducing infant and maternal mortality has been the great advances in medical care and particularly the development of the specialties of obstetrics and pediatrics. Obstetrics has long been recognized as a major specialty. The American Board of Obstetrics and Gynecology, Incorporated, was organized in 1930, and now has about 4,500 licentiates. There are probably half as many more physicians well trained in obstetrics.

It is well to recall that pediatrics as a major specialty is a development of less than 50 years. Most of the departments of pediatrics in the various medical schools of the country are less than 35 years old. Yet it is unquestionable that a great deal of the progress in better health for children has been due to the efforts of this specialty group whose reputation depended upon what they accomplished in this particular field. The American Board of Pediatrics was incorporated in 1933 and has now granted certificates to about 5,500 pediatricians. There are probably another 2,500 physicians well trained in pediatrics. The nation-wide survey of Child Health Services and Pediatric Education conducted by the American Academy of Pediatrics in 1946-47 has historical significance which will be discussed in a separate section.

Developments in four other disciplines have already had great influence in this field. The roles of public health nurse, social worker, nutritionist, and therapist have been of continually increasing importance and have led to the use of the team approach. In most clinics the physician and the public health nurse form the nucleus of a group with the social worker and the nutritionist acting as consultants. In larger clinics these latter two workers often become an integral part of the team.

The work of the public health nurse and of therapists is discussed elsewhere.

Social workers are particularly valuable in understanding the patient or client as an individual and as a member of his family and community. They recognize and deal with interpersonal relationships and other social factors as these affect physical and mental health. Their contribution in the problems of adoption, foster care, dependent and chronically ill or convalescent children, unmarried mothers, and other areas can only be mentioned briefly.

Nutritionists have developed a program of applied nutrition which has as its purpose the provision of an adequate diet for mother and child at a minimum of cost. Nutritionists usually function as consultants of public health nurses and physicians but occasionally give direct service to patients in clinics where they analyze diets, make suggestions for improvement or for economy, explain the physician's orders in relation to diet, and aid in the general educational effort.

The series of White House conferences, beginning with one called in 1909 by President Theodore Roosevelt, have had great influence in focusing attention on this work and in guiding the pattern of development. The White House conference in 1930 on Child Health and Protection resulted in the publication of 32 volumes, much of which is still standard in this field. The Mid-Century White House Conference on Children and Youth which was held in December, 1950, was the fifth of the series. This conference took as its purpose the development in children of mental, emotional, and spiritual qualities that will foster a happy childhood and lead to responsible citizenship.

The theme of the 1950 White House conference is significant of a shifting emphasis in maternal and child health work. This field has always been concerned with

the promotion of physical, mental, and social well-being, but as the program for physical health becomes well established, stress is being placed more and more on mental and social health. It is clear that there is no one place to start the task of building mental and social well-being for each individual. To begin with a newborn baby is to neglect the importance of prenatal factors; to work with parents during the prenatal period makes it apparent that some of the problems which arise are related to the infancy and childhood of the parents; to work with children of preschool or school age demonstrates the importance of understanding, cooperative, and sympathetic parents. The approach must be through the many individuals, agencies, and professions that are working for the child and the family. Children must be given the knowledge and incentive with which to seek good health for themselves and in turn for their children; and at the same time parents and prospective parents must be stimulated to promote their own health and that of their children. Such a program must be based on an educative process by which all people may appreciate the meaning of health and desire it sufficiently to work for it.

There is also a changing emphasis with respect to age group. Maternal and child health up to the present has been largely concerned with mothers and preschool children. The problems of children of school age have been less well understood and services for this group have been less well developed. If one may venture a prophecy, it is that the next decades will provide more knowledge of the mental and emotional problems of school age children and particularly of adolescence and that services will develop as knowledge increases.

Increasing cooperation between workers in health and in welfare has been fostered by common problems. For example, the rise of juvenile delinquency is important to all those who are concerned with the health of children and points up the value of joint efforts to understand what forces promote good adjustment and what ones favor maladjustment. The steady rise in adoptions which stems in part from the increase in divorce and in illegitimate birth is another common problem. The increasing number of women who work outside the home brings new questions about day care and health supervision of preschool children.

There is a trend among voluntary agencies toward a categorical approach; this is seen in the rise of important groups interested in and working for children with one kind of handicap. These groups have had great success in organizing parents to improve their own understanding of one particular group of children and in raising funds and promoting legislation for this group. The value of such efforts is great but like other advances it brings new problems for solution.

It is worth repetition to end these brief historical comments with the statement that maternal and child health is a part of the total health program of the community. They are inseparable. Improvement of one benefits the other, and close integration and cooperative action of all individuals and agencies is essential.

## MATERNAL HEALTH SERVICES

JOHN WHITRIDGE, JR., M.D.

**Definition.** Obstetrics is defined by Eastman (1950) as "that branch of medicine which deals with parturition, its antecedents and its sequels. It is concerned principally, therefore, with the phenomena and management of pregnancy, labor and puerperium both under normal and abnormal circumstances." The aims of obstetrics, he continues, are that "every pregnancy culminate in a healthy mother and a healthy baby . . . and . . . so to safeguard and ease the whole course [of pregnancy] that both mother and child will conclude the experience in a healthy state both physically and mentally." Maternal health embraces all of the aims and purposes of obstetrics but differs in point of emphasis, in that it is concerned primarily with the ways and means of making available to all women, regardless of race, creed, or economic status, the best that modern obstetrical care can provide. Maternal health, therefore, may be defined as that branch of medical care which has to do with the mobilization of total community resources for the purpose of making available to all in need of it the best possible obstetrical care during the prenatal period, during labor, and following delivery.

As such, maternal health concerns itself with the community standards of prenatal care, of delivery facilities, and of postpartum care. Included, therefore, are the obstetrical ability and training of physicians, the caliber and supervision of midwives, the physical and professional quality of care being furnished in the maternity sections of hospitals, and educational and economic level of the patients themselves, and the degree of coordination attained between the various individuals and groups concerned in rendering obstetrical care. It is of little avail to the unfortunate mother dying of uncontrolled eclampsia in some forlorn hovel that modern obstetrics could probably have prevented the occurrence of this dread complication of pregnancy. Maternal health seeks to answer the question: "Why was this mother not brought under adequate care?" The problem of discovering the cause of eclampsia and newer methods of treatment is left to the science of obstetrics.

**Evaluation of Progress in Maternal Health.** Progress in maternal health can be measured objectively only in terms of mortality rates. It must be understood, however, that mere tabulation of deaths is a grossly unsatisfactory and imperfect mode of assessing the broader aspects of maternal care, since no consideration is given thereby to factors such as permanent or temporary disability or the emotional or mental well-being of mothers. In general, however, it seems justifiable to assume that in those communities where maternal and fetal death rates are low, the quality of obstetrical care being received by patients is of high caliber, and vice versa. The

inadequacy of maternal and fetal death rates in furnishing us with a completely satisfactory picture of maternal health must be granted. Nevertheless, they remain the only objective yardsticks for the measurement of results of maternity care on a local, national, or world-wide basis.

**Maternal Mortality Rates.** Maternal mortality rates are the most commonly used method of assessing the quality and end results of obstetrical care. These rates are expressed in numbers of maternal deaths per unit of births, usually maternal deaths per 1,000 or per 10,000 live births. A more meaningful rate would be obtained were it possible to compare deaths to total pregnancies, but since the registration of live births tends to be more complete than that of either total pregnancies or total births, the ratio of maternal deaths to live births has been adopted by the National Office of Vital Statistics. All rates expressed in the following pages will be in terms of maternal deaths per 10,000 live births in conformity with data compiled by the National Office of Vital Statistics in 1949.

Several important shortcomings should be appreciated in evaluating published maternal mortality rates. Their worth depends upon accurate reporting of all live births and deaths by individual physicians. Many patients undoubtedly die each year of conditions clearly the result of pregnancy or delivery whose deaths are not correctly classified as maternal, because of failure on the part of the attending physician to make any mention of pregnancy or delivery on the certificate of death. Accordingly, recorded maternal mortality rates are somewhat lower than actual rates. This defect, however, is somewhat offset by incomplete reporting of births, but with the present day importance of possessing a birth certificate the percentage of nonreported births is becoming steadily less. Nonetheless, it is of passing interest to note that in 1946 it was estimated that nearly 170,000 live births in the United States were not registered.

An even more important factor in producing errors in maternal mortality rates is the lack of unanimity of opinion relating to the exact definition of a maternal death. In patients succumbing of clearly obstetrical causes such as eclampsia or postpartum hemorrhage, there is no room for disagreement, and deaths of this nature are universally classified as maternal. When pregnancy is associated with conditions such as organic heart disease, tuberculosis, or chronic hypertensive vascular disease, there is considerable divergence in methods of tabulation. For example, a young woman with a severe degree of rheumatic heart disease becomes pregnant and in the latter months of pregnancy decompensates and dies undelivered of cardiac failure. Some favor classifying this as a death due to heart disease and hence nonmaternal, since they can claim quite reasonably that had the patient's heart not been diseased, she would not have died at that time in that fashion. On the other hand, it is well known that pregnancy places a considerable added burden on the heart, and it can be maintained with equal vehemence that if the pregnancy had not existed, death would not have occurred at that time. A reasonable and satisfactory compromise between these conflicting points of view has been reached in some areas by adopting a dual classification, in which deaths from purely obstetrical causes are listed as "maternal deaths," and all other deaths in pregnant or recently delivered women are classified under the heading "deaths associated with pregnancy." By adding the two categories one obtains an index of total deaths associated with pregnancy. This latter figure is a more accurate index of the quality of obstetrical care being ren-

dered, since, as in the case of heart disease associated with pregnancy, the number of fatalities will depend largely on the knowledge and skill of the attending physician, and completeness of care given by him. In assessing progress in maternal health or in comparing one locality with another, the above mentioned differences in interpretation and classification of maternal deaths should be kept in mind. Only through a uniform and clearly understood method of classifying deaths will valid comparisons be possible.

**Causes of Maternal Mortality.** The major terminal causes of maternal deaths are hemorrhage, infection, and the toxemias of pregnancy. These three major types of maternal deaths account for approximately 90 per cent of the total, with the remainder made up of a group of miscellaneous conditions including heart disease, anesthesia accidents, and others not clearly assignable under hemorrhage, infection, or toxemia. The major hemorrhagic conditions leading to fatalities are those associated with abortions, induced or spontaneous; ectopic pregnancy; placenta praevia; abruptio placentae; ruptured uterus; and postpartum hemorrhage. Deaths due to infection include patients with abortions and ectopic pregnancies succumbing terminally of sepsis, and deaths due to sepsis during labor or following viable deliveries. It should be noted that many patients classified under deaths due to infection should more properly be listed as due to hemorrhage, since it frequently happens that bleeding initiates a sequence of events ending terminally in sepsis. Accordingly, national statistics are weighted in favor of infection and correspondingly underestimate the role played by hemorrhage. The toxemias of pregnancy include a group of conditions of obscure etiology characterized by hypertension and albuminuria. Eclampsia is the most treacherous and lethal of these.

Modified from 1947 Chart Book, Children's Bureau, which uses data from National Office of Vital Statistics.

Fig. 15-1. Maternal mortality by race and main causes, United States, 1933 to 1948.

Left, maternal mortality has decreased about 80 per cent since 1933, but the death rate for nonwhite mothers is over 200 per cent greater than the rate for white mothers.

Right, infection has decreased more rapidly than other causes of maternal mortality; and hemorrhage, trauma, or shock has moved into first place in 1948.

In Figure 15-1 may be seen the relative incidence of the three major causes of maternal deaths since 1939. It will be noted that in 1948 hemorrhage for the first time became the leading cause of maternal mortality in the national statistics for the United States. There has been no increase in the absolute number of deaths due to hemorrhage but rather a more rapid decrease in the deaths due to infection. The latter category until 1948 had long been the predominant cause of maternal deaths. There are many and diversified factors influencing the incidence of deaths from these three major causes. Maternal health is more concerned with an analysis of the underlying factors predisposing to maternal deaths than with a discussion of their diagnosis and treatment from the strictly obstetrical viewpoint.

**Maternal Mortality Trend in Recent Years.** During the past two decades there has been a dramatic and gratifying decrease in maternal mortality rates in the United States, a superb achievement of which the medical and nursing profession of this country can be justly proud. In Figure 15-1 may be seen in graphic form a chart of the rates from 1933 through 1948, and it will be noted that during this span of years the rate has been reduced approximately 80 per cent. Expressed in terms of lives this means that had the 1933 rate prevailed in 1948 more than 16,000 additional women would have lost their lives in childbirth in that one year.

A wide variety of circumstances has produced the abrupt decline in maternal mortality noted above. Each of the most important of these will be discussed in some detail from a dual point of view: first, how each factor has operated in the past to produce such magnificent results; second, the steps which remain to be taken to produce even better results in the years ahead.

**The Status of Obstetrical Care Today.** The brilliant achievement in reducing maternal mortality rates described in the preceding section might readily lead one to the conclusion that a state of virtual perfection has been reached. Such a complacent attitude, however, is totally unwarranted. A number of studies of maternal mortality by individuals and by committees of physicians have made clear that approximately two thirds of all maternal deaths can still be considered preventable. By the term preventable is meant that had the patient received ideal care under ideal conditions, her death would probably have been avoided. One of the first studies pointing out this fact was a review of maternal deaths in New York City from 1930 to 1932 (New York Academy of Medicine, 1933). In this analysis a total of 65.8 per cent of 2,041 maternal deaths was considered preventable by a committee of physicians who carefully investigated the events leading up to each and every death. Similarly, Nayar (1950), analyzing 567 maternal deaths in the counties of Maryland from 1937 to 1948, found that the maternal mortality committee had voted 67.0 per cent of these deaths preventable. Other reports have pointed to similar conclusions. One is forced to conclude reluctantly, therefore, that whereas tremendous strides have been made in safeguarding the pregnant woman, the road ahead is still filled with obstacles. Of the 4,122 maternal deaths in the United States in 1948, it is probable that at least 2,700 were unnecessary and could have been avoided if ideal care had been made available.

**Geographic, Racial, and Economic Factors.** Different sections of the United States have for many years rather consistently recorded widely different maternal mortality rates. For example, in 1946 the recorded rate for the east south central section of the country comprised of Kentucky, Alabama, Tennessee, and Missis-

issippi, was 23.6 per 10,000 live births, nearly double the rate of 12.8 per 10,000 live births attained by the New England states. Within these two groups of states even more marked differences occurred. The rate for Connecticut was 9.2 in comparison to 31.4 for Mississippi. Further analysis of data from these two states brings out several factors of importance. Connecticut reported 1,123 nonwhite births, constituting 2.7 per cent of all live births. Mississippi, on the other hand, recorded 31,715 nonwhite births, making up 51.4 per cent of all live births in the state. In Connecticut 98.9 per cent of all births took place in hospitals and 99.9 per cent were attended by physicians. In Mississippi, however, only 38.6 per cent of all births occurred in hospitals and only 63.1 per cent were attended by physicians. Of the 31,715 nonwhite births in Mississippi only 9.6 per cent occurred in hospitals and only 31 per cent were attended by physicians.

While it may be true that certain inherent racial differences exist which may influence mortality associated with childbirth, it would seem apparent from the above that it is not so much a matter of race per se that is important as are facilities for care which are available to a particular group. The basic problem, therefore, becomes an economic one, since, in the less wealthy sections of the country, hospitals are few and are used primarily by the well-to-do. When facilities are limited, the indigent nonwhite goes without. Furthermore, in these areas the ratio of physicians to population is lower. A third factor directly related to economic status is nutrition. Many of the nonwhites are desperately poor, living in hovels, and subsisting on grossly inadequate diets. Many studies have pointed out a relationship between nutritional status and the occurrence of certain complications of pregnancy, particularly the toxemias and the incidence of premature onset of labor. Food habits are usually of many years standing, and one cannot hope to rectify deep-rooted nutritional deficiencies in the short space of a single pregnancy. Dietary intake is unquestionably related to financial status but is also dependent upon the knowledge of what to eat.

All of the above factors are so closely interwoven that it is fruitless to attempt to assign top importance to any single one. It can only be said that on the basis of available evidence poverty, ignorance, lack of access to hospitals and physicians, inadequate diet, poor general hygiene, and poor general state of health often go hand in hand to make pregnancy an unduly hazardous venture. It is often the nonwhite who lives under such conditions.

**Public Health Programs.** In the preceding paragraph attention was called to the startling differences in the quality of maternity care available in various sections of the country. Nearly every portion of the country has communities made up largely of the poor and underprivileged. These groups have in the past contributed, and continue to contribute, a disproportionate number of maternal deaths each year. Even in areas such as the New England states having very low total maternal mortality rates, the nonwhite races furnish a disproportionate number of maternal deaths, nearly two and a half times that of the rate for the white race.

The past two decades have seen a great extension of public health maternity programs designed to make available adequate obstetrical care for those economically or geographically unable to obtain it elsewhere. For the most part these programs have consisted of the establishment of prenatal clinics at strategic points throughout a given area. In some instances the prenatal program has been supple-

mented by home delivery service either through the cooperation of local physicians or the employment of certified nurse midwives.\* Programs such as these under the direction of departments of health have, in many areas, played an important part in providing a much needed service. Further extension of this type of service is urgently needed in those states with higher percentages of nonwhites and large segments of the population bordering on poverty. Even in those states with already established public health maternity programs, renewed effort in the direction of better case finding and improved cooperation between health department and local practicing physicians will lead to better health and happiness for the mothers and infants of their communities.

**Prenatal Care.** One of the first basic advances in obstetrical care in this country came with the acceptance of systematized prenatal care. At the turn of the present century the prevailing custom was for the expectant mother to notify her family physician or midwife of the fact that she was pregnant and to engage him or her to attend her at the onset of labor. Rarely was the patient seen by a physician prior to the onset of labor or the appearance of serious disturbances of the nature of hemorrhage or convulsions. This haphazard practice has been gradually replaced by a system of careful prenatal supervision beginning in the early months of pregnancy. No accurate figures are available on a nation-wide basis concerning the percentage of pregnant women today who receive adequate prenatal supervision. It is highly probable, however, that in excess of 90 per cent of all pregnant women are receiving at last minimal prenatal examinations and supervision.

The essential components of adequate prenatal care are: (1) a careful and complete medical history; (2) a complete physical examination, including internal pelvic mensuration and bimanual pelvic examination to determine the presence or absence of abnormalities of the reproductive tract; (3) urinalysis; (4) blood pressure determination; (5) blood studies, including serological test for syphilis and determination of the Rh factor and hemoglobin level; (6) advice and instruction concerning diet and general hygiene; and (7) a tactful warning about the signs and symptoms of developing abnormalities. Prenatal care which does not include all of the above cannot be considered adequate. Continued education of the public has led to patients knowing about and demanding complete prenatal care.

The initial examination during each pregnancy includes the above and is followed by monthly visits until the thirty-second week, visits every two weeks until the thirty-sixth week, and weekly visits from then until delivery. The minimal required examinations and procedures at each follow-up visit include determination of blood pressure and weight, palpation of the abdomen for position and size of the fetus, auscultation of fetal heart, and urinalysis. The patient is questioned concerning the presence of any abnormal symptoms, particularly headache, visual disturbances, or vaginal bleeding. Further instructions for her general care or diet are given as indicated, and particular attention is paid to the mother's mental and emotional status, and information is given the patient concerning labor and delivery. This routine is considered adequate for normal patients, but the frequency of visits should be greatly increased if there is any evidence of developing abnormalities, particularly toxemia.

\*A certified nurse midwife is a graduate registered nurse who has successfully completed a recognized course in midwifery covering theory and practice.

Prenatal care is being rendered by physicians in their offices, by prenatal clinics attached to hospitals, and by prenatal clinics established and operated by departments of health. In a few remote rural areas an excellent quality of prenatal care is being given by certified nurse-midwives. Irrespective, therefore, of economic status prenatal care has been made available to the overwhelming majority of women in this country. The establishment of free clinics by health departments during the last two decades has done much to make this type of care easily accessible to a group previously deprived of it.

In relation to the major causes of maternal mortality, prenatal care has done more than any other single factor to reduce both the incidence of and mortality from the toxemias of pregnancy. Eclampsia has come to be considered a preventable disease, but its prevention depends upon systematic prenatal follow-up with meticulous attention to, and understanding of, the implications of excessive weight gain, moderate upward blood pressure trends, and the appearance of albuminuria. Other important results of adequate prenatal care have been the early detection and treatment of syphilis in the mother with prevention of the transmission of this disease to the offspring, the detection of Rh iso-immunization, and the discovery of the presence of contracted pelvis. The very core, therefore, of any program of maternity care is the maintenance of adequate prenatal care for the entire community. Only in this way is it possible to detect and make provisions for the proper care of the abnormalities of pregnancy and assure to the mothers of the country the safeguards and advantages of modern obstetrical care.

**Development of Obstetrics as a Specialty.** At the beginning of the present century the specialist in obstetrics was unknown. Deliveries throughout the country were being conducted by untrained midwives and by general practitioners with a minimum of training in the art of obstetrics. During the past 50 years there has been a steady increase in the number of physicians specializing in obstetrics. At the present time there are more than 2,500 physicians certified as competent specialists by the American Board of Obstetrics and Gynecology. There is probably an equal number of thoroughly competent obstetricians who, for one reason or another, have not been inclined to apply for board certification. Assuming that each of these 5,000 competent obstetricians is performing approximately 200 deliveries annually, approximately one million births, one third of the total number, are being conducted by specialists.

Intensive postgraduate training has been necessary to produce each qualified obstetrician. Most of this instruction has been obtained through residences in obstetrics established by teaching hospitals, wherein the young physician spends from three to five years in intensive training in obstetrics and gynecology. These residencies are much sought after by those desiring to complete their training in obstetrics. The organization in 1930 of the American Board of Obstetrics and Gynecology has done much to emphasize the necessity for formal postgraduate training and to encourage young doctors to become fully qualified in their specialty. The problem for the immediate future rests in increasing the number of approved residencies for obstetrical training in order to turn out each year an ever-increasing number of physicians qualified in obstetrics.

**The Role of the General Practitioner.** Although the trend toward specialization has been steady, at least 60 per cent of all births in the United States are still being

attended by general practitioners. The general practitioner today finds himself in an unenviable position. It is quite impossible for any single individual to master all of the basic details of the ever-increasing subdivisions of medical science. He cannot, and should not, be expected to be an expert surgeon, internist, neurologist, pediatrician, gynecologist, and obstetrician, at one and the same time. The average busy general practitioner cannot possibly give the same brand of obstetrical care in complicated cases as the specialist. The general practitioner, therefore, should wherever possible confine himself to the conduct of normal pregnancies, labors, and deliveries, and be willing to refer to the specialist those patients with abnormalities. Ethical teamwork of this nature will lead to the eventual benefit of both types of physicians and more important, to patients. The day of the performance of difficult obstetrical procedures by the partially trained physician is waning, and with its complete disappearance will come even better results to the mothers and children of the country.

**Maternal Mortality Committees.** Reference has been made to the studies of maternal mortality committees and their findings concerning the preventability of maternal deaths. This new and unusual technic of self-appraisal by the medical profession was initiated in the early thirties. These committees, comprised usually of obstetricians, have studied carefully the events pertaining to each and every maternal death in their respective communities. Their frank and unbiased appraisal of the facts has brought into the open many deficiencies existing in community resources for the care of pregnant women. The extent of the influence of such committees cannot be measured on a numerical basis, but it is the opinion of all who have been associated with their activities that, by calling attention to existing deficiencies, they have done much to raise the standards of care being rendered by hospitals and individual physicians.

The first step in the establishment of a maternal mortality committee is the procurement of backing from the appropriate medical society, since it must be emphasized that the venture is a project of self-examination, sponsored and conducted by the medical profession itself. In areas where this type of committee has been in operation for a number of years, the cooperation of practicing physicians has been outstandingly good, and legal implications have been absent. It has been realized that the activities of these committees have been impersonal, and designed for the ultimate benefit of both patients and physicians. There should be no thought of "policing" or retaliatory action against physicians who are judged to have erred.

Notification of a maternal death is obtained from the vital statistics division of the local health department. Upon receipt of this information, contact by one of the committee members is made with the attending physician of the deceased either by personal interview or by letter. All pertinent information is gathered from the physician, from his records, and, with the physician's permission, from the hospital records. At the committee meeting, which often is held in a public gathering open to all members of the medical profession, the facts are presented anonymously and discussed frankly, and several questions are submitted for vote. First, was the death maternal? Second, was it preventable? Third, if preventable, to whom should the responsibility for the death be assigned—the physician, the patient, the hospital, or the community? Often as not the attending physician is present to listen to the discussion of his management of the case. In those areas where information is gathered

by mail and meetings held privately, the physician is informed by letter concerning the committee's opinion of the responsibility for his patient's death together with a brief description of any preferred methods of treatment or diagnosis. The entire project has great educational value both to the members of the committees and the attending physicians.

As previously noted approximately two thirds of all maternal deaths subjected to this type of analysis have been judged to have been preventable. In the majority of instances the physician has been charged with the major responsibility for the fatality while in others the patient has been held largely to blame by failure to seek medical care or to follow instructions. The following phrases have been abstracted from the study of maternal mortality in New York City previously referred to: "ignorance and insufficient training of the attendant prevented him from giving the high quality of care which he was attempting to provide for his patient." "Prenatal care was inadequate and improper." "Physical examination was careless and incomplete." "The high incidence of operative interference during labor was an important factor in the results." "Frequently the operation chosen was the wrong one. Often it was undertaken at an improper time." "The incapacity of the attendants, either in judgment or skill, contributed significantly to the large number of avoidable deaths." "Hospital standards were inadequate in many instances." "The actual physical equipment was inadequate in some hospitals."

Whereas statements of this type may appear at first glance to be blunt, they have been recorded in impersonal fashion. Many physicians have learned never-to-be-forgotten lessons from frank appraisals of this nature. Hospitals have made provisions for prompt transfusion facilities and better nursing care and have established separate maternity sections as the result of having their shortcomings pointed out by maternal mortality committees. These committees have based their findings on the assumption that ideal care should have been available and consequently have done much to influence physicians and hospitals to provide such care. There can be little question but that maternal deaths in every section of the country should be subjected to periodic review by a maternal mortality committee. In those areas in which they are lacking, their organization and operation will do much to improve community maternal health.

**Educational Aspects.** The fundamental basis of past progress in maternal health and of our hopes for further improvement in the years ahead is essentially one of education. This phase of maternal health is by far the most important and at the same time the most challenging. While it is unquestionably true that both physicians and their patients are today better informed concerning good maternity care than ever before, perfection has by no means been attained. The reports of maternal mortality committees or a careful scrutiny of many community-wide resources for the care of pregnant women will reveal certain glaring deficiencies. Patients, either through ignorance or laziness, are failing to seek medical care during pregnancy. In other instances physicians and hospitals are failing to render a satisfactory brand of modern obstetrical care. The basic answer to meeting these two general deficiencies lies in a more intensive educational program directed toward patients and those who are destined to care for patients.

Most women today are familiar with the maxim of early and regular prenatal examination and supervision by a physician. The higher the educational level of

the individual patient, the more is this likely to be true. The great majority of women failing to seek medical attention early in pregnancy come from the ignorant and underprivileged groups. The major task of reaching these offenders falls to the lot of departments of public health and other agencies dealing with indigents or near-indigents. The public health nurse in her daily rounds among her patients plays a role of inestimable value in teaching the importance of early and adequate prenatal care. Simple basic truths have been spread through a community from person to person in this fashion. Great credit must be given to public health nurses for the part they have played in education of the public. In the future ever-increasing efforts of this nature are necessary, particularly in areas where poverty and ignorance abound.

Supplementing the power of the spoken word has been the use of written material. Timely articles in popular publications, books by prominent obstetricians, and pamphlets outlining in simple terms the basic principles of prenatal care and hygiene during pregnancy have been effective in producing a better-informed public. In some instances authors of this type of material have been guilty of distorting the facts somewhat in an effort to be dramatic. Such has been true in regard to the Rh factor and its implications in regard to pregnancy. In general, however, the results of this type of educational program have been eminently beneficial. The present trend toward sex education in high schools and colleges opens an additional avenue for instruction in the hygiene of pregnancy. The incorporation of the basic facts concerning prenatal care in the education of the young women of the country long before marriage and motherhood are contemplated would seem to have great merit. Greater emphasis on the role played by prospective fathers is needed and the education of fathers can likewise begin in high school or college or through the establishment of parents' classes.

As pointed out in the discussion of maternal mortality committees, in most instances the blame for maternal deaths has been assigned to the attending physician or physicians on the basis of incorrect diagnosis or faulty treatment. It can be concluded, therefore, that greater numbers of physicians better qualified in the fundamentals of obstetrical care are needed. Since there has been a tremendous increase in the volume of scientific knowledge to be acquired by medical students, it seems highly improbable that the medical school curriculum can devote more time to the specialty of obstetrics. The obstetrical training of physicians must come in their postgraduate years and should have two clearly recognized goals. The first of these is to create fully qualified obstetrical specialists. The second is to give the physician planning on general practice sufficient obstetrical knowledge to enable him to conduct competently normal pregnancies and deliveries. This fundamental distinction is of importance. In the creation of a qualified specialist a minimum of three years of intensive study is needed. The American Board of Obstetrics and Gynecology requires three years of service in an approved hospital residency in these specialties before a candidate is eligible for certification. In regard to the physician contemplating general practice the ultimate goal differs in that the emphasis should be on the conduct of normal cases, plus sufficient ability and experience for the early recognition of abnormalities. No attempt should be made to train the general practitioner to perform difficult obstetrical procedures. The day of "kitchen table" obstetrics is over.

An additional finding of maternal mortality committees has been a definite failure on the part of attending physicians to seek consultation. Closely integrated with the obstetrical training of general practitioners to recognize deviations from the normal must be emphasis on the value of competent consultation. Lack of easily available consultants, plus an apparent reluctance to seek consultation, have been the major factors at work. Many smaller communities, particularly in rural areas, have no local practicing obstetrician. Several schemes are being tried in various portions of the country to meet this situation. In some localities the larger teaching hospitals are cooperating with smaller hospitals in making readily available a staff of recognized specialists in all of the major branches of medicine. In other areas, health departments have undertaken to furnish consultants to the more remote hospitals and communities. Evidence indicates that in those regions where such plans are in operation the quality of community obstetrical care has improved. Until such time as there is a better distribution of obstetricians, plans of this type are to be desired.

**Place of Delivery.** Until the past few decades hospital care for the pregnant woman was reserved for the poor or the dying. At the beginning of the present century the overwhelming majority of all births took place in the home, and few self-respecting mothers would consider hospitalization for delivery. In various portions of the world with their differing customs and ideas there is still difference of opinion concerning the merits of hospital delivery. Those who contend it is unnecessary and undesirable point out that it is illogical to teach that childbirth is a normal and natural process, only to insist upon hospitalization for delivery. They further emphasize the dangers of cross infection in nurseries and on postpartum wards and state that being at home in familiar surroundings is of great value to the mother's mental attitude. While it must be granted that where competent prenatal care has revealed an entirely normal pregnancy, labor and delivery are usually quite uneventful; nevertheless, sudden and unexpected catastrophies do occasionally occur in the most normal of patients. Foremost of these is the danger of sudden profuse postpartum hemorrhage with its ability to kill rapidly. Second, there is the possibility of the delivery of a severely asphyxiated infant. There can be no question but that the modern maternity unit of a hospital is better equipped to handle these emergencies than would be possible either in the home or by rapid transfer of the patient to a hospital.

Whatever one's personal feelings concerning the advantage or disadvantage of hospital delivery, the trend in the United States has been steadily toward a larger and larger percentage of deliveries in hospitals. In the short space of 12 years, from 1935 to 1947, the percentage of hospital deliveries in this country more than doubled, increasing from less than 40 per cent in 1935 to more than 80 per cent in 1947. The fact that this trend has occurred concomitantly with the rapid decline in maternal mortality is probably more than coincidental, and the majority opinion in this country today is in favor of hospital delivery. Skeptics point out that physicians have urged hospital delivery because it is more "convenient" for them. There can be no denying this fact, but rather than constituting an argument against hospital delivery, it is actually a factor in favor of it. The physician who attempts to give labor and delivery care in homes scattered throughout a community cannot possibly give the same quality of care as when he can group his patients in the

"convenient" environment of a well equipped hospital. He is more rested and able to give more time to his patients.

**Hospital Standards.** In assessing the value of hospital delivery it must be emphasized that the quality of hospital care is of paramount importance. A poorly organized, inefficient hospital maternity service can be more of a hazard than a safeguard to mother and infant. Coincident with the trend toward hospital care for maternity patients has been a steady raising of hospital standards. The studies of maternal mortality committees and the experience of the Emergency Maternal and Infant Care Program during World War II pointed out serious shortcomings in the quality of obstetrical and newborn care as given in many hospitals. Aside from the quality of care, there is the matter of preparing for an added number of patients. Approximately 600,000 women annually are still being delivered in their homes in this country. To prepare for these additional patients and to improve the standard of care already being given is a task of no insignificant magnitude.

In planning for adequate care for maternity patients certain basic considerations are of paramount value. Maternity units should be physically separate areas of hospitals and should have their own nursing staffs. In this way maximum protection against cross infection is afforded both mother and newborn infant. The common use of a single open ward or hospital area by obstetrical, surgical, and medical patients cannot be condoned. Infection still ranks as one of the leading causes of maternal deaths, and penicillin does not excuse the abandonment of time-honored aseptic precautions.

Standards for maternity sections of general hospitals are set forth by the Surgeon General of the U. S. Public Health Service as required by the Hospital and Construction Act. Under these requirements, it is established that there should be one delivery room for every 20 maternity beds and one labor bed for every 10 maternity beds. Eighty square feet of floor space is the minimum per bed in two- or four-bed rooms, with a minimum of 100 square feet of floor space in every one-bed room. It is further recommended that in hospitals of 100 beds or more, the maternity department should be housed in a separate wing or floor.

Labor and delivery room areas should be planned to provide maximum protection for mother and child against sudden unforeseen emergencies. Foremost of these are protection against shock and treatment of severe asphyxia of the newborn. Intravenous fluids, provisions for prompt blood transfusion, provisions for oxygen therapy for both mother and newborn, and standard drugs and equipment to meet all obstetrical emergencies are necessities. With hemorrhage the leading cause of fatalities in parturient women, the establishment of a blood bank assumes primary importance. Smaller hospitals unquestionably find the administration of a blood bank more difficult than do the larger hospitals, since the turnover of blood is less, and the problem of outdated blood becomes more acute. The fact of the difficulty of maintaining a blood bank, however, does not excuse its absence. Blood properly collected and stored can be safely used for 21 days from the date of bleeding. Even the smallest and most remote hospital can with some thought and effort establish a minimal blood bank, perhaps in cooperation with one or more neighboring hospitals. If all else fails, the presence of two or three pints of group O, Rh negative blood will be sufficient for most emergencies and will serve to tide the patient over while donors are being procured. Group O, Rh-negative blood can be safely given

to any recipient without the necessity for cross matching. Whatever the administrative obstacles, the fact remains that provisions for prompt replacement of blood must be given top priority in planning a modern obstetrical unit. Only with blood readily available and an alert physician in attendance will the loss of life from hemorrhage be materially reduced.

Adequate nursing coverage is vital to the efficient operation of maternity units. Patients in labor merit constant attention, particularly when amnesic or analgesic drugs have been administered. In numbers, the nursing staff should be adequate to provide attention to patients in labor, delivery room coverage, and service to postpartum patients without the necessity of obtaining nurses from other portions of the hospital. A competent scrub nurse should be available whenever the physician desires one. There is no more reason why a physician should undertake a difficult delivery without an assistant, than that he should begin a major surgical operation unassisted. Aside from mere numbers the nursing staff should include coverage at all times by at least one nurse who has had extended postgraduate training and experience in obstetrics.

The majority of women in the United States today receive some form of medication for the relief of pain either during labor or for delivery. Each year are recorded a number of deaths due to "accidents of anesthesia." Most of these pathetic catastrophes are preventable and are due to lack of experience on the part of the person administering the drug or agent. For some strange reason it is assumed in some areas that anyone able to hold a can of ether is capable of administering obstetrical anesthesia. It is more difficult, however, to administer competent obstetrical anesthesia than for major surgical procedures since the oxygen requirements of the fetus and the effect of the anesthetic agent upon the fetus must be considered during the process of providing adequate pain relief to the mother. The same thought should be given to the availability of a competent anesthetist for an obstetrical service as for a surgical service.

Organization of the professional staff of hospitals into services is becoming widespread. The pattern being established includes the appointment of a chief of service with authority to set down certain basic rules for the conduct of his service. In obstetrics, staff members are given either full or limited privileges dependent upon their individual training and experience. Staff physicians with limited privileges are usually required to confine their activities to normal and low forceps deliveries. In the event of complications of pregnancy or abnormal labors, they are required to call for assistance from one of the staff members having full obstetrical privileges. This type of staff organization has done much to reduce the incidence of ill-advised traumatic procedures with their accompanying hazard to mother and infant. In many smaller hospitals programs of this nature are handicapped by the fact that there is no fully competent obstetrician on the staff of the hospital. This problem can be met in one of two ways, either by making the best of what is available, or seeking aid from the nearest hospital or community possessing competent obstetricians. The ultimate solution will come only when obstetricians move into the smaller communities. It is to be noted, however, that one of the major factors preventing younger, well-qualified obstetricians from locating in smaller communities in many instances is the unsatisfactory standards of the local hospital. With the steady improvement in hospital standards throughout the country will come a better distribution of physi-

cians of all types between urban and rural areas. At the present time there is an overabundance of competent specialists in the larger cities with a corresponding lack in rural areas and small towns.

**Scientific Advances.** Coincident with the improved obstetrical training of physicians, the acceptance of prenatal care, and the trend toward hospital delivery have come many additions to the tools and technics available to those furnishing care to parturient women. Of major importance among these advances are the sulfonamides, the antibiotics, the freer use of whole blood transfusion, the establishment of blood banks, the advent and increased use of accurate x-ray pelvimetry, better surgical technics, particularly the low cervical caesarean section, and improved technics and safeguards in analgesia and anesthesia. Each of the above has contributed immeasurably to the increased safety of childbirth. With the value of each of these measures well proven it is the duty of every individual charged with the responsibility for the care of pregnant women to be familiar with their use and to see that they are made available when needed.

**The Midwife.** The development of obstetrics as a speciality and the trend to hospital delivery has steadily tended to eliminate the midwife in this country. The number of deliveries performed by nonmedical persons in this country has fallen from 12.5 per cent in 1935 to 5.4 per cent in 1946. It should be noted, however, that the national average of 5.4 per cent is dependent largely on the high percentage of deliveries conducted by midwives in certain southern states with a large number of nonwhite births. To illustrate, in 1946 36.9 per cent of all deliveries and 69.0 per cent of all nonwhite births in Mississippi were attended by nonmedical persons. In contrast, many New England states recorded 0.1 per cent or less deliveries by nonmedical persons. All states recording more than 10 per cent nonmedical deliveries belong to the south and southwest portion of the country where the nonwhite population is high, distances great, facilities for hospitalization meager, and the number of physicians scant.

For the moment, therefore, the midwife must remain in some areas until she can be replaced by physicians and hospitals. In the meantime, much can be done to safeguard the lives of patients who must depend on the midwife for delivery care. Individual states are obtaining legislation to require midwives to secure licenses to practice. Licensure should depend upon the ability to pass an examination on the basic knowledge of obstetrical technics. The legal power to examine and train midwives is usually given to the state health departments and supplemented by the responsibility of supervising their activities. Wherever possible, all patients are examined by a competent physician at least once during pregnancy before being relegated to midwife care. If abnormalities are detected by the physician, every effort is made to obtain medical care for the patient. In this fashion, midwives will be limited in their activities to normal patients. In the event of the development of unforeseen emergencies, the midwife should have ready access to a physician for help and consultation. Only through steps such as these can the lives of patients in the hands of midwives be made reasonably safe. In due time, however, it seems fairly clear that the midwife will fade from the scene in the United States. In countries where physicians and hospitals are totally inadequate, the problem differs considerably in magnitude but basically involves the proper training and supervision of the midwife, plus making medical care available to her patients in emergencies.

## INFANT AND PRESCHOOL SERVICES

PAUL A. HARPER, M.D., M.P.H.

**The Problem.** The increasing magnitude of the task of those concerned with child health is shown by Figure 16-1 which gives the rise in the birth rate over

Fig. 16-1. Crude birth rate by race, United States, 1927 to 1954.

The relative rise in birth rate has been greater for the white than for the nonwhite population. Health and education facilities must be provided for about 50 per cent more children each year now than in the 1930-1940 decade.

recent years. The implication of this in the planning of health and education facilities is clear; such facilities must be provided for nearly 50 per cent more children each year now than in the 1930-1940 decade.

Figure 16-2 shows infant mortality by race and by main cause, given as deaths per 1,000 live births. Race, economic status, and geographical location each affect these curves; the influence of race is shown. How much of this difference is biological and how much is due to economic status and geographic location is not established. The lower economic and the rural groups both have higher mortality rates than the higher economic and the urban segments of the population.

These mortality curves have been steadily decreasing for the past 50 years and it seems probable that we shall in the near future reach a point where further decreases, at least for the white race, will be more and more difficult to achieve. The first implication of this fact is that there will be a need—indeed, there is already a need—to develop other indices than mortality curves to give us an adequate measure of progress. This problem becomes more apparent when the wide range in infant mortality in the various reporting areas of the country is considered; thus, states

Fig. 16-2. Infant mortality by race and main causes, United States.

Left, infant mortality has decreased 50 per cent since 1933, but the rate for nonwhite infants is still about 60 per cent higher than for white infants.

Right, premature birth is still far in the lead as the main cause of death.

such as Connecticut and Iowa had a rate of about 21 deaths per 1,000 live births per year in 1952, and such states clearly need other indices of progress. On the other hand, Texas, in 1952, had an infant mortality of 34; Arizona, 44; and New Mexico, 47; and for such states the present mortality curves will continue to offer a valuable index of progress for a considerable time to come.

Inspection of the right-hand side of Figure 16-2 shows that most of the decrease in infant mortality has been due to better control of infectious disease; the progress which can still be made in this area is clearly limited. Congenital malformations and birth injury have shown relatively little decrease; both of these are dependent upon new knowledge and better prenatal and paranatal care to effect further reductions. Prematurity is still far in the lead as a cause of infant mortality. It is clear that this is the area which probably offers greater opportunity than any other for continued reduction in infant mortality.

Figure 16-3 shows the main causes of preschool child mortality. It should be noted that the scale has changed from that used for infants and is given in deaths per 100,000 population, age 1-4. Here again the deaths due to infectious diseases have shown a rapid decrease while deaths due to accidents have decreased relatively

slowly and are now in first place. Motor vehicle accidents have caused about 25 per cent of these accidental deaths.

These charts show some aspects of the problem. Of increasing importance is the mass of less exact information which is concerned with physical, emotional and mental health and with the prevention of illness. For example, more than half of all infants and young children have problems related to feeding, toilet training, or sleep-

Fig. 16-3. Preschool child mortality (ages 1-4) by main causes, U. S. A., 1933-1948.

Deaths due to accidents have decreased relatively slowly and are now in first place. Motor vehicle accidents cause over one fourth of all accidental deaths in this age group.

ing, and their parents need advice on these matters. Or, again, planning is influenced by recent work which shows that about 5 per cent of all school children have impaired hearing which requires medical advice. The high incidence of uncorrected defects of eye and teeth is another example of the many problems in this area.

**Relation of the Child's Health to that of the Mother During Pregnancy.** There is increasing evidence that the prenatal health and care of the mother have a direct effect on the health and survival of the infant. On the other hand, recent studies of the influence of nutrition in the mother on the fetus and newborn infant present conflicting results which have important implications for public health policy.

Ebbs (1941) and his co-workers in Toronto studied three groups of pregnant women (see Table 16-1). One group of 120 women had low incomes and poor diets. The other two groups both had good diets, part of them being women with low incomes whose food intake was supplemented with proteins and vitamins and

Table 16-1. Maternal diet and condition of infant at birth

Diet	No. of Women	Miscarriages Per Cent	Stillbirths Per Cent	Prematures Per Cent
Poor	120	6.0	3.4	8.0
Good	260	0.8	0.4	2.7

Arranged from Ebbs and others, J. Nutrition, 22:515, 1941.

the rest were women with fairly adequate incomes who were advised regarding desirable foods. These latter two groups have been combined in Table 16-1 as having good diets. At the conclusion of this study it was found that 6 per cent of those on a poor diet had miscarriages, as contrasted with 0.8 per cent of those on a good diet. The corresponding figures for stillbirths were 3.4 and 0.4 per cent, and for premature births 8.0 and 2.7 per cent. These findings have been confirmed by Balfour (1944); Burke and others (1943). Stuart (1945) and his group in Boston found that there was a direct relationship between the weight of the newborn infant and the quality of mother's diet during pregnancy; thus over 90 per cent of the mothers who had a good or excellent diet produced children weighing over seven pounds, while only 23 per cent of the mothers who had a poor to very poor diet produced babies above this weight.

World War II offered opportunities to study the effect on the fetus of maternal diets which were so poor that they bordered on starvation. Smith (1947) studied the effects of the severe temporary starvation which occurred in Rotterdam and The Hague from late 1944 until June, 1945. The reason for the hunger in these cities was the general transportation strike against the Germans which began September 17, 1944, at the request of the exiled Dutch Government in London at a time when it seemed that Holland would soon be liberated. This did not happen, but the strike held for the entire period until liberation in May, 1945. Little or no food or fuel was transported to the major cities. The Germans guarded roads against smuggling with the hope that hunger would break the strike. The birth weight of infants which were born during the hunger period decreased by an average of over 200 gm. as compared with prewar birth weights. Antonov (1947) made a similar study in Leningrad during the siege of 1942 and found an average decrease in birth weight of 500 to 600 gm. The drop in birth weight was believed to be indicative of general lowered nutritional status in the infant and supported the thesis that the fetus is affected by the nutrition of the mother.

Taylor and his associates (1949) found that premature infants who are born of mothers having severe uncontrolled medical disease or serious obstetrical complications have a mortality rate which is four or five times that of premature infants born to healthy mothers who had no complications during delivery (see Table 16-2). They expressed the view that one of the best ways to reduce premature mortality is by preventing obstetric complications. The importance of a good diet

Table 16-2. Premature mortality by complication of pregnancy—stillborn and neonatal deaths

Classification of Pregnancy	Total Infants Born	Infants Lost	Per Cent Infants Lost
Uncomplicated	344	27	8
Complicated	133	49	37
Total	477	76	16

Arranged from Taylor and others, J.A.M.A., 141:13, 1949

during pregnancy in reducing the incidence of toxemia is discussed and emphasis is placed on the value of bed rest and other conservative measures for carrying nearer to term women with slight bleeding from placenta praevia or premature separation of membranes. These authors concluded that the major responsibility for reducing the mortality rates of premature infants rests with those doing prenatal and obstetrical work.

On the other hand, there are four careful studies which fail to support the above observations. Williams and Fralin (1942) were not able to establish a relationship between the dietary ratings of over 500 women in Philadelphia and the incidence of toxemia, prematurity, stillbirth, or birth weight of their infants. Sontag and Wines (1947) in a study of over 200 mothers and infants in Ohio were unable to find any significant correlation between the mothers' diet and the weight, length, or ossification level of the infant. However, it should be commented that these latter patients are described as from the upper middle class and it is possible that they did not fall below the critical level where a poor diet might affect the fetus.

Speert (1951) in New York and McGanity (1954) in excellent studies in Nashville were likewise unable to show any relationship between nutrition in the mother and the complications or outcome of pregnancy. Both studies were of low and low-middle socio-economic groups.

What is the implication of these conflicting data? A reasonable working assumption is that there is a point or zone below which dietary shortcomings do affect the fetus; that the limits of this zone are not known nor how many people in our national community eat diets which are so poor as to fall below this critical level. Although evidence is accumulating that the number of people on seriously deficient diets is not great, nevertheless the health officer who frequently deals with the lower economic groups has no simple means to pick out the mothers who need special attention. Furthermore, the objective is to promote good nutrition, not merely to avoid malnutrition. It, therefore, seems clear that continued emphasis on more prenatal care and on a better diet for pregnant women will result in more healthy babies. More hospital beds at the disposal of obstetricians for the use of mothers who develop complications during pregnancy is probably one of the best investments of money intended to reduce premature mortality. The human uterus is a far better incubator than any mechanical one.

**Distribution of Health Services for Children.** The Academy of Pediatrics Study. The most valuable publication on child health services of this decade is the report of the nation-wide survey conducted in 1946 and early 1947 by the American Academy of Pediatrics in cooperation with the Children's Bureau and the Public

Health Service (Am. Acad. Ped. 1949a). This survey gathered data from all physicians who care for children, from hospitals which serve children and from public and voluntary agencies both state and local which provide health services to children. The national report is supplemented by individual reports from more than half of the 48 states. Table 16-3 shows that 98.5 per cent of children under medical

Table 16-3. Children under medical care per day per 1,000 in the United States

Source of Care	Number per 1,000 Children	Per Cent
Physicians (home and office visits)	10.7	77.5
Hospital, including outpatient dept.	2.9	21.0
Community health clinic *	0.2	1.5
Total	13.8	100.0

\* Comprises visits to child health conferences, mental hygiene clinics and clinics for the physically handicapped. Adapted from Am. Acad. Ped., 1949, Supplement Table 13.

care on any given day receive this care from physicians in private practice or from hospitals and that 1.5 per cent of these children are seen in child health conferences, mental hygiene clinics or clinics for the physically handicapped. About 75 per cent of all private care for children, both when ill and when well, is given by general practitioners, 11 per cent is given by pediatricians and the remainder by other specialists.

A different distribution is found when the ill child is excluded and the data on well-child care are considered. Health supervision was defined as a visit for "health examination, immunization, regulation of feeding, etc." It is recognized that there was some confusion in individual cases as to whether a child should be classified as sick or well but it is believed that the data are valid. General practitioners reported that about one third of their visits to children were to well children and pediatricians said that more than half of their visits were for health supervision. Table 16-4 shows

Table 16-4. Health supervision for children (0-4 years) by source on an average day in the United States

Source	Number	Per 1,000 Children	Per Cent
Visits to children by private practitioners (home and office)	70,427	5.03	91
General practitioners	(48,729)	(3.48)	(63)
Pediatricians	(20,642)	(1.47)	(27)
Other specialists	( 1,056)	(0.08)	( 1)
Visits by children to child health conferences	6,964	0.49	9
Total	77,391	5.52	100

Adapted from Am. Acad. Ped., 1949, Supplement Table 158.

that physicians in private practice provide 91 per cent of all health supervision for infants and preschool children and that child health conferences give the remainder. The amount of health supervision given by pediatricians is surprisingly large in view of their relatively small numbers; they provide only 11 per cent of all medical care for children but 27 per cent of all health supervision.

Table 16-4 should not lead one to infer that all children were given health supervision by private physician or child health conference. The figures in this table refer only to children who did receive well-child care on an average day. How many children receive no health supervision is unknown. Although the number of visits made to private practitioners for health supervision on an average day is given, the number of children getting this service during the year is not shown. Only in the child health conferences is there a count of both visits on an average day and of the number of children seen during the year. The number of children under five who visited child health conferences was 872,418, or 6 per cent of the nation's 10,900,382 children in this age group in 1945 (American Academy of Pediatrics, 1949b, Supplement, Tables 1 and 118).

Health supervision, according to this study, comprises about one quarter of all medical care for children. There is no information regarding the amount of such preventive work 25 years ago to allow comparison; nevertheless, it is clear that the content of medical practice for children is changing in the direction of more health supervision for the well child.

It would be helpful to know the forces which have fostered this trend. Unfortunately, there are no exact data but it is thought that the most important factor has been the increase of knowledge about the physical, mental, and emotional development of children and about the prevention of illness; that the application of this knowledge has been greatly stimulated by the work of child health conferences and by the development of pediatrics as a specialty; and finally that the public has recognized the value of and wants this type of medical care.

It is worth while to point out that the situation outlined above is quite different from that in Great Britain and some of the northern European countries where the source of well-child supervision is largely from public clinics. In London, about 90 per cent of all well-child care for all economic classes is provided by public clinics. The private physician in those countries has been chiefly concerned with the ill child and the separation of responsibility for the well and the ill child has been much more marked than in this country. In Great Britain, for example, most health supervision is done by nurses and others who are trained as health visitors.

**Geographical Distribution of Health Services.** Health services are not evenly distributed throughout the country. This contrast is brought out clearly in the Academy study by giving the value of 1.00 to the rate of visits in the greater metropolitan counties \* and calculating the relative rates for each of the other county groups (see Table 16-5). Children in the isolated rural counties receive less than one-quarter as many visits for well-child care as do children in the greater metropolitan areas. It might be expected that child health conferences would be more numerous in the rural counties but the contrary is true.

**Public Organization for the Care of the Well Child.** Public programs for the care of the well child are a development of the past 50 years. As already noted they

\* The Academy study classified a greater metropolitan county as one which contains any part of the metropolitan area of the population centers of 1,000,000 or more people, namely, Baltimore, Boston, Chicago, Cleveland, Detroit, Los Angeles, New York, Philadelphia, Pittsburgh, St. Louis, San Francisco, Washington. A lesser metropolitan county contains at least one city of 50,000 or more people. A county that touches a metropolitan county is classified as adjacent. An isolated semi-rural county has at least one incorporated place of 2,500 or more inhabitants and an isolated rural county has no incorporated community of that size.

Table 16-5. Health supervision by source and by county group per 1,000 children under 5 years, United States

County Group	Rate of Visits Taking Greater Metropolitan Rate as 1.00			Total
	General Practitioners	Pediatricians	Child Health Conferences	
Greater metropolitan	1.00	1.00	1.00	1.00
Lesser metropolitan	0.58	0.96	0.53	0.69
Adjacent	0.70	0.13	0.16	0.45
Isolated semi-rural	0.59	0.16	0.12	0.40
Isolated rural	0.38	0.00	0.10	0.23

From Am. Acad. Ped., 1949, p. 128.

grew out of efforts which were begun by voluntary and private groups. In general, these programs have been designed to stimulate and supplement the services of private medical practice and to provide health supervision for a segment of the population which would not otherwise get such care.

Different patterns have developed for each age group. The health of the infant in the neonatal period is largely concerned with care in hospital and has become the responsibility of the health agency through its hospital inspection and maternal and child health divisions. The health supervision of the older infant and preschool child is largely centralized in child health conferences, most of which are operated by health agencies, a few by voluntary groups. Public programs for supervision of the health of children of school age are not as well organized as are services for the other two age groups, and the operation of such programs as exist is sometimes the responsibility of the health department, sometimes of the education agency, sometimes jointly, and all too often is the source of jurisdictional conflict. Public services for each age group will be discussed in order.

**THE NEONATAL PERIOD (BIRTH TO 28 DAYS).** Three major problems which arise in this age period have public health aspects: these are the prevention and treatment of prematurity; the prevention of epidemic diarrhea of the newborn; and the licensing of hospitals with regard to their facilities for both prematures and newborns. Included in this latter category is the approval of plans for the construction of hospitals which are to receive money under Public Law 725, 79th Congress, The Hospital Survey and Construction Act.

A few figures serve to point up these problems. The neonatal mortality is approximately two thirds and the deaths during the first day of life are nearly one third of the total infant mortality. The main causes are the same as those shown in Figure 16-3 for all infants, with the differences that prematurity, birth injury and congenital malformation are each of greater relative importance. Table 16-6 presents the same problem in another way by showing that efforts must be concentrated on the causes of death in the first month and especially on the first day. Many of these matters are the responsibility of the obstetrician and those who care for the mother during pregnancy and delivery, as has been discussed in previous sections. Here, we are concerned with the responsibility of the child's physician and of the health officer.

Table 16-6. Thirty-five year decrease in infant mortality by age groups

Age at Death	Infant Mortality Rate		Decrease
	1915 <sup>1</sup>	1950 <sup>2</sup>	Per Cent
6-11 months	22.0	2.7	88
1-5 months	33.6	6.0	82
Under 1 month	44.4	20.5	54
Under 1 day	15.0	10.2	32

<sup>2</sup> Vital Statistics, Special Reports, Vol. 37, No. 18, 1954.

*Prematurity.* Premature birth is a public health problem of the first rank (Lesser, 1950). That there exists widespread current realization of this fact is largely due to the persistent efforts of Dunham (1955) who has repeatedly pointed out for many years that "premature birth takes a higher toll of infant life than any other condition, and is one of the leading causes of death among the general population of the United States." It accounts for half of all neonatal deaths and one third of all deaths during the first year of life.

Dunham has succinctly summarized the premature problem: "To save these infants we must make increased efforts to prevent premature birth; get more detailed information on deaths now assigned to premature birth alone; spread knowledge of and facilities for the special care known to be needed by premature infants; and broaden through research the scope of knowledge in regard to problems of prematurity."

To accomplish these objectives requires a high degree of "systematized social action" (Mustard, 1944), and the core of most of the varied state premature infant "programs" may be found in the leadership provided by state health departments for the promotion of organized cooperation between physicians, nurses, hospitals and health departments to achieve: (1) the prevention of prematurity by better obstetric care, and (2) the provision of better medical and nursing care and after care for the prematurely born infant.

Some of the methods which have been successfully used to achieve this organized cooperation between interested professional groups are the financial assistance by health departments to hospital premature nurseries, especially those engaged in training and research as well as service, and the cooperation of state medical societies. Another important device has been the cooperation of state health departments and hospital associations with the state Committee on Fetus and the Newborn of the American Academy of Pediatrics. In this latter connection, the "Standards and Recommendations for Hospital Care of Newborn Infants—Full-Term and Premature" of the American Academy of Pediatrics has been a significant contribution to the problem of improving hospital care of premature infants.

The interest of state health departments in establishing public health programs for the care of premature infants is not especially new. In 1937, the Massachusetts Department of Public Health inaugurated a program (McKay, 1949) featuring arrangements with 48 hospital centers outside of Boston which were adequately equipped to care for premature infants, a transportation service, and assistance to the family for payment of hospital expenses.

In recent years, the Children's Bureau has stimulated the development of state projects for the care of prematurely born infants. In 1949, programs of this type were being financed in whole or in part by federal maternal and child health funds in at least 14 states. Details of these programs vary from state to state, and it is obvious that a great deal more testing in actual operation and research must be done before the true effectiveness of this new public health effort is demonstrated. A recent study (Children's Bureau, 1950) of one state program (Colorado) provides valuable initial evidence of this sort. Currently, the Children's Bureau in cooperation with a pilot state is aiding a large scale study of the effect of different kinds of hospital care on the survival of prematurely born infants. An example of an urban public health program is described by Wallace and others (1950).

Lesser (1950) has summarized important features of the various state programs as follows: "training of nurses and physicians in the care of premature infants; development of hospital standards and licensing, with emphasis on facilities and personnel for proper care of premature infants; consultation to hospitals (principally by nursing consultants) to raise the standards of care for full-term as well as premature infants; loan of incubators, together with consultation regarding their use; provision of transportation of premature infants to premature-infant centers; development of designated premature-infant centers and purchase of hospital care from them." He also lists measures designed to prevent prematurity such as: "extension of prenatal services, with emphasis on diagnostic services and the importance of adequate nutrition; obstetric consultation for complications during pregnancy; hospitalization for complicated pregnancy; obstetric consultation to improve management of the mother's labor and delivery in cases of premature birth (since most of the premature infant deaths occur on the first day of life); and publicity and general education activities."

There are many unknowns concerning prematurity. Eastman (1947) points out that there is no specific explanation for 60 per cent of all premature births. More research is needed on the best definition of prematurity, the causes of premature labor, the effect of social and economic conditions, the methods of care, the cause of special handicaps, the effects of different types of care on survival, and the long-range facts of growth and development of these infants. The value of research is illustrated by the recent demonstration that retrolental fibroplasia is due to too vigorous oxygen therapy and that this great source of blindness can be largely eliminated by reduction of oxygen (Rothmund (1954), Kinsey, V. E. (1954) and Lanman (1955)).

*Epidemic Diarrhea, Hospital Licensing and Approval of New Construction.* Epidemic diarrhea of the newborn has become a public health problem during the last two decades. This is partly a result of the various pressures which have pushed hospital deliveries from less than 40 per cent in 1935 to about 90 per cent of all births. The resultant overcrowding and understaffing of nurseries is a matter of public record. There is no doubt that hospitalization is good for the mothers; it is not so clear that it is as desirable for the baby.

For example, although diarrhea of the newborn was not reportable in New York State until 1946, a total of 28 nursery epidemics came to the attention of the State Department of Health during the six-year period, 1942 through 1947 (Trussell,

1949). There were 618 ill infants with 62 deaths. The problem is greater than these figures indicate since these data are known to be incomplete. Similar situations are reported from other states all over the country. Clifford (1947) has reviewed the literature and discussed the etiology, the importance and the control of this disease.

The prevention of epidemic diarrhea and other infections in newborn babies was the chief motivating force which influenced the thinking of the Committee on Fetus and Newborn of the American Academy of Pediatrics in 1954 as they drew up "The Standards and Recommendations for Hospital Care of Newborn Infants." A similar purpose was behind the earlier publication on this subject by the Children's Bureau, Bulletin No. 292, in 1943. These publications recommend that the medical staff of the nursery should be a part of the pediatric staff, be integrated with the obstetrical staff and so organized that the responsibility for all newborn and premature infants is fixed on one physician. There should be one physician, preferably a resident physician, assigned to the nursery who will be on call 24 hours a day and who will visit the nursery daily. Standards of care should be available in writing for physicians and nurses. The nursery should be located in the obstetrical division of the hospital; if there is no obstetrical service the nursery should be in an area away from all units where transmissible disease may break out.

The United States Public Health Service Regulations, Title 42, Public Health Chapter 1, PHS, FSA, require that any construction to qualify for federal aid shall provide not less than 24 square feet per bassinet in full-term nurseries; 30 square feet are recommended. There shall be no more than 12 bassinets in each full-term nursery; eight bassinets are recommended. "Suspect" nurseries must provide 40 square feet per bassinet and not more than six bassinets per nursery. The total number of bassinets in "suspect" nurseries should be about 10 per cent of the total number of bassinets for full-term infants. These regulations were intended for new construction, but are rapidly being applied as minimum standards for current facilities. Thus, the New York State Sanitary Code, Chapter 2, Regulations 35, which went into effect on January 1, 1949, set up standards for all nurseries in upper New York State, of which the chief requirements are as follows:

Facilities for isolating "suspect" or ill infants.

Individual equipment for each infant except for weighing scales.

Common bathing and dressing tables prohibited.

Terminal sterilization of formula, which is to be in individual feeding bottle with nipple and cap attached.

Separate nurses for sick and well infants.

No common carriers for bassinets.

Nurse-baby ratio of 1 to 12, around the clock.

Twenty-four square feet of floor space for infant, or separate cubicle.

Not more than 12 infants per nursery.

No intercommunicating nurseries.

Running hot and cold water for handwashing in each nursery with control by elbow, knee, or foot valves.

It was recognized that overcrowding of nurseries was the result of an unexpected demand for hospital delivery and that hospitals were making every effort to improve their facilities; therefore, the regulations provided for deferment of enforcement of the last five items upon request of the hospital until not later than January 1, 1951. Other states and cities are framing similar regulations. Detailed suggestions regarding

the design and equipment of newborn and premature nurseries, "suspect" nurseries and formula rooms may be obtained from the Division of Hospital Facilities, Public Health Service or from the Division of Research, Children's Bureau, of the Federal Security Agency.

*Rooming-In.* The above standards and recommendations are aimed chiefly at reducing cross infection and, therefore, making the nursery safer for the baby. Recently, there has been considerable interest in other aspects of newborn care. The nursery in any large hospital is not unlike a factory assembly line. Work has to move on schedule and there is little time for individual attention. Both architects and hospital administrators have been prone to cut the nursery facilities and staff to the minimum acceptable standards. It is necessary to see and hear the bedlam in a large nursery during the half hour before feeding time and to note the work load of the nursing staff to understand what is meant.

The "rooming-in" plan is an arrangement designed to correct some of the shortcomings of the hospital nursery by having the newborn infant in the room with his mother for most of the time after the first 24 to 48 hours of life. The objectives are to allow the mother to become acquainted with, enjoy, and express her affection for her newborn baby; to foster breast feeding and enable the baby to have individual attention from his mother from shortly after birth; and to teach the mother the correct care of her new baby while she is still in the hospital. Rooming-in programs have been described by Jackson (1948). These plans are still experimental and more research is needed. Early ambulation and the great reduction in average length of hospital stay are recent and pertinent factors.

**CHILD HEALTH CONFERENCES.** The child health conference is the best device yet developed for providing health supervision to a large number of children who need this care and who do not otherwise get it. This is accomplished through services provided by the conference staff, and through referral to, or cooperative effort with other physicians or agencies. Child health conferences are also one of the chief areas for training doctors and nurses in the care and study of well children.

Child health conferences work under the handicap of interrupted care. They assume responsibility for the child only when it is well and refer it to a private practitioner or hospital when it is ill. As yet, no satisfactory plan has been widely developed for transferring information between the individuals assuming these two responsibilities. The solution of this problem must be accomplished if children are to be as well served as they should be.

It has been noted already that children who receive health supervision obtain most of this service from physicians in private practice and the remainder from child health conferences. There is no information as to the number of children who received no well-child supervision but everyone who has worked in private practice or in organized programs knows that there is a considerable number who receive very little if any health supervision.

It has been noted also that children in rural areas get less health supervision both from physicians in private practice and from child health conferences than do children in urban areas. During the year of the Academy study two-thirds of the counties in the country had no child health conferences, and nearly one third of all the children under five years of age lived in these counties. Table 16-7 shows that the greater metropolitan counties had approximately four times as many conference

Table 16-7. Well-child conferences. Availability of services in urban versus rural areas, United States, 1946-1947

	Number per 1,000 Children Under 5 Years		
	Greater Metropolitan Counties	Isolated Rural Counties	Entire United States
Sessions	23	6	11
Patients	118	27	62
Visits	422	44	182

Adapted from Am. Acad. Ped., 1949, Supplement Table 117.

sessions, four times as many patients and ten times as many visits to child health conferences per 1,000 children as did isolated rural counties. It is pertinent to note that one of the purposes of Title V of the Social Security Act, which provides grants-in-aid to support these services, is stated to be the extension and improvement of services "especially in rural areas and in areas suffering from severe economic distress." It is clear that this purpose is not yet fully accomplished.

The early milk distribution stations and the child health conferences which developed from them were largely supported by voluntary effort. This responsibility has gradually been taken over by departments of public health until at present about 80 per cent of the child health conferences are operated by official agencies, and the remainder by voluntary ones.

The Academy study showed that practically all conferences gave advice on feeding and training and provided public health nursing follow-up services in the home. Eighty per cent of conferences routinely gave immunizations for diphtheria and smallpox and over 60 per cent gave immunizations against whooping cough.

The medical staffing of child health conferences is done by health officers, pediatricians and general practitioners. General practitioners conduct about one half of the clinics in all county groups, both rural and urban. Health officers conduct nearly half of the clinics in rural counties but hold very few conferences in urban counties. The reverse is true of pediatricians, who are responsible for nearly half of the urban clinics and very few rural ones.

Infants and preschool children comprise the age group usually served by the child health conference. The Academy study, however, shows that most of the service is provided for infants and that only about one quarter of these infants are carried through the preschool years. The reasons for this are not clear. However, it is suggested that one of the best ways to evaluate the mother's satisfaction with a clinic service is to determine the relative number of infants who continue to make use of this clinic during their preschool years. Most mothers understand the value of bringing their children to a clinic so long as feeding is a problem and until immunizations are completed. The worth of subsequent visits is less tangible and depends to a large extent upon the interest that the physician takes in the emotional problems of the growing child as discussed below under anticipatory guidance. It is probable that most of the children who discontinue their attendance at child health conference after the first year receive no further health supervision until they reach school.

*Eligibility.* Some conferences admit only children residing in the county or cit

in which the conference is held. About one quarter of the conferences had restrictions based on economic status; such restrictions were found chiefly in metropolitan counties, rarely in isolated counties. Very few (4 per cent) required referral by a physician (Am. Acad. Ped. 1949a).

Eligibility rules are set up to restrict the use of limited public facilities to those who need them and also to protect from tax-supported competition the private practitioner upon whom the nation depends for its medical care. The question occasionally arises as to whether these services are being used by a significant number of people who could well afford to pay for such care. We have noted that 6 per cent of the nation's children under five years visited child health conferences in 1946. Data on family income in this country at the time of the study showed that 10.7 per cent of the families had an income of less than \$1,000 a year and that 18.5 per cent of the families had an income of less than \$1,500 per year (U. S. Department of Commerce, 1949). These figures suggest that there are families who cannot afford to pay for well-child care and whose children do not now receive such care through child health conferences.

*Frequency of Visits for an Individual Child.* Schedules and suggestions for frequency of visits are given in most of the state and local manuals on the child health conference. As many as four different types of visits are described in these manuals, as follows: complete conference with physical examination; conference including interview with physician where the physician inspects the child but does no physical examination; conference with the nurse alone who inspects the child and interviews the parent; and home visit by a public health nurse.

The American Academy of Pediatrics and the Children's Bureau recommend that the well child be seen every month during the first half year, about three times during the second six months, every three months during the second year, and every six months from two to six years of age. Most health department manuals recommend that complete physical examinations be done routinely at somewhat less frequent intervals, and many of them recommend the interspersal of other types of conference.

The current practice in the conferences operated by the Johns Hopkins University School of Hygiene and Public Health, which developed from experience in private practice, is for the nurse to make a home visit within 48 hours after the mother leaves the hospital; other home visits are made if necessary; and then for the mother and child to attend the clinic at monthly intervals for the first six months or until the initial series of immunizations is complete. Subsequent visits are at one- or two-month intervals for the remainder of the first year, depending on the needs of the particular child. Visits during the second year are at three- to four-month intervals and at 6- to 12-month intervals thereafter until the child goes to school. The type of visit, especially as regards the content of the physical examination, is variable and is further discussed under the section entitled "Content of Well-Child Care."

The early home visits are extremely valuable. The new mother is on her own for the first time and usually appreciates an opportunity to ask questions and settle apprehensions. It is also made possible for her to telephone the nurse or the doctor during these early days at home. This is a modification of the "telephone hour" which many practicing pediatricians find valuable. Mothers with their first baby need

to come more frequently than multiparas and of course mothers and children with problems need extra visits. Problems tend to be concentrated at certain age periods, thus, many questions arise during the first few months, which is the period of rapid increase in caloric needs, of frequent additions to the diet and a reduction in number of feedings, particularly night feedings. This is often followed by a brief period of smooth sailing which leads to a new series of problems as the baby begins to stand, and to walk and "get into things" from 9 to 12 months of age. At this time the mother often has questions about discipline and sleep, about new feeding problems and about toilet training. The appointment schedule is made flexible to allow for such eventualities.

*Frequency of Conference.* The frequency of conference will depend upon availability of staff and patient load. Ordinarily, conferences should not be held less than once a month, this being the maximum span of time ordinarily desirable between visits for regulation of feeding during infancy and for the giving of immunizations. Two months is usually too long and a six-week interval does not easily allow for an established conference day, such as every fourth Thursday of the month; such a fixed date makes it easier for the parent to remember and plan attendance.

*Appointment System and Patient Load per Physician Hour.* A recent survey of child health conferences by Harper and Wishik (1951) obtained data about the patient load per physician hour, which is pertinent to a discussion of an appointment system.

Table 16-8 shows that over one third of the health departments reported that their clinics averaged more than 10 patients per physician hour. The average for

Table 16-8. Patient load per physician hour in child health conferences. Averages from 200 health departments in 33 states

Health Departments	Average Number of Patients per Physician Hour				
	Under 5	5-9	10-14	15 +	Total
Number .....	35.0	96.0	45.0	24.0	200.0
Per cent .....	17.5	48.0	22.5	12.0	100.0

From Harper, P., and Wishik, S., *Am. J. Pub. Health*, 41:312, 1951

the entire country was 8.4 patients per physician hour or about seven minutes per patient. The patient load is actually greater than is indicated in Table 16-8 because of the method of tabulation. For example, one health department reported "28 patients per clinic session of one to two hours." This was tabulated as 14 patients per physician hour.

Such a heavy patient load encourages the system wherein all patients are told to come at 1 o'clock, where they are registered and "talked in" by the nurse between 1 and 2 o'clock, see the doctor between 2 and 3:30 and are "talked out" by the nurse as opportunity offers. Usually, such a program results in a noisy, crowded clinic, deters some mothers from coming who have other children whom they cannot leave for such long periods, and is wasteful of the patient's time.

The use of an appointment system which gives both the date and hour of visit will greatly improve the service of most child health conferences. It conserves time

for both the staff and the client. Such appointment programs are being gradually introduced and a discussion of some of the problems involved may be useful.

Hansen (1950) has studied broken appointments in a child health conference where the people had never before been accustomed to an appointment system. She found that about one third of the appointments were broken over the study period in the first year of the new system. Illness in the child or family was the cause in nearly one half of these instances: the family had merely transferred responsibility from the "well-baby doctor" to the "sick-baby doctor" and failed to notify the former. Obviously, this source of broken appointments does not occur when the same physician sees the child both when he is well and when he is ill. Inclement weather, change of address, change to another conference, or criticism of the conference's service were the other most important causes of broken appointments.

This study made clear the need to explain the purpose and value of the appointment system to each mother and to emphasize her responsibility if she is to participate in the benefits. It also suggested the desirability of continual alertness about the waiting time of individual patients and about reasonable criticisms which should not be neglected.

One method of avoiding waste of physician's time because of broken appointments is to schedule two patients for the first appointment and for occasional subsequent appointments. This means that if both patients arrive on time, one of them must wait, but this is clearly an improvement over the system of having all patients come at the same hour. On the other hand, periods should always be allowed for the patient who comes without an appointment and who urgently needs to be seen, or for the unexpected problem that takes more than the allotted time. Clinics where group teaching of mothers is done may find that careful planning is necessary to arrange a suitable appointment system.

The seven minutes average time allocated to each patient by physicians in child health conferences across the country contrasts with the custom of most pediatricians in private practice to allow 15 to 20 minutes for return visits of well children and longer for new patients and for problems. Lightening of the patient load in child health conferences should be attempted, but it is clear that the amount of physician time per patient will not, for a long time, approach that available in pediatric practice. The problem for administrators of child health conferences, therefore, is to so utilize nursing and physician staff that the best use is made of available personnel. This will be discussed further under the section devoted to the activities of the public health nurse. However, it is pertinent at this point to state our view that a physician should average at least 10 minutes per child; the reasons for this will become clearer in the section devoted to anticipatory guidance. This amount of time should be made available if necessary by having the child see only the nurse on some visits and so reduce the number of patients per physician hour.

Arguments for this point of view include the fact that child health conferences have been influential in the past in setting standards of well-child care in many communities and should continue to keep their standards high; furthermore these conferences are the chief area for training in well-child care.

*Content of Well-Child Care.* It will be helpful to define what is meant by "well-child care." The services to patients which are provided in our own conferences may be listed under 10 headings, as follows: (1) complete history (including records of

height, weight, etc.); (2) physical examination; (3) regulation of feeding; (4) immunizations; (5) laboratory; (6) anticipatory guidance; (7) advice in handling of behavior problems; (8) periodic appraisal of child's physical, mental, and emotional status and growth; (9) nursing advice and follow-up; (10) consultation with or referral to private physicians, nutritionist, medical social worker, etc.

To this might be added a variety of methods for the education, particularly of mothers and of staff, in the management of the growing child. These items will be discussed briefly.

**History.** "Let the mother talk" is a rule that cannot be quoted too often. Her talk may be guided by an occasional comment or question, but she should be allowed and encouraged to express her problems in her own language; merely putting her difficulties into words will frequently show her the solution. Contrarily, one of the poorest ways to obtain a satisfactory history is to set out routinely to obtain the answers to a predetermined series of questions.

The patient may first be seen by the nurse, who takes a brief history and writes down the salient points. The physician, when he sees the patient should review this history and encourage the mother to present her own problems in her own way. One or two remarks are made to break the ice, followed with, "How is everything going?" or "What can I do for you?" or something similar. The physician tries to allow a mother whatever time is necessary to obtain an adequate understanding of any problems she may have. Only after this has been accomplished is the clinic form introduced, with the explanation that additional facts are needed for the record. It should be emphasized that history-taking is something that goes on all during the visit. It is necessary to be alert to the partially revealed problem which may become apparent during physical examination, during the giving of immunizations or at any other time.

**Regulation of Feeding.** The feeding of infants and children has been so simplified and standardized that this phase of a physician's work has decreased both in importance and in consumption of time. It is no exaggeration to say that over 95 per cent of young babies can be adequately fed on a formula of cow's milk (either evaporated or whole) sugar and water, plus added vitamins. However, the physician has such a keen recollection of earlier days when feeding was a real problem that he frequently hesitates to delegate any responsibility for regulation of diet to the nurse. Yet it is probable that a better division of labor would result if the nurse assumed more of the work of routine addition of solid foods and the physician devoted more attention to anticipatory guidance and to discussion of the patient's current problems as pointed out below.

**Physical Examination.** Two kinds of physical examination are done in our child health conferences: complete examinations at certain age levels; and partial examinations at each visit. Complete examinations are made on the initial visit, at 6 months, at 12 months, at 24 months and at 36 months and whenever the physician feels that an additional complete physical examination is necessary. Limited examinations are done on every visit at which the child sees the physician. The child is stripped for rapid inspection of color, nutrition, skin turgor, and for any gross abnormality. Attention is then given to things which have been found important to observe as the months roll along. A different thing is emphasized each month. For example, the sternocleidomastoid muscle of all newborns is felt to find the occ.

sional infant who develops a hematoma with resultant shortening and wry neck. About the third month of age the heart is re-examined to detect any murmurs or other abnormalities which were not present at the initial examination. About the fifth month observation of the legs is begun, during that period when it is sometimes difficult to distinguish between the bowing which is physiological and that which is due to rickets. A little later, concern is about the retraction of foreskin in boys and patency of the hymen in girls. When the child first begins to walk, attention is focused on his legs, feet, and gait, with a thought for the rare case of congenital dislocation of the hip. These are examples of the way in which limited examinations are geared to the growth and development of the child.

Immunizations. Our current practice is to give three doses of a triple vaccine containing antigens against diphtheria, pertussis and tetanus at monthly intervals beginning at the second or third month. A booster injection is given about a year later and again in the fourth or fifth year. A smallpox vaccination is given during the first year.

The trend toward giving immunizations at an earlier age has received great impetus from recent work. The classical studies which demonstrated that the infant has a more efficient mechanism for developing antibodies after six months than before this age have been extended and amplified. It has now been shown that most infants can, during the first few months of life, develop antibody levels to the above three antigens which are sufficient for protection, although not so high as the same stimulus would produce at a later age and new information has been found which accounts for some of those infants who fail to develop protective levels. Bell (1948a,b) has shown that there is an adjuvant effect from the giving of diphtheria and pertussis antigens in combination which results in a higher level of immunity against diphtheria when infants are immunized before six months than when an infant after six months is immunized for diphtheria alone. (See Table 16-9.)

Table 16-9. Adjuvant effect of combined diphtheria-pertussis antigen. Combined antigen given before sixth month versus diphtheria alone given at 6 months or later

Antigen Given	Age at 2nd Dose	Number Tested	Schick Positive	
			Number	%
Diphtheria-pertussis	2-5 mo.	201	15	8
Diphtheria alone	6 mo. +	236	23	10

Arranged from Bell, J. A., J.A.M.A., 137:1009, 1948.

The strongest argument for the early institution of immunization procedures is the need for protection against pertussis. Pertussis has been and still is an extremely dangerous disease in the very young infant even though there is now evidence that hyperimmune sera and some of the antibiotics may offer effective treatment. At the present time nearly half of the mortality due to pertussis occurs in the first six months. It is clear that active immunization must be given early if it is to be effective. A discussion of the ability of the very young infant to develop protection is given in Chapter 1 under whooping cough.

It is also to be noted that the great reduction in clinical and subclinical diphtheria by means of active immunization has led to a new problem. A generation ago, before active immunization was so widespread, it was safe to assume that most

infants were protected against diphtheria during the first few months of life by antibodies acquired transplacentally from their mothers. Now the situation is changing and fewer mothers have a sufficiently high antibody level to afford significant protection to their infants during the early months of life.

The two chief arguments for the inclusion of tetanus in the triple antigen is the avoidance of the need for giving antitoxin containing horse serum at a later age, and secondly, the fact that about half of the children admitted to hospitals with clinical tetanus have not had antitoxin. These children either had not had any recognized portal of entry or their wound had been so minor that antitoxin had not been given. Active immunization against tetanus provides the only means of protecting such individuals.

Booster doses of the triple antigen should be given about one year after the end of the initial series and at three or four year intervals thereafter. This practice has developed as a result of studies which showed that active immunity in many children is quite transitory but that a single stimulating dose will not only restore but surpass the pre-existing high immunity levels. The number of booster doses which should be given is still a moot question and will probably always require some individualization.

At this point we digress briefly from this discussion of the work of the child health conference to note other methods of mass immunization for those children who are not immunized by their family physician. Immunization clinics, preschool roundups and school health programs are among the administrative measures which are used to get a large number of children injected. These procedures all have their place, especially in areas where child health conferences are infrequent or do not exist. (This will be discussed further in the sections on immunization and on health programs for children of school age.)

**Laboratory.** Hemoglobin determinations, urinalysis, serological tests for syphilis and tuberculin tests are the only laboratory procedures done with any frequency. None of these is routine, although we are coming to the view that regularly scheduled hemoglobin determinations would be valuable in our nonwhite population.

**Anticipatory Guidance.** Anticipatory guidance is the term used to describe attempts to discuss the child's behavior with parents in advance of the time when such behavior patterns may pose real problems. About a dozen of the most commonly occurring situations of early childhood have been selected and listed on record forms as suggested topics for discussion. For example, if there is opportunity to talk with the mother before delivery, and if she has an older child, she is told that rivalry and jealousy of the new baby are natural reactions in the older brother or sister and the methods of dealing with this problem are considered.

On the first visit with the new baby we discuss the need for flexibility in the amount and time of feeding and explain this on the variation in appetite which is common to all of us. We say that the breast-fed baby takes what he wants, and since no one knows the exact amount taken, no one is concerned. But the bottle-fed baby gets a prescription for a given number of ounces of formula to be divided equally into the prescribed number of bottles. We say that this does not mean that the baby should always take just that number of ounces, no more, no less. In this way we try to prepare the mother to allow her child some part in deciding how much he shall eat. At a later age we include one session where we mention thumb sucking, handlin

of the genitals, fear of strangers, etc., and say that these are reactions to be expected in most babies and are not a cause for anxiety.

It is necessary in this type of work to be continually alert to the danger of talking too much to the mother about possible problems which she may encounter at the risk of not allowing her sufficient time to discuss her own immediate problems. Brief mention of a few items serves to inform the mother that the physician is interested in her problems and also acts as an opening wedge for further discussion if the matter becomes of concern to her at a later time.

Full-blown behavior problems are becoming less important as a part of well-child supervision, particularly as staff members become adept in anticipatory guidance. For example, 20 years ago anorexia was an important subject in pediatric circles. One of the prominent pediatricians of that time said that anorexia and the treating of feeding problems had built his house for him. Most pediatricians now would feel that the development of a severe feeding problem in a baby who had been continuously under their supervision would reflect on their professional ability. However, behavior problems of this type are still frequent in areas where child health services are newly introduced. Our own experience and that of other clinics indicates that more than one half of all children, particularly first children, have problems concerned with feeding, elimination, or sleeping. These rarely become serious if there is proper guidance by the physician and intelligent handling by the parent.

It may be argued that the accomplishment of this type of well-child care will require too much time. On the contrary, it is the experience of most pediatricians that discussing these problems with the mother actually saves time. It is true that a longer appointment must be allowed when such discussions are initiated, but the cumulative effect of repeated small doses of anticipatory guidance is such that a little of this may be included even in a 10- to 15-minute visit.

This outline of the content of well-child care clearly suggests that to achieve success in this field there is need for continuity of contact between doctor and patient over a relatively long period of time. The mother does not usually bring her difficulties out into the open on her first visit, and such things as feeding problems and temper tantrums may require several months for solution. The physician should take time to listen to and to discuss the patient's problems but from a practical viewpoint it must be recognized that the patient load per physician hour in the majority of child health conferences is too large to allow this.

*The Public Health Nurse.* The public health nurse is primarily a health educator. This fact should not be forgotten in the press of her responsibilities for the smooth operation of the clinic program and she should not do work which could better be assigned to a clerk or to a volunteer worker. The new mother-new baby situation offers a particularly fine opportunity for the nurse to help and thus to do some teaching. In many agencies a large part of the nurse's time is devoted to this part of the population.

The nurse is also the one who gives some continuity to the child health conference work; she sees the patients at home between clinic visits and should be available by telephone. The question is how to make most effective use of her time and ability in combination with that of the physician.

There can be no standard solution to this problem; the patient load and the interests and abilities of both nurse and physician will require varying patterns.

However, some types of practice have been found to foster good teamwork. When the nurse takes the initial or interval history, the doctor should read it preliminary to his talk with the patient.

In large clinics, where more than one nurse is present and where clinic facilities permit, it may be most effective to have a nurse to work with the doctor. At least the nurse should be in the room when the doctor gives his final instructions. She should participate in this, bring to his attention facts which he may not know, and make certain that the patient understands what has been recommended. This pattern obviates need for the nurse to "post conference" the patient separately and avoids the confusion which sometimes results from two interpretations of the same orders. It is clearly undesirable to have an inflexible rule that the nurse shall have a conference with the mother following her visit with the doctor, as occasionally happens, even in situations where the physician takes time to listen to and discuss the mother's problems and to assure himself that she understands his directions. The need for a "post conference" between nurse and mother should be determined on an individual basis whenever possible. It has been noted already that listening to the mother is a most important part of history taking; it is also essential to all other phases of a well operated conference.

The question of whether or not the nurse should give the immunization is frequently warmly debated. It may be pointed out that nurses in hospitals are routinely expected to give hypodermic injections, which is certainly as responsible a procedure as is the giving of an immunization. Our practice is to have the nurse give the immunization when the child comes to the conference for that alone. However, it has been found preferable for the physician to give the immunization when this is only a small part of a complete visit.

The practice of interspersing occasional nurse conferences between the regular medical child health conferences is worthy of further trial. The physician is not present. A good indication of the value of such conferences will be obtained rather rapidly by observation of their popularity with mothers. At this point it is pertinent to note recent studies (Fisk, 1950) which put the cost of the nurse home visit at over \$3.00 each. This may be an added argument for the nurse conference.

*Personnel.* The basic staff for operating a child health conference is a physician, a public health nurse, and some clerical assistance. It is probably useless to try to operate a conference without a public health nurse, for in this situation services are available only on the clinic days when the physician is present. A nurse is required to provide any degree of continuity and to give advice and help between clinic visits. Additional staff which are available in larger clinics either to give direct service or, more frequently, to give consultation include a medical social worker, a nutritionist, a dentist and a child psychiatrist. The contribution of the dentist to these programs is described in Chapter 17.

Suggestions regarding organization, layout and equipment of a child health conference are given in the Children's Bureau publication No. 261, entitled "The Child Health Conference"; in Architectural Record's Building Types Study No. 6 and by Handley (1948).

*Evaluation of Clinic Services.* There are a great many people involved in providing health supervision. In many child health conferences these workers are largely independent of one another. Most health officers have no real information

about the quality or efficiency of services being rendered in the various conferences under their supervision, except as they occasionally visit those clinics and form personal estimates of the caliber of the individuals working there.

One of the greatest needs is for some method of continual evaluation of the work being done in the various conferences operated by a single administrative agency. Statistics which merely give the total number of child visits or the number of immunizations performed have very limited value. It is more important to know how many patients are seen per doctor hour, how many times the average child is seen during the first year, during the second year, and so forth; it is more valuable to know how many children fail to complete their immunizations by the sixth or seventh month than to know how many total immunizations have been given. The great need is to devise some simple, relatively easy method of providing day-to-day or month-to-month figures which will give the health administrator some index as to the quality of work and the efficiency of his various clinics.

*The Child Health Conference as a Training Area for Health Supervision.* The changing content of medical practice for children in the direction of more health supervision for the well child has been noted, together with the fact that approximately one quarter of all visits to children are for health supervision. This change in the content of practice has not been accompanied by a similar change in medical education and hospital training; these latter are still largely concerned with the ill child.

The child health conference is at present the single most important area for obtaining experience in health supervision, yet the Academy survey of pediatric education showed that more than one half of the interns and residents on approved pediatric services failed to obtain adequate training in this area. Rotating interns and general residents receive even less experience in health supervision. This is confirmed by a recent survey of 217 health departments in 33 states by Harper and Wishik (1951) which revealed that only 13 per cent of these agencies used any of their child health clinics for the training of interns or residents. This failure to utilize the training opportunities in these conferences contrasts with the view expressed by the great majority of health officers that training should take place in the child health conference. It is pertinent to comment on the factors which underlie this situation and to consider corrective measures.

It must be admitted that child health conferences as usually operated do not provide adequate training in health supervision. The great defects are lack of adequate facilities with which to work, the heavy patient load per physician hour, the lack of any teaching program in most clinics, even in these conferences which are used for training, and the lack of continuity in the relationship between the student physician and the mother and child clients. One result has been the notorious lack of enthusiasm on the part of house officers for work in such clinics even though they recognize that experience in health supervision is valuable.

These points may be illustrated by noting some of the measures required to provide adequate training in a child health conference. Space must be provided for each house officer to interview and examine. An appointment system must be set up so that the same house officer sees the same patient on successive visits. The patient load per student physician must be limited to the number that he can handle with thoroughness; our experience is that the physician in training needs 20 to 40

minutes per patient, including time to discuss problems with senior staff. All of this will require more paid staff of teaching caliber and will offer certain administrative problems. It is clear that this is a program to be undertaken and financed jointly by a health department and teaching hospital or medical school.

*Comment.* Child health conferences have contributed greatly to the problem of providing health supervision for children who need such services and also are one of our chief areas for training in the care of well children. But it is also clear that these conferences work under the handicap of discontinuous service; that they foster separation of responsibility for care when a child is well and when he is ill. Such separation of responsibility has been and still is necessary, but this does not alter the fact that the child will be best served when the same physician, or group of physicians, assumes responsibility for his care both when ill and when well, provided only that these physicians bring the same enthusiasm and ability to the field of health supervision that in the past they have devoted to the care of the ill child. The changing content of medical practice in the direction of more health supervision is accelerating. Such work already constitutes more than half of the practice of pediatricians and the interest of the general practitioner in this field is growing.

**CONSULTATION SERVICES.** Many states have a panel of pediatric consultants who agree to provide consultant services for children who need such assistance, usually at a flat fee fixed by the state health agency. More formal pediatric consultation clinics have grown up in other states; those in Maryland will be described. Such clinics are sponsored by the State Department of Health and are held in 13 of the 23 counties of the state, usually at monthly intervals. They are staffed by Board pediatricians who are in private practice and who do this work on a per diem basis, and by the two full-time pediatric consultants on the staff of the State Department of Health. Patients who offer diagnostic problems are referred from child health conferences or by their private physician. Such clinics are usually held in the local hospital or health department where x-ray and laboratory facilities are available, including electrocardiogram and basal metabolism in some instances. If diagnosis cannot be made with the evidence at hand, arrangement is made for referral to a local hospital or to one of the teaching centers if that seems advisable. When the diagnosis is established, a summary of the cases is sent to the referring physician, together with suggestions for continued therapy. It is emphasized that these clinics are for diagnostic rather than therapeutic purposes. They have proved to be a valuable adjunct to the Maternal and Child Health program.

## HEALTH SERVICES FOR CHILDREN OF SCHOOL AGE

ALAN FOORD, M.D.

"Health services for children of school age" is defined as *services for the promotion of physical, mental, and social well-being in children of school age*. This age group includes children between the ages of approximately 6 and 20 who are or might be in any of the usual 12 grades of the American school system, and does not include nursery school or kindergarten groups or those who have completed twelfth grade work, regardless of their chronological age. Health has been defined by the World Health Organization as "a state of complete physical, mental and social well-being, not merely the absence of disease or infirmity" (Chisholm, 1948). Thus, health services for children of school age include those rendered through health supervision—personal and environmental, and through health education and guidance.

It is assumed that a person is the product of the interaction of his heredity (or genetic potentialities) with his environment and that, with few exceptions, at least some alterations in the environment are possible when necessary to permit the best development of whatever heredity has seen fit to give to an individual. It seems clear, therefore, that efforts toward a better world will be largely concerned with providing an environment for children which will further the "healthy development" of each individual. Provision of an optimum postnatal environment for each child will depend first and foremost on the parents, their health and knowledge of health, and their desire and willingness to help their children to maintain health from birth onward. In addition, the health and health facilities of the community are powerful environmental factors in the child's growth and development, and the school must be recognized as possibly the most powerful of these factors.

The health services (diagnostic, therapeutic and educational), as previously defined, which may be provided during the school years, will depend upon the home, the community, and the school. Though the preschool years are generally considered as the most important to the development of a healthy body and personality, the school years—those in which a child passes through puberty and adolescence to approach adulthood—are certainly a close second. For the sake of clarity, health services for children of school age, though interdependent throughout, will be discussed separately as they relate to and are supplied chiefly by: (1) the home, (2) the community, and (3) the school.

### HEALTH SERVICES IN THE HOME

The health services which a child receives whether in the home, the community, or in the school will depend largely upon the parents. The parents' approach to health may be anything from that of waiting until a person is all but dead before seeking medical care to that of desiring regular, periodic health supervision for the whole family. Self-medication may be the exception or the rule. The family may be one which can afford only free clinic care, one which receives all medical care from a general practitioner, or one which insists on specialists throughout—pediatrician for the children, obstetrician for the mother, internist for adult members, and specialist's care for those diseases recognized as specialties.

Physicians, nurses, social workers, teachers, and many others working in the interests of public health are all in a position to influence parents to seek better health for themselves and their children; but only as people become fully aware of the meaning of health will they desire it enough to seek it out at all costs. Thus, those wishing to promote better health for all children must work toward better health education for parents, must bring pressure to bear on some parents to make environmental and physical corrections possible for their children and themselves, and must make various services available to them at a minimum expense of effort, time, and money.

At the time of entrance into school a child's concept of health will be largely that of his or her parents, whose knowledge of health matters will depend upon their previous education, the extent to which physicians and nurses with whom they come in contact take time to explain and teach, what their friends say, what they learn from their religious experiences, what they read in books or periodicals, and the extent to which they are influenced by advertising. Though in some instances the health knowledge and practices of the parents may be excellent, in general this disorganized approach to health education tends to produce much misinformation and to perpetuate it.

The home environment, which is determined by the parents and their adjustment to each other and to life, is the strongest single force regulating the degree to which children attain mental and social well-being. In some instances this environment will deter or even prevent the development of mental and social well-being; in others well-being will be furthered, but almost without exception some improvement in even a good home environment will result directly or indirectly from well-organized health services in the community and in the school.

### HEALTH SERVICES IN THE COMMUNITY

Every community has health services of some sort even if they are only those of the police and fire departments. The degree to which the health and health services of a community are developed depends upon the interest of the adult population. The health conditions and facilities of the community have a direct effect on the school-age child particularly in such areas as environmental sanitation, control of accident hazards and housing. There is also an indirect effect, depending upon the degree to which parents utilize such resources as physicians, clinics, hospitals, etc. All too often is it only through the efforts of the public health nurse visiting in

the home that parents make use of existing health facilities, which may be anything from boys' clubs to a prevention-of-deafness clinic or a free hospital bed. The health services in the school are merely part of the health equipment of the community and thus must be oriented to and integrated with the rest. Properly integrated with the home and the community, the school health service can be a major force in the healthy development of the child of school age.

### HEALTH SERVICES IN THE SCHOOL

**General Considerations.** The school, be it private, parochial, or public, offers an ideal place for promoting health through supervisory, educational and clinical services. On the other hand, the school is in such a position that it may affect health adversely, particularly through failing to provide a satisfactory physical and emotional environment for its pupils. Therefore, it is evident that the health of school children must be the concern of everyone in the school, not merely the school nurse or physician.

Promoting health through services in the school cannot be accomplished without considerable cost, nor is it easy to demonstrate clearly the benefits resulting from each dollar spent. For this reason, many look with some skepticism upon the present day efforts to bring school health into a position of major importance. Past experience has shown that large sums of money can be quickly wasted on school health programs which provide rapid screening for physical defects without consideration of the "whole child" and without proper follow-up to assure correction of the defects which are uncovered. However, a well-rounded, thoroughgoing school health program, which is directed at the "whole child" in relation to the home and the community, and includes careful follow-up, is worth every dollar spent, provided we believe that the world will be what the children of the next generation make it, and see clearly the many ways in which the school, in its particularly strategic position, can act directly (and also indirectly through influencing the parents) to further the healthy development of the child (Chisholm, 1948) and the child's ability to live harmoniously in a changing total environment.

The school health services will benefit many of the pupils by providing medical supervision for those children who will receive little, if any, at home because their parents: (1) have insufficient health knowledge, (2) cannot afford adequate medical care or need help in availing themselves of existing low cost medical care facilities, (3) are insufficiently aware of the value of health to be willing to spend money to promote it, or (4) are unable to persuade their children to accept a diagnosis of illness and its treatment, a circumstance encountered most often in respect to dental caries.

Any or all of the pupils may benefit as a result of routine health examination (history and physical examination) carried out every few years, which always uncovers some children with unrecognized remedial conditions of ill health. With few exceptions parents are helped by some degree by counseling and guidance which usually accompanies or results from routine health examinations of their children. Such guidance may also be offered as a result of the teacher's observation of the children, quite apart from routine medical appraisals. By keeping all school personnel health-minded through a well-rounded and active health program, the school

*can improve the well-being of all its pupils regardless of socio-economic status*, for it will be the alert teacher who most often notes individual deviations from good health in the pupils and acts to effect correction of the condition, be it of a physical, mental, or social nature. Just as the teacher is a key person in the detection of ill health, so is he or she of paramount importance in maintaining the health of the physical and emotional environment of the school both through actions and example. It is probable that the future will show us that the school is indeed the most logical and convenient place for providing the coming generations with useful, up-to-date health information, given as far as possible before the children acquire incorrect or outdated notions in this respect from home or outside sources.

Many authorities feel that the optimum in medical care is that given by a single physician throughout a person's life, with referral by him to specialists as indicated. This theory has many pros and cons, and a discussion of it is not relevant at this point. The fact must be recognized, however, that in reality very few people are satisfied with or able to utilize the services of a single physician throughout life. Their dissatisfaction may be due to a change in their feeling of unequivocal acceptance of the physician and his ability or due to a change in geographical relationship, one or the other moving to a distance which makes continuance of the relationship inconvenient or impracticable. Objections have been raised to school health programs on the grounds that routine health examinations, if carried out at all, should be a function of each child's private physician, who knows the child's history and who will understand the child better in illness if he has had contact with him when well. The advantages of having the child's private physician carry out routine health examinations must be balanced against such factors as the willingness and ability of the family to pay a private physician for such services and the lack of interest and training of so many physicians in well-child supervision.

Many schools object to referring routine health examinations to a private physician because his report to the school people following the examination adds very little if anything to their knowledge of the child. This objection can be avoided if the private physician is supplied with an adequate but simple report form with instructions for its use and a statement to the effect that the information thereon will be treated as confidential by school personnel. In addition, the private physician should be informed in advance by the school health service of their observations and opinions of the child. Thus a multiplicity of records and additional clerical time will have to be used to make the interchange of patient information between private physician and school comparable to that between school physician and school.

However, the private physician working in his office or the clinic physician working in a clinic cannot influence the over-all school health services the way the personal contact of the school physician with the school personnel does. Some rather tangible benefits to the health mindedness of the school personnel and of the physician himself will accrue from the work he and the nurse do in the school together with the teachers.

Some school systems have taken the stand that it is preferable to have a school physician examine all the children, referring only those found to have health problems to their private physicians for treatment; others have taken the opposite stand by having no school physician and referring all routine health examinations and children thought by the teacher to be in ill health to the private physician. Between

these two extremes is the presently more acceptable practice of requesting parents to take their children to their private physician for routine history and physical examination, but of further stating that if they are unable or do not desire to do this, the child may be examined by the school physician. This practice provides the parents with a choice in the matter as well as insuring adequate health examinations for children whose families are financially destitute. Any children found to be in need of medical care are, of course, referred to their private physician or clinic of choice; thus, an active health service in the school sometimes refers more patients to private physicians than they can accept.

**Administration of School Health Services.** School health services in this country vary greatly in structure and extent since there has been almost no consistency in the methods used or the goals desired in organizing them whether at city, county, or state level. In general, the health program has been considered as limited to the activities of the school physician, school nurse, and physical education teacher, but is now gradually being recognized as extending to all parts of the total school program.

Health services of private and parochial schools will not be discussed separately as there is no apparent reason to consider the health needs of the children in these schools as differing appreciably from those of the public school children. However, health services for secondary schools do differ from those for the elementary due to the fact that the secondary school is usually departmentalized, which structure results in a tendency of faculty members to emphasize the teaching of specific subjects rather than the over-all well-being of the pupils. Thus, in the departmentalized school the well-being of the pupil often becomes secondary to his or her ability to learn algebra, Shakespeare, and so forth. Pupils transferring to the departmentalized school lose the health supervision which depends upon and results from the day-long contact with a well-trained home-room teacher. Furthermore, school children usually make this transfer at a time when they are feeling the impact of adolescence. It is essential, therefore, to provide high school students with adult advisors or guidance counselors so that there will be someone to whom they may turn and someone who will take an active and unsolicited interest in their over-all health. The other major difference between elementary and secondary school health services is the emphasis put upon having physician and nurse work directly with the high school pupil instead of through the parents, so that the pupil may learn how to assume responsibility for the maintenance of his or her own health.

Administrative organizational patterns of school health services or program fall into four general categories: (1) a joint enterprise shared equally by the departments of education and health; (2) a program run entirely by the department of education; (3) a school health council or committee administering the program and its budget; (4) a program limited to the individual school administered by its personnel with or without the participation of the school's parent-teacher association.

**JOINT ADMINISTRATION BY EDUCATION AND HEALTH DEPARTMENTS.** Administration of school health programs as a *joint enterprise of the health and education departments* is at present the organization of choice to apply at federal, state, county, and city levels. It is usual to have a school health council made up of various interested parties act as an advisory and discussion group for those in the health and education departments who are administering the program. Suggestions and objec-

tions, particularly in regard to health education, may be aired in such council meetings and their proponents offered either grateful acceptance or satisfactory rebuttal.

Some of the reasons for preferring joint administrative structure to administration by the education department alone are as follows:

(a) An agency primarily interested in health and health methods acts as a balance to an agency (the school) which by tradition has been primarily interested in teaching and has not been educated to any great degree in health.

(b) Health departments are not restricted in regard to the type of school to be served by the program, whereas the departments of public education often are permitted little if any activity in private and parochial schools.

(c) The health department is responsible for the health of the people in the community throughout their lives, including the school years, in preventing disease and aiding in medical care and rehabilitation of those suffering its assault.

(d) The health department is in close contact or associated with the various health facilities of the community; thus, it is in a position to know how best to utilize them and can in addition learn from them and from other contacts the deficiencies in health services and health education. For example, evidence of inadequate health education is encountered daily in prenatal clinics and child health conferences, where nurses and physicians encounter the parents' great lack of understanding of nutrition, growth and development, and even of their own anatomy and physiology.

(e) The health department employs public health nurses who have personal contact with the pupils' homes and with many of the community health facilities and who, therefore, can furnish the school with much very useful information. (The school child's health cannot be disassociated from the health of his family or that of the community.)

(f) The health department has the personnel and experience necessary to supervise the nurses and physicians working in the schools.

**ADMINISTRATION OF HEALTH PROGRAM BY EDUCATION DEPARTMENT.** In many areas the department of education administers the school health program without any help from the health department. Occasionally, advice is sought from the local medical society. Such a situation is usually blamed on lack of interest in the program by health department members or on a personality clash in which the members of the two departments find themselves unable to get along. In either instance, all efforts should be made to resolve the problem. Frequently, there is not enough money in the health department budget to pay for a good school health program, whereas the education department has some funds for this purpose. The education department will handle this latter problem better by transferring funds to the health department than by attempting to operate the program alone with resultant duplication of services, at least at the supervisory level, and poor integration with other health efforts in the community. Furthermore, if the education department contributes financially, it has an additional justification for demanding good service.

**HEALTH PROGRAM ADMINISTERED BY SCHOOL HEALTH COUNCIL OR COMMITTEE.** School health councils or committees are sometimes given the authority and budget with which to administer school programs. Such organizations cannot be expected to function smoothly and efficiently, for much of the activities of the program must be through the medium of the health and education departments. In

general, they may act as a middleman in the situation where health and education directors do not see eye to eye, but this same purpose can be served by a *nonaction* group as previously described under joint administration, leaving the health and education departments free to move in direct lines of administration.

The membership of school health councils of either type may include representatives of the medical and dental society, the parent-teacher association, the education department (including "health chairmen," curriculum planners, and/or classroom teachers), the health department, the church (sometimes one each from Hebrew, Catholic, and Protestant groups), the legislative body at the appropriate level, social service and welfare organizations, and sometimes voluntary health agencies. It is not unusual to find the health officer and the superintendent of education or one each of their assistants acting as co-chairman of such councils for a state, county, or city. A council at the community level should consider the advisability of including the community coordinator, if there is one.

**HEALTH PROGRAM WITHOUT DIRECTION FROM SOURCES OUTSIDE THE SCHOOL.** Where there is no direction from higher sources, it should be sought out from city, county, or state level. Good advice and possibly assistance can be expected from the state maternal and child health director or one of his or her assistants. A school health council at the local level of the individual school itself can do much to promote all aspects of health, but can move ahead more certainly and rapidly and encounter fewer pitfalls if given guidance by trained and experienced people. Here again, it is preferable to have the local council one which functions as previously described and not an action group which either dictates school health policies or pays for the program. Such action groups seldom are capable of considering the over-all approach to public health. They are likely to settle on a program in which funds are raised to pay for a school nurse, chiefly for the security of having her present to do first aid and handle emergencies instead of the far more important functions of teacher-nurse conference, home visiting, and over-all health supervision.

### COMPONENT PARTS OF HEALTH SERVICES WITHIN THE SCHOOL

Although closely interwoven one with another, health services in the school may be divided into at least three parts to facilitate discussion, namely: (1) health of the school environment; (2) supervisory, screening, and clinical health services; and (3) special services including health education. It is not uncommon to find the term "school health program" used in the more narrow sense to designate only the clinical, screening, and supervisory services.

**Health of the School Environment.** The health of the school environment is made up of two component parts—the physical and the emotional. Neither part can be neglected, for both have a strong influence on the health of school children. Unfortunately, however, defects in the physical plant of a school are usually much more obvious than defects in the emotional content, and thus there is a tendency to appropriate funds for building new schools or remodeling old ones without making comparable efforts to supply a thoroughly healthy emotional environment for children. Although a good physical plant has definite value, a really sound emotional environment offers far more lasting health benefits to the child than does the physical.

lege of attending a school which incorporates the latest advances in architectural design, interior decorating and equipment.

**PHYSICAL ENVIRONMENT.** Avoidance of health hazards is of primary importance in the design of the school plant. The school site should be located away from noise, smoke, odors, and fumes. The acreage should be generous to permit large outdoor play and athletic areas as well as pleasant landscaping. Traffic hazards are to be carefully avoided but not to the point of sacrificing accessibility to public transportation (American Association of School Administrators, 1949).

The exterior and interior of school buildings when well designed are now inviting and cheerful, in contrast to the forbidding exteriors and the stern and often dim interiors formerly considered appropriate for schools. In the classroom a floor area of 25 to 30 square feet per pupil is recommended. Recreation and lunch areas are placed and equipped in such a manner that they may be accessible and useful after school hours to adults, the idea being to encourage the use of the school as a center of recreational as well as educational activities in the community. Construction is planned to minimize fire hazards and such accidents as falls down stairs and in corridors.

Special consideration is given to lighting (Hamon, 1948), interior decorating, acoustic treatment and equipment. Wall and ceiling finishes are chosen to give optimum lighting with minimum glare from shiny surfaces and to keep brightness difference \* within a comfortable ratio, still preserving enough color contrast and variation to avoid monotony. Floors are finished in as light a color as practical and constructed with the idea of maximum durability without creating a slippery surface. Prismatic glass block is used in many school buildings to obtain maximum use of natural lighting without glare or the need for shades. Artificial lighting, with louvered fluorescent or incandescent fixtures, is designed to give a minimum of 25 foot-candles in the darkest corner. No one has as yet found a mechanical device to solve the problem of improper use of lights and shades by the classroom teacher. Each teacher should know the essentials of good lighting, but it is often advisable to have the school custodian make routine inspection of classrooms to serve as a reminder to the teacher to pause long enough to take note of the light, temperature, and humidity in the room.

Some of the changes which are being made in classroom equipment include the use of green glass chalk boards and of light color furniture finishes to avoid excess brightness difference, both in respect to the paper or book on the working surface of the desk and to the light finishes of walls, floor, and ceiling. The tendency at present is to use movable, table-type desks in elementary schools, thereby permitting special groupings for recitation, and other variations in the arrangement of the room. All ceilings should be acoustically treated to maintain a minimum level of noise without the need to suppress the normal enthusiasm of school-age children.

The heating, ventilating, and humidification equipment for schools is designed to produce classroom temperatures of from 68° to 72° F, the reading being taken

\* Brightness difference—"the difference in brightness among the various reflecting surfaces and light sources within the total visual field as measured in foot-lamberts. Optional terms: Brightness contrast, such as the brightness difference between white paper and black print, brightness ratio, the brightness difference between the visual task and the surrounding field." "Lighting Schoolrooms," Pamphlet No. 104, Federal Security Agency, U. S. Office of Education, 1948.

30 inches above the floor, and a relative humidity close to 50 per cent. Here again, in addition to possible mechanical difficulties, the problem of the human control factor is encountered, particularly in the avoidance of excess heat. The person responsible for regulation of ventilation must keep in mind that a classroom which has a temperature of 70° F when the pupils enter it may soon be excessively hot, due to the heat radiated from the bodies of its occupants. Fifteen cubic feet of air change per person per minute is generally considered adequate to prevent staleness of air and accumulation of body odors.

Plumbing fixtures, such as drinking fountains, sinks, and toilets, should be chosen according to the size of the children who will use them, particularly in elementary schools. The proper maintenance of washrooms which includes an adequate supply of soap, towels, and toilet tissue is of great importance to the teaching of health habits or personal hygiene. Tooth brushing equipment, however, may be kept in his desk or locker. Locker and shower rooms should be designed to be comfortable in regard to space, temperature (75° to 80° F), lighting, and odors, as well as practical from the standpoint of maintenance and cleanliness. There should be at least two toilets in each general toilet room. Roughly, one toilet to 30 to 45 girls and one to 60 to 90 boys is considered minimum (American Association of School Administrators, 1949), provided boys' toilet rooms are also equipped with urinals.

Last, but by no means least, the well-designed school building has facilities for teachers, so that they can rest, smoke, converse, and in general get some respite from the constant pressure of the classroom.

The foregoing paragraphs describe a physical school environment which is highly desirable but not always attainable, particularly when funds are sufficient only for the rehabilitation of existing structures. Some reconditioning of old school buildings is usually worth while when the community cannot afford needed new construction. Often a small expenditure for materials such as paint and light fixtures is all that is needed for an enthusiastic parent-teachers group to transform dingy, drab schoolrooms and corridors into a cheerful, well-illuminated environment for their children.

**EMOTIONAL ENVIRONMENT.** How healthy the emotional environment of the school is depends largely upon the degree of physical, mental, and social well-being of the personnel. The personnel includes everyone from the janitor to the principal but it is the classroom teacher, more than anyone else, whose attitudes determine the emotional environment most directly affecting the pupils. The total well-being of the teacher involves many factors. Among these, the influence of the principal on the happiness which the teacher derives from working in the school cannot be overlooked, for there is a strong feeling among school people that the teacher should follow the lead of the principal. Thus, conflicts may often arise, despite good health in the teacher, if the principal is poorly trained or emotionally immature.

Long range planning for improving the emotional environment of public schools must take into account, first and foremost, the need for raising the prestige and the salary scale of school personnel. At present, there is still too great a tendency for people to gravitate into teaching simply because they have no specific desire for other occupations. Public school teaching must be given the status of a career—a career which is considered to be of the utmost importance to humanity. Also

with the giving of status there must be a salary scale which will not only permit but will attract highly qualified men and women to choose this career. There should be no rules forbidding employment of married women in teaching positions, but instead, rules providing for removal of teachers who show themselves repeatedly to be emotionally immature, and thus obviously unable to guide children toward the attainment of mental and social well-being. If there is any one aspect of greatest single importance in the contribution which public schools can make to child health, it is that the teachers be people who are well adjusted in their own lives, who have good physical health, and who have had thorough training in education including specific training in health education. They need also to believe in the inborn desire of children to love and be loved, to imitate and to cooperate with their elders. The belief that children are by nature uncooperative, spiteful, and sinful leads to an approach based on rules, regulations, and punishments, all designed to rid the child of his or her unfortunate heritage. The person who believes in such an approach to children should never be trained or employed as a teacher, for a child's reaction to such treatment will almost surely be one of anger, frustration, and a desire to "get away with" antisocial activities.

**ENVIRONMENTAL CONSIDERATIONS FOR EXCEPTIONAL CHILDREN.** The term "exceptional children" is used to designate those children who for any reason deviate from the usual to such an extent that special adjustments in their environment and management are indicated. Thus, such a child may be too brilliant or too dull to get along well with the rest of the group, may have impairment of vision or hearing, may have a cardiac or an orthopedic handicap, may be hospitalized for chronic illness, may be emotionally too insecure to join a large group, or may be merely a poor reader and unable to keep up with the pace set by the majority.

Whatever the disability, special arrangements must be provided for these children so that they will have suitable opportunities for health and education (Mackie and Fitzgerald, 1949; Loviner and Nichols, 1946; Education Briefs, 1948). Such arrangements may take the form of anything from special schools to simply special classes which meet only occasionally. In general, it is highly desirable to keep the education of exceptional children within the framework and the actual building of the regular public school, thereby giving these children the chance to mix with others of their own age group and to learn how to get along. Children who attend a special school throughout their schooling period are often at a disadvantage when they graduate and are forced to face an unsheltered existence in the community. For this reason, the present trend is to equip all new multistoried school buildings with elevators for those who cannot climb stairs and to provide some schools with special teachers and facilities for sightsaving classes, for instruction of the hard of hearing, for physiotherapy for children with orthopedic problems including cerebral palsy, and for "ungraded" or "opportunity" classes. Speech and reading difficulties are so common that it is more practical to provide speech and remedial reading teachers to all schools on a part-time basis, each serving several schools within a city or county.

The education of the child with epilepsy deserves special consideration. In many areas the child known to have epilepsy is denied entrance into the public school system and often no other provision is offered for his education. The majority of children with epilepsy can be well controlled with proper medication, and thus given the same educational opportunities as those free of this condition. Thus, the first

step in making public school education available to the epileptic child is that of procuring the best possible medical management of his disease. Of those children whose seizures are not completely controlled by medication or removed by surgical intervention, a small percentage will have to be institutionalized, but there is a remaining group of children who should not be denied entrance into public school, because of occasional convulsive seizures. Parents and teachers alike must be brought to realize that the occurrence of a seizure in a child in a classroom need not be considered as a detrimental experience for the other pupils (Yahraes, 1947). Such an episode, when properly handled by a teacher who has been forewarned of the presence of the condition, will not result in severe emotional disturbances in other pupils who are present.

When circumstances are such that a special class is the best answer to the need, every effort must be made to return the exceptional child to his group as much as, or as soon as, possible. School administrators must guard against regulations which demand a specific attendance level in special schools or classes, for such regulations may prolong an individual child's presence in such groups unnecessarily. The teacher who knows that the class will be abandoned if there are less than 15 pupils in it naturally hesitates to return the fifteenth to regular class, thereby losing this benefit for the other 14. However, for the most part, obtaining funds to provide special equipment and special teachers for children with demonstrable physical handicaps is relatively easy as compared to obtaining sufficient funds to provide those classified as normal with an environment conducive to complete health.

**Supervisory, Screening, and Clinical Health Services.** There are, and probably always will be, some children enrolled in public schools who have had little if any health supervision. In addition, there are many instances in which well-trained teachers recognize deviations from good health in children who have had the benefit of fairly adequate health supervision. The school offers an extremely convenient and inexpensive place to carry out immunizations and screening procedures. Screening programs for vision and hearing constantly uncover unsuspected impairments of these special senses. In addition to these reasons for establishing adequate health supervision in the schools, there is the added advantage that such supervision in the school can be given by people who are in a position to be far more objective in their judgments than parents can be and can relate a child's social and emotional adjustment to that of his peers, whereas parents must first relate these adjustments to their own immediate family. The school nurse and the home-room teacher are in particularly strategic positions to carry out the follow-up so important in obtaining correction of illnesses and abnormalities which have been discovered in children. It is not unusual to find that it is the teacher, not the doctor, who has persuaded a parent or a child to carry out the medical or dental recommendations.

Schools which have no clinical, screening, or supervisory health services should be properly prepared before these services are organized. First and foremost a need for school health services must be recognized by the department of education, the teachers in any individual school and the parents. Once it has been agreed that health services are needed (a need which is probably universal but often unrecognized until pointed out by public health groups) the education and health departments usually can move ahead rapidly with plans to supply them. One cannot overemphasize the importance of including in the planning representatives of the

appropriate medical and dental societies and of the school or schools to receive the services. Ophthalmologists and otolaryngologists who practice in the community should be consulted if vision and hearing testing programs are to be organized. Within the education department, those responsible for curriculum planning are essential members of any group working out details for school health services.

An effective approach to the actual initiation of the supervisory, screening, and clinical health services within a school or group of schools is through the medium of a *school health institute* at which the program is explained, a demonstration *teacher-nurse conference* between a classroom teacher and a public health nurse is given and a pediatric history and physical examination are carried out using one of the pupils in the school as the patient. Following this introduction, *teacher observation cards* \* are distributed and the public health nurse begins her duties, full or part time, as the school nurse. If the program is to include a school physician he should not start working in the school until the nurse has had an opportunity to do the groundwork.

**Supervisory Health Services. TEACHER OBSERVATION AND TEACHER NURSE CONFERENCE.** The key figure in the present day school health program at the school level is the teacher—particularly the home-room teacher in the elementary school. The teacher's importance to the promotion of the health of his or her pupils cannot be overestimated. Through careful observation, the teacher can pick out very nearly all children with significant deviations from physical, mental, and social well-being, help to correct some of these by giving special attention to the child and his family, refer others for help, and follow up those referred in order to be sure that the needed help has been obtained. Besides being the person in the best position to note deviations from health in the pupils, the teacher is the person upon whom the health of their physical and emotional environment will depend most. The extent to which the children are taught to appreciate physical, mental, and social well-being also depends largely on the teacher. Obviously, many teachers do not have adequate knowledge with which to promote health in the various ways which have been outlined. It is imperative, therefore, that those now in training to become teachers be given the best possible courses in health supervision and health education and that similar opportunities for such education be supplied to teachers in service (Wheatley, 1948).

A great deal of health education can be supplied to the teacher who is in service through the introduction into the school of a school health program. The teacher who attempts to make objective observations of her pupils and discusses these with the school nurse soon discovers how much health information he or she has gained. It must be emphasized that the teachers should observe and later discuss in the teacher-nurse conference *all* of the pupils in the classroom, not merely those with obvious abnormalities. A conference about all the children in the class is essential to give both teacher and nurse a clear concept of what may be considered normal for the group and to give the nurse an opportunity to suggest instances in which minor

\* Teachers should have a record card for each pupil on which to record their observations of the pupil's health. This record card should be a form which permits chronological notes to be made at any time and which lists some of the items which are considered important to good observation of the well-being of each student. Uniformity of such record forms can be accomplished if the state department of education has them printed and supplied at cost to the various schools.

abnormalities may have been missed. The results of teacher-nurse conferences should be education of the teacher, education of the nurse in the problems confronting the teacher, and definite plans for correction of health defects which have been brought to light. Using the information gained, the nurse may move ahead to obtain more pertinent information from contact with the home or from medical records or to help parents arrange for medical, dental, or psychiatric care as indicated. *Referrals from teacher-nurse conference to the school physician should be given priority over all other health examinations.* Finally, opportunity must be provided for the nurse to keep the teacher posted on the progress of those children considered in conference to be in need of further investigation or medical care.

**PRESCHOOL ROUNDUPS.** During the spring, some schools ask parents to bring to school for an introduction those children who will enter first grade in the fall. The purpose of this visit is to acquaint the parent and child with the school, the principal, and the first grade teachers, and vice versa, and as such is highly commendable. Unfortunately, some school systems use this opportunity to have physical examination carried out and immunizations given. The introduction of a five- or six-year-old child to a school certainly is not made easier by giving him injections. Such procedures are to be condemned. With the exception of the referrals from the screening done by the teacher, and or school nurse, physical examination and correction of physical defects are better postponed until after the child has entered first grade and some time has been available for teacher observation.

**Screening.** In addition to the all-important screening which is accomplished by teacher observation, certain other types of screening are strongly advocated for use in schools. Such screening includes the usual psychometric examinations, reading readiness tests, vision testing, hearing testing, and height and weight measurements. It is recommended that evaluation of the interest level and of the emotional maturity of each child be considered as a source of information which can be most useful in guidance and counseling. With the exception of hearing testing and the more complicated psychological examinations, it is felt that the types of screening mentioned above can be carried out by the teacher and can be used as aids in teaching health as well as being an educational experience for the teacher.

**VISION TESTING.** That some sort of routine vision screening examination is indicated is obvious from the report of the study conducted in St. Louis, Missouri (Children's Bureau Publication Number 345, 1954) in which 26.9% of 606 first grade and 609 sixth grade school children were found to be in need of eye care. Children of elementary school age seldom recognize the presence of subnormal vision and often become the slow students and daydreamers of the class without anyone realizing that they cannot see as well as their classmates. As aforementioned it is entirely possible and thoroughly desirable to test the vision of every pupil annually as part of the school curriculum. In the elementary school, the home-room teacher is the person of choice to carry out the testing; certainly teaching the younger children about vision, eye care, vision testing, and the use of the "illiterate E" is the function of the teacher. Vision testing in the high school is more often allocated to the school nurse (National Society for the Prevention of Blindness, 1945). Carefully trained volunteers, usually parents, may do vision screening at any grade level but failures should be checked by the school nurse before referral to ophthalmologist.

The teacher's observation of the pupils for signs of eye disease and poor vision

The teacher's observation of the pupils for signs of eye disease and poor vision is a very valuable case-finding method whether or not vision testing is done routinely. Teachers should be reminded repeatedly that children who have passed their vision test are none the less subject to eye disease and should be referred for ophthalmologic diagnosis without fail should they be observed to exhibit signs and symptoms suggestive of eye trouble.

Two problems which have arisen in connection with vision testing are: (1) the type of equipment which should be recommended, and (2) the objections raised by ophthalmologists that schools refer too many children who, on careful examination, prove to have normal vision.

When the first problem is encountered, it is best settled by consulting the Council on Physical Medicine of the American Medical Association. Of the many testing devices available, the Snellen Test Chart and the Massachusetts Vision Test Kit have been the only two types of equipment which have been approved in the past. Data accumulated by the aforementioned study of vision testing conducted in St. Louis indicate that the more complicated testing equipment, though finding the greatest percentage of those needing referral, triples the time needed for administering the tests and results in almost twice as many incorrect referrals as compared with the Massachusetts test or the Snellen (high standard) combined with careful teacher observation. Whatever type of testing device is chosen by a school or school system, instructions for its proper use should be closely adhered to. Particular attention must be paid to proper lighting of the chart surface (10 to 20 foot-candles) and to placing the reading material at the proper distance from, and height in relation to, the pupil being tested. Vision testing is best carried out in an area which is quiet and adequately illuminated. The teacher administering the test should be thoroughly familiar with the procedure and the pupil being tested should receive prior explanation of the test objects and responses necessary. It is recommended that the testing be sufficiently complete to screen out pupils with subnormal visual acuity, farsightedness and muscle imbalance.

The problem of over-referral to ophthalmologists can be met by holding a conference with those physicians who will receive the referrals or with a committee appointed by the local ophthalmological society. Such a group should pass upon the equipment and the referral criteria to be used. It is most important to have all concerned realize fully that: "The average school child who is in need of ocular attention seldom presents himself for help. We must instead search for him. Any good type of screening examination will pick out a majority of those in need of help but it will also single out a large number needlessly and there seems to be no way around this dilemma which exists because of the psychology of the child. Ideally, it is obvious that every school child should have a complete ophthalmologic examination. If only screening examinations are done, generally speaking, we must be prepared to examine completely two children to find one that really needs help" (Scobee, 1950).

**HEARING TESTING.** Hearing testing of school children has disclosed a remarkably high incidence of unrecognized impairment of hearing, figures varying from 5 per cent to over 10 per cent having been reported. As is so often true in cases of subnormal visual acuity, the child with impaired hearing seldom knows that he or she does not hear as well as others, and again the end result often is a child who

becomes inattentive, and falls behind in school work, usually developing nervousness and conduct disturbances concomitantly.

Speech disturbances are commonly found with impaired hearing; whether present in conjunction with subnormal hearing or not, they should be brought to the attention of the school nurse or physician and arrangements made for diagnosis and appropriate therapy (Johnson, 1948).

Prevention of deafness programs are turning to the school as the best possible place to carry out routine audiometry of school-age children. The problem of finding a room in the school building which is sufficiently quiet for audiometric testing can be met by constructing a portable booth lined with sound-absorbent material which can be taken to any school which the audiometrist designates.

Hearing testing is a procedure which should be done by a trained technician using a pure-tone audiometer (Dahl, 1949) of any make accepted by the Council on Physical Medicine of the American Medical Association. An experienced technician can test the hearing of as many as 45 children per hour using the sweep-check method and later retesting more completely any children failing the sweep-check test. Individual testing of each child is preferred to group testing. The use of the recorded voice test method is not advocated. The practice of appraising the adequacy of hearing by determining the child's ability to hear a watch tick or the examiner's whispered voice is to be thoroughly condemned. Such tests have been shown to be grossly inaccurate. Testing hearing in this way is a waste of time, and, what is more important, represents a serious threat to the child whose hearing is below normal but adequate to hear the watch tick or the examiner's whisper and therefore not investigated further.

Facilities for a more extensive program being wanting, the best practice is to test the hearing of at least the first, fourth and seventh grade pupils routinely and of those referred as a result of teacher observation or school health examinations. The value of screening the lower grades for hearing impairments cannot be over-emphasized, particularly because the marginal hearing loss, if discovered early, is more likely to prove to be amenable to correction (Crowe and Burnham, 1941; Davis, 1947). But even if the hearing impairment cannot be corrected, the child will benefit from having his disability known and appropriate steps taken to minimize its effect whether by use of a hearing aid (Watson and Tolan, 1949) or special training such as lip reading. When people know why a child's ability to communicate with others is below average, they are far better able to modify their approach accordingly.

**MENTAL AGE AND READING READINESS.** Testing of mental ability and reading readiness will not be discussed here other than to point out the importance to the child of being placed in a group with which he or she can keep up. For example inability to comprehend the reading material has been found to be the basis of gross misconduct in many pupils, the conduct disturbance often disappearing when remedial measures begin to reduce the reading disability (Betts, 1946).

**PHYSICAL GROWTH.** Many school systems have some sort of weighing and measuring program. Periodic recording of the height and weight of each pupil can be part of good teaching of growth and development as well as a means of detecting growth failures. For the most part, charts which give the teacher only the limits of normal for height and weight at a given age do more harm than good, parents being greatly disturbed when told that the child is so many pounds or inches below the

normal for that age. Growth curves used to portray each individual child's rate of growth graphically are preferred. Forms for recording growth curves are exemplified by the "Physical Growth Record for Boys" and "Physical Growth Record for Girls" of the National Education Association (Joint Committee in Health Problems on Education) and the American Medical Association and by the Wetzel Grid (Wetzel, 1942). Such records give the teacher, child, and parents the opportunity to follow the individual growth pattern. Deviations from the expected rate of growth as individually determined can be taken as indicative of some disturbances in the child's health and thus serve as an acceptable reason for referral for medical opinion. Some school systems have chosen the Wetzel Grid as preferable to other types of growth curves because the graph represents a composite of height and weight, in other words of body size, which is then plotted against age in a second graph to show the rate of growth and compare it to averages for each age level.

**Clinical Health Services.** Clinical health services in the school health program divide roughly into diagnostic and therapeutic, medical, and dental.

Dental services are provided as a part of maternal and child health programs in many states, usually in connection with programs for children of school age but occasionally through child health conferences. Though still very inadequate in many areas, school dental programs are growing as efforts increase to: (1) reduce the incidence of dental caries through teaching good dental hygiene and applying sodium fluoride (Easlick, 1949), and (2) to preserve teeth already affected by systematic and prompt filling of the cavities. Federal funds budgeted in 1949 to promote these purposes under Title V of the Social Security Act were about \$800,000 to which may be added a somewhat larger amount of matching funds. Some of these funds were used at various dental schools to support graduate training in dentistry for children and also to provide refresher courses in this subject for practicing dentists.

Some school dental programs are limited to those children who cannot otherwise afford dental care, while others have no limitations and provide prophylaxis, fillings, and extractions for all; they seldom include orthodontic procedures. The program may offer dental care without cost or at cost, the former usually being the type restricted to children with insufficient funds. It is usual to start the program in the lowest grades and expand it by one more grade each year. In this way the amount of dental correction necessary in each grade included in the program is kept at a minimum. In view of the fact that in this country one may expect at least one new carious surface per year in about 98 per cent of the population, it seems wasteful of professional time to do dental inspections. Thus, it is preferable to have inspections carried out as part of prophylaxis or treatment except when it becomes necessary to give the parent an estimate of the amount of dental work needed and how much it will cost.

The school medical program is usually limited to the work of a part-time school physician with the help of a full- or part-time school nurse. It is desirable to have the school personnel feel that these two people are faculty members with interest in the "whole child" including his or her education. The school nurse and physician have much to contribute to the health of the school environment provided they are made to feel that they "belong"; when treated as people who should "keep their noses out" of education, their contribution will be slight.

Very little therapy is attempted in school medical programs other than first aid. There are some conditions, however, which are so frequently encountered in school children that one wonders if treatment of them might not be justified. Such condi-

tions include acne, epidermophytosis, impetigo, scabies, postural defects, and fallen arches. Then, too, there is the question of whether or not the school might be an ideal place for guidance and counseling of children and their parents in the management of some of the milder emotional disturbances which cannot be referred to overcrowded mental hygiene clinics and overworked child psychiatrists. The school health service as a medical care program is presently being investigated in some areas as a possible answer to assuring correction of abnormal conditions uncovered as a result of teachers' observations or routine health examinations.

**THE HEALTH EXAMINATION.** History and physical examination of well children will not be discussed in detail. Suffice it to say that the history should be extensive enough to provide a general picture of the child's health, past and present, a brief review of systems, some insight into the present health and economic status of the family, and a rough idea of the child's habits and personality. The physical examination should omit vision and hearing testing, provided these are being carried out as screening procedures, and examination of the chest should concentrate on the heart. Laborious examination of lungs is of very little value, and chest x-rays are relatively easy to obtain.

The child should be stripped at least to underwear shorts, and a short gown provided for older girls to avoid embarrassment. The physician's impression of the child's general appearance, posture, and state of nutrition is most important and should always be recorded. Many feel that abdominal palpation is worth the few minutes it takes, and cardiologists consider palpation of femoral pulses valuable. Taking of the pulse before and after exercise is probably of very little value. Examination of ears with an otoscope sometimes uncovers significant abnormalities of the outer ear or drum. Ophthalmoscopic examination of the eyes is of value only if done by an ophthalmologist as a screening procedure—the amount a school physician can discover by a brief inspection of the retina without dilatation of the child's pupils is hardly worth the time consumed in darkening the room and showing the child how to keep the eyes fixed on a distant object. The spine and musculo-skeletal structure, particularly of legs and feet, should be examined. Older children should be checked for epidermophytosis. There is a general feeling that the genitalia of older girls should not be examined, at least not by male physicians. This attitude is probably a disservice to girls in that it teaches that this portion of the anatomy is unimportant from the standpoint of evaluating their total health and adds to, rather than detracts from, their reticence to seek medical opinion when abnormal genital conditions arise. The value of examination of the genitalia in the male is unquestioned.

As aforementioned, the home-room teacher usually records height and weight measurements for the pupils in the elementary school. In the secondary school this procedure is frequently delegated to the school nurse, or simply neglected. Whenever the pupil's physical growth is not being followed by the teacher or the nurse recording of the height and weight should be part of the physical examination. Though many physicians consider it a waste of time, taking and recording of the pupil's blood pressure on at least one occasion seems justifiable, and can be done by the nurse whenever this seems desirable.

Health examination of school children can be enhanced by proper preparation of the child for the experience. The teacher, nurse, or doctor can speak with each

class prior to scheduling health examinations to explain that they are merely a visit to the doctor for promoting health and *have absolutely nothing to do with obtaining a passing mark in order to graduate*. The pupils should be encouraged in this and other ways to bring up questions about their own health and ask for interpretation of the findings of the physician. The health examination should not carry with it the threat of immunization procedures, which can better be carried out en masse at another time.

Other factors which will enhance the medical services of the school are:

- (1) Quiet examining room with dressing cubicles which permit privacy.
- (2) Hand-washing facilities for examining room.
- (3) An examining table and standard equipment such as desk, chairs, flashlight, tongue blades, clinical thermometer, etc.
- (4) A school nurse in attendance.
- (5) A rest room with cots for ill children awaiting transportation home *which can be supervised from the school administrator's office when the school nurse is not on hand*.

(6) A small waiting room for parents (waiting should be kept at a minimum) in which health education pamphlets are available for them to read.

**FREQUENCY OF HEALTH EXAMINATION.** The majority of school health programs require periodic medical examination (history and physical examination) of a pupil which may vary in frequency from several each year (for athletes) to a single examination carried out in the first grade and never repeated. Highest priority must be given to examinations requested as a result of teacher observations, and second to an examination of all children at the time of entrance into school. Physical examination before graduation from or leaving school is next in importance.

Repeating a history and physical examination (of the type described) each term for athletes is probably not justified. These pupils are in general the most physically fit in the class and under continual observation by the health and physical education teacher who should be far better prepared than most on the teaching staff to note signs and symptoms of illness in the student group. However, the fact that some physical education teachers are not well versed in health supervision and the fact that some coaches of major interscholastic sports concern themselves only with winning games cannot be overlooked. To safeguard the health of pupils engaging in strenuous physical education activities and competitive sports, there must be regulations preventing them from returning to the activity or sport following an injury or major illness without written permission of a physician. Teacher observation of the pupils' health and teacher-nurse conference must be considered an indispensable part of the activities of physical education teachers. Brief history and physical examination of athletes at the beginning of each season can be used as an additional means of screening out those who have residual disabilities from injuries received while engaging in sports during the previous season or from illnesses which have occurred since the previous physical examination was carried out.

A relatively complete history and physical examination of each pupil, carried out about every three or four years throughout the 12 years of schooling, is considered to be a worthy objective, if annual physical examination is impossible. But widely spaced health examinations are the method of choice only when teacher

observation can be relied upon to cover conditions of ill health which occur in the intervening years.

**FOLLOW-UP.** There is, of course, almost nothing to be gained by uncovering conditions of ill health if their correction is not possible, whether due to lack of facilities, lack of family funds, or failure to make recommendations clear to parents and then check back to be sure that the desired action has been taken. Thus, if there is no way to obtain correction of the defect, the discovery of an impairment of vision or hearing has its only value in a better understanding of the child's slowness and a better classroom seating arrangement for him. First of all, facilities must be available within or near the community to meet the demand of referrals of health problems from the school—another important factor in favor of active health department participation in the program. If the health services of the community are inadequate to the demands of school referrals, the health department must take the steps needed to correct the situation. Provided the community has the needed services, the next consideration is that of making them available to every child regardless of race, creed, color, or economic status. There then remains the job of working with the child and his parents so that they will avail themselves of the needed services—a task which can be very time consuming and frustrating. Here again the team of teacher and nurse is most effective, for, if both work toward the same end, these two members of the school staff are the ones who can most often influence the child and or the parents to obtain the recommended care. It is well for both teacher and nurse to keep a follow-up record of the children so that both can strive continually to have the child's needs met.

**THE SCHOOL PHYSICIAN.** The school physician usually works on a part-time basis and is present in the school for a certain number of hours or mornings each week. The physician should plan to work at the school at regular intervals throughout the school year rather than to attempt to complete his or her work within a few weeks time and move on to another school, leaving the first school without medical consultation for the rest of the year. Regardless of their previous training it is well worth the effort to provide a series of seminar discussions to acquaint physicians who are new to the program with its intent and procedures and to follow these with occasional meetings of the doctors in school service in order to keep them up to date on new developments and to add interest to their work. Many physicians who have had all their previous experience with ill children can testify to the knowledge gained in regard to history and physical examination of the well child by participation in such discussions. The purposes of the history and physical examination as carried out in the school are: (1) to obtain an opinion of the total health of the child which will help school personnel and parents to understand and guide him or her as wisely as possible; (2) to uncover unsuspected deviations from normal; (3) to obtain sufficient information concerning deviations to be able to refer the child to a private physician or clinic for further medical care and to plan medical care with the parent. Both physician and nurse should strive constantly to make the total experience an educational one for the parents and child.

The presence of the parent at health examinations of elementary pupils is of extreme importance. For the child who is in high school, it is felt best to invite the child to bring the parent if he or she wishes to, the emphasis then being on promoting the child's own ability to supervise his or her own health. Health exam-

inations of this type cannot be carried out in 5- to 10-minute periods; school physicians must plan for at least 20 minutes per pupil and must realize that often this period needs to be extended when problems in guidance and counseling arise. Probably the best procedure is for the school to notify the parents that the child should have a health examination and to request their approval of having this done in the school if they do not wish to take the child to a private physician for it. Once the parents have signified their desire to have the examination carried out in the school, an appointment should be made either with the child in the upper school or with the parents of children in the first seven or eight grades for a specific time and day for the examination. The appointments with parents should be far enough in advance to permit them to choose the most convenient time and date.

The school physician, in addition to carrying out health examinations, must be the liaison person between the school and other private physicians in the community. He is in a position to check with private physicians when they make special requests for modification of school curriculum for health reasons and is also in a position to push for good medical care of the children referred to private physicians and clinics. The value to the total school health program of having a school physician has been discussed.

**THE SCHOOL NURSE.** As aforementioned, a public health nurse is considered to be the best person to act as school nurse. The importance of the nurse to the school health program is second only to that of the teacher. By attending health examinations carried out in the school, the nurse can know firsthand just what the physician's recommendations are, and can be most helpful to the physician, parents, and child in planning whatever medical care is indicated. By visiting in the child's home, the nurse can obtain valuable information for both the teacher and the physician. The conferences between the nurse and the teacher have been described as being of educational value to both, as well as important to the total health of the children. School nurses should be considered as faculty members, and their knowledge of health matters and the health status of the pupils recognized as an important source of information to teachers and students alike. It is hoped that schools will recognize the true value of the nurse as aforementioned and avoid forcing her to use up her time performing such duties as simple first aid to scrapes and bruises, acting as a diagnostician of rashes, abdominal pains, etc., which should be immediately referred to the family and their physician, and doing the clerical work of arranging transportation home for ill children.

**SCHOOL HEALTH EMERGENCIES.** The most important single factor in the handling of health emergencies arising in the school is to know how to contact the parents. Every school administrator should keep an up-to-date file for every pupil which supplies the following information: (1) how to contact the parents at any time; (2) how to contact some other responsible person if unable to get the parents; (3) the name and address of the private physician of choice; and (4) name and address of the hospital of choice. Every effort should be made to have some one or two members of the school staff trained in the principles of first aid, but the rule should be one of "hands off" as much as possible, with the emphasis put on notifying the parents. Simple first aid for cuts, scrapes, etc., should be carried out as far as possible by the classroom teachers, and for this purpose classrooms should be

equipped with first aid kits. Minor injuries of this nature when handled within the classroom can represent a health education experience for the entire class.

**RECORDS.** Forms for recording teachers' observation of the pupils' health have been discussed previously. The results of hearing and vision screening and height and weight measurements should be recorded either on the teacher observation record, on separate records, or on the pupil's medical record. All such records should be brought with the child whenever he or she is referred to the health suite.

Several other record forms must be considered as important to the school health service.

The aforementioned form for the use of the private physician when carrying out health examinations in his office must be self-explanatory, brief, and to the point, but must request sufficient information to give the school a clear, concise picture of the child's total health status including historical and physical findings.

The information necessary to the proper handling of school health emergencies, as discussed in the preceding section, is best kept on a specific form. The most important detail in the use of this form is that it be brought up to date at the beginning of each semester.

A master chart for recording the activities of the health suite is often very helpful in keeping track of cases needing follow-up and in making reports of the number of children seen, the findings, and the degree to which those running the program have been able to initiate steps for correction of conditions of ill health.

The school physician must have a separate form for recording the history and physical examination of each pupil who receives a health examination at the school. This form should be designed to contain as little changing information as possible—addresses, occupation of parent, etc., are better kept on a separate form filed with the rest of the academic record. The record should contain the name, birth date, sex, and race of the pupil, the names of the parents or guardians and the names and year of birth of siblings. The name and address of the school of attendance should be recorded and space permitted for changes in these. A section is usually provided for filling in the record of immunizations (initial and booster doses) and of acute communicable diseases. A small space is often provided in which to indicate the whereabouts of additional information of a nature too confidential for inclusion in the record. A check list is desirable as a means of saving the physician's time and as a place where those responsible for follow-up can tell at a glance what is to be done. A code may be used in conjunction with the check list to indicate positive findings and whether follow-up, observation, or mere recording is indicated. It is well to request physicians using the form to indicate also when specific items of history or physical examination have been omitted. For example, it is quite common to omit examination of the genitalia of older girls. When this is the case, the check box should be marked "N.E.," or with some symbol standing for "not examined," rather than leaving it blank or marking it "O" or "Neg." Suggested items for inclusion in the checklist are given on page 699.

The remainder of the form is best devoted to lined space for notes written in chronological order, not only by the physician but also by the nurse, guidance counselor or whoever has pertinent information to contribute. A wide, left-hand margin permits the recorder to write his or her name and title, the date, and the nature of the note to the right, such as "health examination," "teacher-nurse referral,"

## HISTORY LEADS

Date

“parent-physician conference,” etc. The calendar months are sometimes printed along one edge when the record is in card form as a convenience to those wishing to use metal tabs for flagging.

The committee which recently revised the pupil's medical record for the state departments of education and health in Maryland outlined the following principles for its use:

- (1) The record should be considered as highly confidential by all school personnel.
- (2) It should not contain information which might be detrimental to the child, as the record follows him or her throughout the school years. Such information, if important, should be kept in a locked, confidential file.
- (3) In case of transfer, the records should be sent to the child's new school, even if it is in a different state or country.
- (4) The record should be available to the appropriate school personnel, particularly the home-room teacher, by permission of the principal, not the physician.
- (5) The principal should be the custodian of the pupil's medical record just as he is of the pupil's academic record.

LABORATORY. At present the majority of school health programs do not include routine laboratory tests. Experience in the past has shown that routine analysis of the urine usually uncovers little other than orthostatic albuminuria, but the cost of testing for albumin and sugar and determining the specific gravity is slight and can be educational as well as occasionally the first step to early discovery of an abnormal condition. On the other hand, routine hemoglobin determinations do turn up a few children with unsuspected mild to moderate chronic anemias either of the nutritional type or secondary to blood loss. With this in mind, routine hemoglobin determinations might be considered as part of a good school health program at least for high school girls if not for all pupils. A few positive serologies will be found by routine

testing but so few that the value of such a program lies more in the field of health education (Allison and Johnson, 1946). Chest x-rays and tuberculin testing should be in accordance with the tuberculosis control program of the community.

**IMMUNIZATION.** Though initial immunization procedures should be completed during the first 12 to 18 months of a child's life, there are always some children who reach school age without having been given any protection against diphtheria, whooping cough, tetanus, or smallpox. All of the children in an elementary school will need "booster" doses of immunizing agents once or twice during their six years of attendance.

The first contribution which the school health service can make toward improving the immunization program of the community is to help parents reach the point of wanting to have their children protected and then reminding them when "booster" doses are indicated. For children attending school, the school itself is the most convenient and least expensive place in which to have immunizations given whether as a full series or as "boosters." Clinic sessions can be arranged in which 60 to 100 children can be vaccinated or given injections of toxoid within an hour by one physician assisted by a nurse and a teacher or parent helper. Arrangements for such a clinic include scheduling, obtaining written requests from parents or guardians, and providing a supply of sterile needles and syringes sufficiently large to obviate waiting for resterilization. An ampule of adrenalin should be kept on hand for use in case of the very rare untoward reaction. Only immunizations should be done in such clinic sessions and the children should be informed in advance so that they may know what to expect, why this relatively unpleasant procedure is important to their health, and that there is no reason to fear a surprise "needle" when they go to the health room or suite at other times. The agent and the quantity administered and the date should be recorded on the pupil's medical record and a certificate showing the same data should be given or sent home to the parent.

**COMMUNICABLE DISEASE CONTROL.** Once again the classroom teacher is the key person in maintaining the health of his or her pupils by excluding children with communicable diseases. The observant teacher who pauses long enough at the beginning of the school day to note the general appearance of each pupil can detect signs of illness very quickly, for the teacher knows the child's usual appearance so well that the slightest deviation from normal is immediately apparent. There should be no need for the teacher to request the sanction of the nurse or physician in sending home children who appear to have a febrile or communicable illness. When the nurse is present in the school, it is most desirable, however, to have pupils check out with her so that she may be informed of the condition responsible for the exclusion, make certain that any needed medical or nursing care will be obtained, and list the pupil as one to inquire about at a later date.

In some areas of this country those attempting to eradicate tuberculosis are making full use of the school as the most convenient place to carry out mass tuberculin testing and chest x-rays. Other areas, which have a higher incidence of tuberculosis, are instead making use of the school for the giving of BCG (*Bacillus Calmette Guérin*) vaccine. Whatever the approach may be, the school health program should cooperate fully with the local tuberculosis program. In general it may be said that, with the rare exception of the area with a very high tuberculosis rate, control measures in the school age group will work more toward eradication of the

disease if tuberculin testing followed by chest films annually of positive reactors is carried out. The giving of BCG vaccine to negative reactors will, of course, eliminate the tuberculin test as an efficient and inexpensive means of continued case finding within the group.

Other aspects of communicable disease control include proper ventilation, hand-washing facilities and spacing of seats. Methods of diminishing the bacterial content of the classroom atmosphere are still in the experimental stage. (See page 157.) Self-exclusion of the teacher for communicable disease and annual chest films of all school personnel, including the bus driver, are of great importance. It must be remembered that the school bus and school cafeteria represent areas where spread of communicable diseases from one class group to another can be expected.

It is not unusual to encounter a public demand for closing of schools when epidemics arise in the community. Keeping the school open but providing enough additional time and personnel (if needed) to permit careful daily inspection of each pupil and prompt return to the home of suspects usually does far more to limit the epidemic than closing the school. In addition to disrupting the curriculum, closing the school will take some parents out of work, promote more widespread circulation of the pupils and leave health supervision and isolation of suspects up to the parents. Thus, many children either in the early (but highly infectious) stages of a communicable disease or throughout a mild attack will be permitted freedom of movement about the community instead of being kept at home, as a result of early recognition of the illness and exclusion by the school, at a time when the school-age child is immediately suspected if seen at large during school hours.

**Special Services, Including Health Education.** Special services for the promotion of health of the school child may include the pupil personnel activities, physical education programs, the school lunch program, and special classes such as those in health education, and human relations.

**PUPIL PERSONNEL ACTIVITIES.** The foregoing paragraphs have described the great and time consuming part played by the teacher in a school health program. Educators frequently ask the question: "But when will the teacher teach if all these things are expected of him or her?" It is true that proper attention to health increases the teacher's load and for this and many other reasons one must not expect the busy classroom teacher to take the initiative in planning activities intended to promote health. Any large school will benefit greatly from the services of a pupil personnel director—a person skilled in health and health education, who has had social service training and can act as a coordinator of the health program as well as a guidance counselor for the pupils. High schools often include a vocational guidance counselor on their staffs, but such people are seldom qualified to do more than this. A guidance counselor with the training of a psychiatric social worker can be of tremendous benefit to the total school health program and also to individual pupils by helping them to obtain medical care or by personally providing therapy for the less severe emotional disturbances.

**THE PHYSICAL EDUCATION PROGRAMS** (O'Keefe and Fahey, 1949). The physical education programs of today take cognizance of the importance of making the activities interesting to the pupils and of providing instruction in physical activities which may be useful to the child after graduating from school. These may include tennis, golf, swimming, and even fishing. The attempt to build strong bodies through

exercise is not forgotten, but the overemphasis on competitive sports has lessened. Some school systems depend upon the physical education teacher to teach health and act at the high school level as the person who takes the place of the elementary school home-room teacher in observing the health of the pupils and conferring with the nurse or physician about each child. In general, directors of physical education programs in large schools should not be coaches of major interscholastic sports.

**SCHOOL LUNCH PROGRAMS.** School lunch programs are designed to provide one thoroughly nutritious meal a day at a cost so low that it is available to all of the pupils. Federal subsidization through the School Lunch Act (Public Law 396, 1946) has made this possible in many schools. The school lunch must not be overlooked as an excellent educational medium through which children may learn some basic facts about nutrition and good table manners in addition to overcoming poor eating habits and food fads (Bryan, 1946).

**HEALTH AND SAFETY EDUCATION** (Wilson, 1948). Health and safety education is integrated throughout the curriculum with other subjects, often without the con-

Fig. 17-1. Accidents, of which more than one third are motor vehicle, are the primary killer of school-age children. Comparable rates for 1952 as reported by The National Office of Vital Statistics were: all causes, 59; all accidents, 22.5; heart diseases, 3.95; pneumonia and influenza, 3.15; and tuberculosis, 0.95.

scious recognition of the teacher or pupils. Conscious effort must be made by health and education people to give more of this information to adults and particularly parents. The data presented in Figure 17-1 suggest the importance of safety education and some specific areas where more health education would be most desirable (National Safety Council).

The teacher properly educated in health will pass this knowledge along to the students without the need of special classes, but there is some value to providing a course in health and personal hygiene at the high school level. School nurses, school physicians, or health educators may be used to teach such a course, but the subject should not be treated as something that anyone with a bit of health knowledge can muddle through well enough to satisfy the requirements. Together with the home economics or homemaking courses, the health education course should provide the pupils with up-to-date information about their own anatomy, physiology, and psychology, so that they may understand the true meaning of physical, mental, and social well-being. The true facts about such things as menstruation, marriage, child-bearing, and child rearing should be offered in an effort to dispel some of the erroneous ideas which so many young couples and young parents seem to accumulate before marriage or parenthood. The content and teaching of a course in health and personal hygiene must be such that the pupils can readily relate the subject matter to themselves, their bodies and minds, and the function of each, or (the more impersonal material) to their community, family, or friends. Health education which deals with fine details such as annual increments of growth, calories per ounce of food, or the names of the bones in the human body is worse than useless, for it is seldom remembered and serves largely to make the course unpopular with the students.

**CLASSES IN HUMAN RELATIONS AND DEMOCRATIC LIVING.** Most people constantly find themselves at odds with their environment, sometimes in the form of minor irritations with community or family conditions, sometimes in the form of major disagreement with and inability to accept some of the basic dictates of the culture (Prescott, 1938). Usually, some change must be accomplished either in the person, the environment, or both, in order to avoid unbearable friction. Attempts to effect such changes are always in progress and should not be discouraged; but the mental and social well-being of most of us would be furthered greatly by our learning how better to get along more permissively and peacefully with people and conditions as we find them. Many schools are attempting to organize courses in democratic living, covering such subjects as human behavior, family relationships, beliefs, and values. The teaching of human relations in the classroom as developed by Bullis and O'Malley (1948) cannot be overlooked as a possible way to wide-scale promotion of mental and social well-being. Human relations classes are designed to help both pupils and teachers to learn how to get along better in their given environments. Case conferences held within the school, which include the teacher, nurse, principal, psychologist, physician and psychiatrist and provide direct help to teachers with some of their classroom problems, also contribute much to this effort.

**Summary.** The health of the child of school age will most certainly be affected by the school which the child attends. The ideal is of course to have this effect one which promotes the physical, mental, and social well-being of the child. Numerous ways in which this promotion of health may be approached have been described, but the extent to which any school or school system goes in furthering health will

depend upon the attitude of the parents, teachers, school administrators, and professional health people of the community at local, county, state, and national levels.

It is recommended that school health programs be a joint undertaking of the departments of health and education at all levels with federal and state directors of school health activities acting largely in an advisory capacity to create interest in, coordinate development of and give essential financial support to county and city programs.

That the school represents a convenient and logical place to provide certain health services goes without argument; the type and scope of the program will vary, however, depending upon local conditions.

The teacher's observation of the pupils' health should be accepted as an integral and most important part of any teacher's daily routine. Any deviations from good health thus noted must be referred for medical attention, and an "air-tight" follow-up system devised to keep those concerned appraised of whether or not the needed care has been obtained.

Vision testing can be and should be a part of every school's curriculum, and there is every reason to feel that pure-tone audiometry should be made available for all school children. Community resources must provide services for diagnosis and care of any vision and hearing defects which are uncovered.

Immunization procedures are easily carried out in schools with a minimum of wasted time and effort.

Consideration should be given to the opportunity the school affords for prevention and treatment of emotional disturbances.

Whenever funds and facilities permit, the school health program should include a public health nurse and physician trained in well-child care and working together in the school, part or full time depending upon the circumstances.

The teacher is recognized as the person upon whom school health programs must depend most heavily. If our school teachers are indeed the key people in promoting physical, mental, and social well-being in each and every school child it is obvious that their prestige, salary scale, working conditions, and knowledge of health must be greatly improved. Above all, in the selection of students, teacher training institutions must take more cognizance of the emotional maturity of the applicant. An emotionally mature teacher, if well trained, can carry on an acceptable school health program alone, even in a one-room rural school, by giving attention to the physical and emotional environment, by intelligent observation of the pupils (with referral through the parents to needed care), and by giving both the pupils and the parents an understanding of how to further "the healthy development of the child" and the child's "ability to live harmoniously in a changing total environment."

## SERVICES FOR THE PHYSICALLY HANDICAPPED CHILD

EDWARD DAVENS, M.D.

Crippled children have been of concern to governmental and voluntary agencies for many years. Prior to the passage of the Federal Social Security Act in 1935, however, few states had developed a comprehensive program of services on a state-wide basis. During the initial 20 years of federal aid to the states for services to crippled children, much valuable experience has been gained in the development of a nation-wide program of medical, surgical, and other professional services for the physical restoration and social adjustment of children with various types of physical handicaps. Much also has been accomplished in the integration of these services with the already established programs of vocational rehabilitation. On the federal level, responsibility for administration of this part of the Act (Title V Section 2) is vested in the Children's Bureau of the Department of Health, Education, and Welfare. On the state level there is a varied pattern of administration, although in the majority (32 out of 53 "states" \*) the state health department is the responsible agency, and this appears to be the dominant trend. Other state agencies which administer this program include departments of education (3), welfare (9), state universities (4) and special commissions (5).

**Definition.** The definition of a crippled child varies somewhat from state to state. As originally interpreted, some gross disability of muscles, bones, or joints or interference with locomotion was implied. Thus, the principal causes of crippling listed on current state registers are infantile paralysis, cerebral palsy, clubfoot, osteomyelitis, congenital malformations, rickets, spinal curvatures, and tuberculosis of bones and joints. In more recent years, there has been a tendency to include the chronic physical diseases or disabilities which interfere with normal growth and development, education, or social adjustment. Many state programs now include various conditions requiring plastic surgery, severe dental problems requiring orthodontia, disabilities arising from impaired vision and hearing, speech disorders, rheumatic and congenital heart disease, epilepsy, and diabetes. This broadening definition is symbolized by increased use of the term "physically handicapped child" to replace "crippled child." The age limit established in all of the state programs is from birth to 21 years.

**Number of Physically Handicapped Children.** Information concerning the actual numbers of physically handicapped children of all types is incomplete. As

\* The term state as used here includes Alaska, the District of Columbia, Hawaii, Puerto Rico, and the Virgin Islands.

December 31, 1952 the various state registers contained the names of 756,000 physically handicapped children (U. S. Children's Bureau, 1953). Since this figure is largely composed of children with various types of orthopedic defects and congenital malformations and other conditions requiring plastic surgery, it represents only a fraction of the total number of physically handicapped children. Estimates of other important types of physical handicaps among children give a clue to the total magnitude of the problem. With respect to rheumatic heart disease, Paul (1943) concludes that the rate among school children varies between 0.3 to 4.0 per cent, and among college students from 0.6 to 1.0 per cent. Assuming 30 million children of school age and a rate of 1 per cent, there would be approximately 300,000 school children in the United States with rheumatic heart disease.

In the case of epilepsy, several studies (Hershey, 1945) indicate that one in 200 young men was rejected in the military drafts of World Wars I and II because of a history of epilepsy. At this rate there are in the neighborhood of 260,000 epileptics in the United States among the 52,000,000 individuals under 21 years of age.

Statistics on hearing loss are plentiful, but not very accurate because of variability factors such as method of testing, frequency of calibration of the instruments used, criteria for screening, acoustic conditions of testing room, presence of acute ear disease, and inherent subjective factors. For these reasons statistics on hearing loss are usually reported on the basis of children whose hearing appears sufficiently impaired to warrant further study. Most studies indicate that on this basis 5 per cent of school children have significant impairment of hearing (Lesser, 1950).

Speech disorder, either secondary to hearing impairment or associated with emotional disturbance, neuromuscular dysfunction, or congenital malformation, is an extremely common type of physical handicap which has profound implications for the educative process and for normal social adjustment. The prevalence of this type of disability has been variously estimated to be between 5 and 10 per cent of the school age population (Johnson and others, 1948).

Until recently, the only available estimate of incidence of cerebral palsy was the formula of Phelps (Perlstein, 1947) based on "repeated samplings done in New Jersey, Maryland, and other areas." According to this estimate, seven infants with cerebral palsy are born every year in each 100,000 population, of whom one dies before reaching six years of age. The prevalence of cerebral palsy in persons of all ages according to Dr. Phelps' estimate would be 400 per 100,000 population. This includes cases of all grades of severity. In a recent survey (N. Y. State Legislative Committee, 1949) in Schenectady County, New York, the prevalence of cerebral palsy in a sample of 22,528 persons was found to be in essential agreement with Phelps' estimate.

## VOLUNTARY ORGANIZATIONS

For many years various private agencies and fraternal societies have done pioneer work in developing programs to help the physically handicapped child. A characteristic of these efforts has been the categorical approach in which one or more organizations would interest themselves in a single type of physical handicap. However, the International Society for Crippled Children, founded in 1921, gave leadership to public efforts in behalf of all physically handicapped children and

sponsored legislation in their behalf. As successor to the international organization in this country, the National Society for Crippled Children and Adults was organized in 1939 and with its 2,000 affiliated local and state societies provides an over-all program of a variety of activities in the fields of health, welfare, education, recreation, rehabilitation, and employment for all types of handicapped persons.

The custom, starting in 1934, of nation-wide celebrations of the birthday of Franklin D. Roosevelt to raise money to control infantile paralysis, resulted in 1938 in the organization of the National Foundation for Infantile Paralysis "for the express purpose of leading, directing, and unifying the fight on every phase of infantile paralysis." This Foundation has stimulated the organization of local chapters covering nearly all of the 3,050 counties. One half of the funds raised each year is retained locally to assist in providing medical, surgical, nursing, physical therapy, and hospital care, as well as provision of orthopedic appliances and certain special equipment for hospitals. The chapters also contribute to the training of doctors, nurses, and physical therapists in the care of poliomyelitis patients. National funds are used to finance many important research projects related to poliomyelitis and to provide an "epidemic fund" for use in areas of greatest need. There is close cooperation in most states between the program of the Foundation and that of the official state agency responsible for services to crippled children.

In recent years, there has been a rapid rise of interest in the problems of the child with rheumatic fever, rheumatic heart disease, and, quite recently, congenital heart disease. The American Council on Rheumatic Fever, which functions as a part of the American Heart Association, is directing development of training programs, scientific research, and public education, working through affiliated state societies.

The National Society for the Prevention of Blindness conducts a vigorous educational program in behalf of children and adults with various types of visual handicaps, initiates special studies, and stimulates the development of adequate vision-sight conservation programs locally, especially in schools.

In 1949, the American Epilepsy League and the National Association to Control Epilepsy merged to form the National Epilepsy League which is now actively carrying out an educational program and promoting interest in establishing more adequate public health programs for this prevalent, misunderstood, and neglected disability.

There are a number of groups which focus their activities on speech and hearing disorders. The American Hearing Society (formerly the League for Hard of Hearing) which has 111 chapters chiefly in the larger cities, carries out educational activities and assists with developing of public health programs to prevent deafness, to conserve hearing, and to rehabilitate individuals with impaired hearing. The Volta Bureau is a pioneer agency which conducts a national educational program of speech and hearing disorders with emphasis on teaching the "oral method" of communication, and in general acts as a national clearing house for all information concerning speech or hearing disorders. Important professional organizations concerned with developing high standards of professional training for nonmedical specialists dealing with speech and hearing problems are the American Speech and Hearing Association, the American Speech Association, and the Audiology Association. The American Academy of Ophthalmology and Otolaryngology has several standing committees on the conservation of hearing and related problems.

Responding to a tremendous upsurge of interest in cerebral palsy, the Nation

Society for Crippled Children and Adults organized in 1946 a National Cerebral Palsy Division. Other national groups interested in this condition include the United Cerebral Palsy Association and the National Association for Cerebral Palsy.

In addition, there are numerous fraternal societies, clubs, and other groups such as Shriners, Rotary, Lions, Elks, Kiwanis, and American Legion which are interested in crippling diseases, usually in a specific type of handicap.

This partial list of private agencies provides unmistakable evidence of the intense and widening popular interest in the field of children with long-term illness or disability. On the other hand, it illustrates the increasing trend toward a categorical or segmental approach to isolated public health problems which should be integrated with the total community health program. Unfortunately, preoccupation with the individual category often has resulted in forgetting that one is dealing with the health of the "whole child," which means his physical, mental, and social well-being, not merely the absence of disease or infirmity. That the child was a physical handicap has all the health problems of any growing and developing child in addition to the special problems which may be associated with his particular disability is a principle far too frequently overlooked. Another disadvantage of the too-exclusive categorical approach arises from the frequency with which physical handicaps are multiple. For example, approximately 30 per cent of children with cerebral palsy also have convulsive seizures, and a large additional group have speech disorders. The child with a cleft palate is not just a case for the plastic surgeon, but needs the attention of the pediatrician, speech therapist, and prosthodontist or orthodontist as well. The child with a "reading disability" seldom has problems confined to the visual apparatus alone, but not infrequently has hearing impairment, emotional disturbances, and other problems. The tendency to duplication of service, lack of economy and poorly balanced emphasis inherent in the one-interest agency approach has been discussed in detail by Gunn and Platt (1945). That there are also important advantages to be gained from the one-interest agency is undeniable. A discussion of both sides of the question can be found in the study of voluntary agencies (Gunn and Platt, 1945) which was sponsored by the National Health Council.

## STATE PROGRAMS

Although there is a basic similarity among the various state plans for crippled children's services, each is adapted to the particular needs of the state and is supervised by the official state agency. A recent review (Davens, 1955) summarizes the progress states have made in developing services for crippled children during the 20 years since the passage of the Social Security Act in 1935.

State programs have worked out methods of cooperation among themselves and other allied agencies. An example is the working arrangement with the National Foundation for Infantile Paralysis which operates a medical care program for a specific crippling disease. Of exceptional importance is close collaboration with related public programs such as special education and vocational rehabilitation services.

In a few states eligibility for care must be determined by court order in the county court in which the child resides. In the remaining states the official state agency has the sole responsibility for determining eligibility for care. Laws and state policies vary concerning residence requirements. The Children's Bureau Advisory

Committee on Crippled Children on several occasions has recommended discontinuance of any requirements concerning length of residence as a prerequisite to eligibility for care. This would seem to be a desirable course since migration across state lines has greatly increased and since the program receives financial support from federal funds. There is now a wide acceptance of the principle that the physical restoration of the child with long-term handicapping illness is largely a public responsibility and provision of care should not be limited to the indigent. Consequently, financial eligibility policies in this particular specialized type of medical care program are less controversial. It is worth while to examine the reason for this.

In most crippling conditions the therapeutic services needed are not short term, infrequent, and inexpensive; rather they are likely to be long in duration, frequent, and extremely expensive. Many families are unable to meet the full cost, and financial assistance in whole or in part is needed. Poverty is a relatively unalterable condition, and its cure is beyond our scope, for the present at least. Methods of mitigating its impact on society consist in supplying a basic minimum of food, clothing, and shelter, using rigid formulae of income as a guide. In the case of a physical handicap, on the other hand, medical science has provided the tools to remove or minimize the disability transforming the individual from the potential status of a public dependent to a useful, happy, and employed citizen. Rather than schedules of income level, the criterion here should be based on medical need, using the skills of the medical social worker either by interview or consultation to determine on an individual basis what financial contribution the family can be expected to make.

An important responsibility of a state agency developing a program for all physically handicapped children is the achievement of a reasonable balance of emphasis between the different categories of handicap and the establishment of priorities for expenditures based on sound public health criteria. The fact that present funds available for this purpose are limited gives further emphasis to this consideration. There are a number of useful criteria in determining the quantity of effort and dollars which should be allocated to a particular handicap:

- (a) The number of children affected.
- (b) The amenability of the handicap to medical therapy and preventive measures.
- (c) The cost per child to secure maximum benefit.
- (d) The likelihood of the child's becoming, if untreated, dependent, unemployable, and a permanent public responsibility at far greater cost.
- (e) The unfavorable effect of the handicap on the emotional status of the child and his family.
- (f) The extent of interference with satisfactory progress in school.
- (g) The progressiveness of the condition.
- (h) The availability of special personnel and facilities for treatment.

When faced with the problem of budgeting a limited amount of funds for a complete program for all physically handicapped children, points (a), (b), and (c) above are of greatest importance. It would seem that the wisest policy from the public health standpoint would be to plan in such a way that the available resources are directed toward securing the maximum benefit for the greatest number of children at the least cost per patient.

## ESSENTIAL SERVICES

Regardless of the nature of the particular handicap, the basic approach in a program providing complete care is essentially the same. Whether one is developing services for children with orthopedic defects, cleft palate, hearing impairment, speech disorder, rheumatic heart disease, or epilepsy, the essential components to insure the advantages of continuous and interrelated care of high quality are the same. The objectives of medical care must include promotion of positive health; prevention of disease, disability, and attendant economic insecurity; cure or mitigation of disease; and rehabilitation of the patient. The quality of medical care is of exceptional importance in dealing with physical handicaps of children because to achieve the best results that modern medical science has to offer, the teamwork of various types of medical and other specialists is required, and the stakes one is playing for are the entire future development, educational achievement, and vocational adjustment of the individual.

Continuity of care is of special importance in the planning of services for care of long-term illness in growing and developing children. Such care involves attendance by the same physician, dentist, nursing team, social worker, and so forth throughout the course of the child's illness or disability. There may be need, of course, for various types of medical consultants and for referral to different qualified personnel such as clinical psychologists, clinical audiologists, speech therapists, and others. Nevertheless, the principle of continuity of care should ensure that the child remain under coordinated management throughout all phases of treatment. Continuous care must not only be well integrated, but also complete in its various aspects. High quality of service is difficult to achieve unless home, clinic, and hospital care are all developed with smoothly functioning interrelationship. The full range of health service—from prevention through vocational rehabilitation—should be developed for each type of handicap and should be made readily available to the child and his family in such a way that the total needs of the particular child are the chief consideration.

Keeping this principle of continuity of care in mind, it is convenient to consider separately the essential services in a program for physically handicapped children; these may be listed as (a) prevention, (b) case finding, (c) medical and other professional diagnosis and treatment, (d) hospital and convalescent care, (e) special education, vocational rehabilitation and other after-care.

**Prevention of Physical Handicaps.** As in any other public health program, planning for the total needs of physically handicapped children should incorporate all available preventive measures. The most effective accomplishment of this objective follows when there is smooth integration of services for physically handicapped children with the health program for all mothers and children. It has already been pointed out that handicapped children have all the health problems of any growing child in addition to the special problem imposed by their disability. Even more important, however, is the fact that diligent and unremitting application of preventive health measures to all expectant mothers and children will be reflected in substantial reduction both in the quantity and severity of the crippling conditions to be found on the crippled children's registers.

Easily available and improved obstetrical care should be a cornerstone of efforts

to prevent physical handicaps. A wide variety of problems is susceptible to this approach. Congenital syphilis is also called "negligent" syphilis (Huse and Aufranc, 1950) because negligence in maternity care is the only reason for its continued existence at the rate of 14,000 reported cases each year; all this, in spite of the effectiveness and availability of penicillin.

Erythroblastosis fetalis, a cause of cerebral palsy, can be controlled in some measure by more adequate antenatal care with attention to recognition of Rh incompatibility. The association of maternal rubella with abnormalities of the infant's hearing, vision, and cardiac function are now well established. Improved obstetrics will also diminish the incidence of various types of birth injuries. According to Dunham (1948) premature infants are peculiarly susceptible to birth injury because of immaturity of the various body structures and tissues. Since birth injury is an important causative factor of physical handicaps, the prevention of prematurity is pertinent and already has been discussed above.

Associated with improved measures for control, there has been a decline in the numbers of cases of tuberculosis of the bones and joints on state crippled children's registers. In the light of our present knowledge about this disease, there is no reason why crippling from tuberculosis should not be brought under complete control.

This is likewise true of rickets. The fact that this latter condition is still a cause of crippling at all is a severe indictment of the preventive program.

Both among infants and preschool children, accidental burns rank second as a cause of death and disability (Wolff, 1948). Motor vehicle and various types of home accidents are extremely important in the preschool and school-age years, constituting the most important cause of death from any cause in the latter group and also providing a major source of long-term physical handicap. Every state crippled children's register contains the names of children with paraplegia or other serious handicap due to accidental gunshot wounds. In the southern states accidental lye burns resulting in esophageal stricture are common. There is room for significant improvement in reducing physical handicaps through better means of accident prevention.

Analysis of causes of blindness gives dramatic evidence of how much disability is preventable. In a study of causes of blindness among 20,591 recipients of aid to the blind (Hurlin and others, 1947) it was found that 1,551 cases were due to trachoma; 899 cases resulted from trauma associated with accidents; 1,589 were charged to syphilis; 428 to ophthalmia neonatorum; 101 resulted from poisoning; 36 from smallpox; 132 from meningitis; and 111 from measles. Preventive measures for retrolental fibroplasia, recently an alarming contributor to blindness among prematurely born infants, have been established. Elimination of prolonged and excessive oxygen among the smaller newborn infants is effective (Gordon, 1954).

The general principle of early diagnosis and adequate treatment has wide application as a potent preventive measure. In this connection, recent studies (Houser, 1952) demonstrate that recurrences of rheumatic fever are prevented or greatly reduced when the child is brought under adequate medical supervision during and after the initial attack of the disease. In this way, the crippling effects of rheumatic heart disease are either completely avoided or greatly reduced.

There is increasing evidence (Proctor and others, 1948) to support the view that early recognition of impaired hearing and the prompt institution of otological

therapy including irradiation of the lymphoid tissue of the nasopharynx can prevent progressive loss of hearing due to chronic disease of the middle ear. In the field of speech disorders, there have been some encouraging demonstrations in nursery schools of the effectiveness of early and intensive speech therapy in minimizing speech difficulties associated with hearing impairment. As our knowledge of the nature of rhythmic speech disorders such as stuttering increases, preventive measures (Johnson and others, 1948) will be more extensively applied.

Early diagnosis and prompt, intensive treatment with antibiotics has continued to greatly reduce the disability from osteomyelitis. The new vaccine recently developed for poliomyelitis promises to eventually control the paralytic effect of this disease (Francis, 1955).

The principle of early diagnosis, prompt treatment, and application of the full range of aftercare services, particularly physical therapy, has greatly minimized the paralytic effects of poliomyelitis.

**Case Finding.** The goal should be to achieve continuing rather than sporadic case-finding. The best method of accomplishing this is the stimulation of interest in periodic health supervision of young children on the part of physicians, nurses, teachers, social workers, and parents. A new guide (Child Health Committee, 1955) provides an excellent summary of current concepts and procedures for such health supervision.

Physician-reporting to the health department has been unsatisfactory (e.g., in the case of rheumatic fever) in some potentially handicapping diseases and satisfactory (poliomyelitis) in others.

In general, special surveys are an expensive and disappointing method of case finding. Experience in such programs as conservation of hearing and rheumatic fever and heart disease indicate that provision of easily available specialized clinical diagnostic facilities is a far more effective method of learning about the extent and nature of the problem. The accurate diagnosis by specialists also permits classification of the cases according to severity which is essential information in planning treatment services.

In some cases—for example, congenital malformations—birth certificates have been successfully used as a case-finding technic.

School censuses are another source, but have the drawback usually of discovering only gross handicaps at a stage where the advantages of early recognition and treatment are lost. However, newer methods of case finding in school programs by various screening technics are showing excellent results in ferreting out the more subtle types of physical handicaps such as visual defects, mild hearing loss, speech disorders, and rheumatic fever. For a discussion of these technics, which include daily teacher observation of school children, teacher-nurse conferences, vision testing, audiometer testing, and mass photo-fluoro-roentgenographic surveys, see the section on school health services, Chapter 17.

Close working relationships with welfare departments in the matter of adoption and foster home placement provide another source for locating children in need of physical rehabilitation. Liaison with hospital newborn nurseries and with the various other hospital care programs (e.g., in welfare department) are other sources which require further exploration.

**Diagnosis and Treatment.** Skilled diagnostic services are furnished in state clinics staffed by qualified surgeons, pediatricians, and other medical and nonmedical specialists. These clinics are conducted either in permanent centers or periodically in various rural communities so as to be accessible to any part of the state. Most widely developed are clinics for orthopedic problems and for cases requiring plastic surgery. In the interest of continuity of care, every effort should be made to insure that the same physician who makes the diagnosis, treats the child in the hospital and also participates in the after-care. As in other health programs, the interprofessional teamwork between physicians, public health nurses, medical social workers, and others is being used with conspicuous success in this phase of the program. Increased teamwork between various specialists actually involved in the diagnosis and treatment is another current trend. An example is initial planning conference between the plastic surgeon, the pediatrician, the speech therapist, and the prothodontist or orthodontist in working out a regimen of therapy for cleft palate cases (Baker, 1949).

In the case of diagnosis and treatment of children with hearing impairment and associated speech disorder, the cooperative endeavor on the part of the otolaryngologist, the clinical audiologist, and the speech therapist in a closely-knit clinical program, permits the consideration of the fundamentals of hearing disability as a "communicative disorder" and fosters "the psycho-social adjustment of the hard-of-hearing person" (Pauls and Hardy, 1948).

In most states, the clinical facilities for orthopedic handicaps, including poliomyelitis and defects requiring plastic surgery, are better established and have statewide coverage. However, there has been rapid advance in the development of state programs to provide services for other types of physical disability. Most of these newer programs are on a demonstration basis, however, and frequently only a part of the state, often a single county, is served.

Children with cerebral palsy are another group for which clinical services are being rapidly developed under both public and private auspices. Cost of treatment and training is extremely high. In 1947, the California State Legislature made a substantial appropriation to initiate a state program for the care and training of these children and in 1949, following a special study (N. Y. State Joint Legislative Committee, 1949), the New York State Legislature did likewise. In addition, a few other states have taken initial steps to develop well-rounded programs for these children although in most instances the geographic area covered is limited.

It is difficult to make any general statement regarding speech and hearing programs in the States. 42 or more States make at least some provision for services to children with impaired speech or hearing. Sixteen States have programs for children with hearing impairment which are more complete than the others. In some cases services are limited in coverage, either geographically or in completeness of program offered. A few States have demonstrations in speech or hearing, most of which have been training rather than service projects.

In 1955, at least nine States had a program for children with convulsive seizures, and eleven or twelve others were serving a few children with epilepsy.

The Children's Bureau reports that official state agencies operating programs of services for crippled children provided diagnosis and treatment in clinics to 221,000 children in the calendar year 1954. The total number of clinic visits was 468,000.

**Hospital and Convalescent Care.** During the calendar year 1954, official state crippled children's agencies alone provided hospital care to 43,000 children, purchasing a total of 1,207,000 days of care (average of 27.8 days per child). These same agencies provided convalescent home care to 4,000 children for a total of 413,000 days of care (average 99.9 days per child). In addition, of course, very large quantities of hospital and convalescent care for physically handicapped children were purchased by numerous other public agencies and voluntary agencies such as the National Foundation for Infantile Paralysis, Community Chest agencies, religious and fraternal groups, and others. All this implies a considerable amount of responsibility on the part of the agency providing the care regardless of whether it is public or private. This responsibility involves such considerations as selection of hospitals on the basis of their ability to provide the type and quality of care needed, and in long-term cases whether they have educational and occupational therapy facilities and whether there are adequate social services to maintain contact with the family and arrange for after-care in the home if needed.

With respect to the first of these responsibilities—the selection of hospitals on the basis of their ability to provide the type and quality of care needed—it is well to view the whole problem of long-term illness rather than the segment of the problem posed by special needs of handicapped children. Undoubtedly, long-term illness has become one of the outstanding unsolved problems of our day, even though the use of this term rather than “chronic illness” reflects a more hopeful attitude of mind (Bluestone, 1947). The very large numbers of persons, children and adults, requiring long-term care presents a serious problem to hospital and convalescent sanatoria administrators. In a joint statement (American Hospital Association, 1947) the American Hospital Association, American Public Welfare Association, American Public Health Association, and American Medical Association recently pointed out that “the general hospital as at present constituted is often unsuited to the care of long-term patients, since it is geared primarily to the therapeutic and general requirements of the acutely ill. It may lack adequate departments for physical therapy, and rehabilitation, as well as sun porches, recreational facilities, educational facilities for children and an understanding of the social and psychologic needs of the chronically ill.” Moreover, care provided in the acute general hospital for long-term care is much more costly in spite of the fact that it is often unsuited to the patient's needs. The report finds encouragement in the construction of new facilities for long-term care by the Hospital Survey and Construction Act, but deplores the continued tendency in some areas to build such hospitals in remote areas with no relation to teaching medical centers and the general hospital. It goes on to point out that “hospital facilities for long-term illness should be built in the very closest relation to teaching centers and general hospitals.” Most state agencies administering programs of care for physically handicapped children have established standards for hospitals and convalescent homes from whom they purchase care. In a rapidly increasing number of states there are hospital licensing laws which are frequently administered by the state health department, and there is an encouraging trend toward provision of hospital consultation service in the fields of pediatrics, obstetrics, nursing, and nutrition in association with the hospital inspections which are a part of the licensing program. Standards for convalescent care of children (Subcommittee, N. Y. Academy of Medicine, 1948) have been carefully worked

out. A recent study (U. S. Department of Labor, 1949) of a single convalescent home restates current thinking on the general principles and meaning of convalescent care and contains an excellent bibliography.

A health agency purchasing hospital care for physically handicapped children, particularly if it be a state agency, frequently finds it is desirable to enter into a written agreement with the hospital. Items which are frequently covered by such agreements include the responsibility of the agency for payment for services authorized and rendered, for submitting to the hospital information about the patient, and for assuring proper follow-up care; the use of an inclusive per diem rate for all services and reference to the method of calculating this rate; the method of authorizing services; a provision for the hospital to accept payment only from the agency for services authorized by the agency; and reference to the standards of hospital care required by the agency purchasing the care.

With respect to authorization of care, it is customary for the agency purchasing the care to furnish the hospital selected with formal authorization for the care, stating the period to be covered and any other conditions which may have been agreed upon.

When federal funds are used to purchase care for handicapped children (also used by vocational rehabilitation programs) payment is made at an inclusive per diem rate to cover all the services provided to a patient by a hospital. This rate is calculated according to a formula \* which insures that the rate of payment is not in excess of the average cost per patient day. Maximum or ceiling rates are frequently adopted by state agencies, however.

Finally, any agency purchasing hospital care for physically handicapped children should accept the responsibility of cooperating with any other agency, public or private, in order to develop procedures and rates of payment which are as uniform and reasonable as possible. In the case of an agency operating a crippled children's program, there is special need for cooperation with maternal and child health services, vocational rehabilitation services, National Foundation for Infantile Paralysis, and similar agencies in matters pertaining to purchase of hospital care.

**Special Education, Vocational Rehabilitation and Other After-care.** The ultimate aim in physical restoration is the successful educational, social, and vocational functioning of the individual. Any program of services for the physically handicapped child which does not take into account provision for adequate special education, vocational rehabilitation and other after-care is seriously remiss. Furthermore, it must be recognized that the resultant benefit a child receives from after-care depends upon the adequacy of the resources in his home community. It is feasible to solve certain medical or surgical problems in diagnosis or treatment by bringing specialists to clinics in rural areas or even by transporting children beyond state borders, as is done for example when certain children are transported by air from Alaska to Seattle for operation. It is not possible, however, to provide the day-by-day public health nursing, medical social and physical therapy services in the home or the long-continued special education and vocational guidance which are needed unless these facilities are developed within the child's own home town or county.

As local public health departments develop there is a growing tendency to pro-

\* Children's Bureau and Office of Vocational Rehabilitation, Department of Health, Education, and Welfare, and Veterans Administration, Joint Hospital Form 1, September 1954.

vide public health nursing, medical social, physical therapy, occupational therapy, and other needed after-care services as a part of an integrated public health program. State nursing, medical social, and physical therapy consultants are being used to assist the local health officer in improving the education and productiveness of their respective professional local staff members. These consultants assist local nurses, social workers, physical therapists and others in carrying out their duties relating to the follow-up of children with physical handicaps who have had initial medical diagnosis and treatment, but who are in need of various types of continuing care such as interpretation of handicap to family, home nursing, physical therapy, special diet, appointments for return visits to clinic or hospital, home occupational therapy, routine well-child supervision, and a host of other items which form the pattern of really complete after-care.

The essential contribution of special education to the rehabilitation of the physically handicapped child is now widely accepted. Even after all available medical, surgical and other professional skills have been brought to bear on the cure or mitigation of the physical handicap, there will continue to be children who deviate sufficiently from the "normal" to require special skills on the part of the teachers or other school personnel. The current terminology used to designate this group is "exceptional children." This term refers "to those who deviate from what is supposed to be average in physical, mental, emotional, or social characteristics to such an extent that they require special educational services in order to develop to their maximum capacity." These special educational services may include a radical modification of the curriculum, special methods of instruction, special equipment, or an adjusted school schedule.

World War II, by demonstrating that the handicapped are excellent workers, gave tremendous impetus to the special education movement and, by 1948, 41 states had enacted laws authorizing or requiring local school districts to make special provisions for one or more types of exceptional children. Thirty-four of these states have provided funds to help the local districts finance the program. Statistics gathered for the year 1947-48 indicate that approximately 365,000 exceptional children were enrolled in special schools and classes or home or hospital instruction provided by local school districts (National Society for the Study of Education, 1950). This figure includes children with mental, emotional, and social deviations as well as physical handicaps.

For a detailed discussion of the principles of special education, the essentials of a well-rounded program, and the needed educational provisions for specific types of handicaps, the reader is referred to the 49th Yearbook of the National Society for the Study of Education.

Vocational rehabilitation, as provided today by the states assisted by the Federal Government through grants-in-aid, is a service to preserve, restore, or develop the ability of disabled persons to engage in gainful employment. In relation to services for physically handicapped children, it is the crucial end stage where the child with handicap is assisted in preparing for and finding suitable employment. United States Public Law 165 enacted in 1954 liberalized and extended the Vocational Rehabilitation Acts of 1920 and 1943 which extended grants of federal funds to states to develop programs for vocational rehabilitation. The purpose is to increase the number of persons rehabilitated from 60,000 to 200,000 per year by 1959.

(Whitten, 1954). This act is administered by the Office of Vocational Rehabilitation in the Department of Health, Education, and Welfare. Similar to the crippled children's programs, state plans describing policies and procedures and administrative organization are required. In 1953 state rehabilitation agencies reported 61,308 persons were vocationally rehabilitated (U. S. Office of Vocational Rehabilitation, 1954). During this same year, total expenditures were approximately \$22,947,851 from federal funds and about \$11,635,557 from state funds. The need for close cooperation between vocational rehabilitation and crippled children's services has already been cited. The Children's Bureau and the Federal Office of Vocational Rehabilitation have agreed upon certain policies designed to avoid duplication of services, and most state agencies administering these two programs have adopted similar agreements which, among other things, provide for referral of crippled children of employable age to the state vocational rehabilitation services.

In summary, the essential components of an adequate total program of services for physically handicapped children are as follows:

Provision should be made for the inclusion of all types of physical handicaps which interfere with normal growth and development, or successful educational, social, and vocational functioning of the individual.

By integration with the over-all public health program, persistent emphasis should be placed on the prevention of physical handicaps rather than indulging solely in a salvage campaign to mitigate disabilities which need never have occurred.

The case-finding effort should be organized on a continuing rather than a sporadic basis by stimulation of interest on the part of physicians, nurses, teachers, social workers, and parent groups. The goal should be toward early diagnosis and treatment.

Medical and hospital care should be readily available to all children on the basis of medical need and there should be no limitations because of residence, race, creed, or color. Methods of removing the financial barrier between the child and the needed care should be worked out on an individualized basis with the assistance of the medical social worker. Various other professional diagnostic and therapeutic skills should be available and the trend toward interprofessional teamwork encouraged. High standards of quality of care should be fostered at all times.

Modern convalescent sanatoria should be provided for the various types of illness or disability in stages not requiring general or special hospital care. For those children needing prolonged convalescence at home, an organized program of after-care should be available to assist and supplement the care afforded by the family physician. Among the services needed are those of the public health nurse, the medical social worker, the nutritionist, the physical therapist, the occupational therapist, and the home teacher.

Teachers or other personnel with special skills should be available in the schools for the education of those children who, after the application of all medical and surgical skills, continue to deviate significantly from the "normal."

Vocational rehabilitation services should be fully available in any part of a state to assist the child (or adult) with a residual handicap to develop or restore his ability to find suitable employment. Finally, a public educational program should be planned to remove, insofar as possible, the unreasonable and unfounded prejudices which interfere with the employment of handicapped persons.

For the effective accomplishment of these objectives, nothing short of united effort of an informed community will suffice.

## SENESCENCE, CHRONIC DISEASE AND DISABILITY IN ADULTS

LESTER BRESLOW, M.D.

**Relative Importance.** During the past half century, advances in the standard of living, including preventive medicine, have vastly altered the pattern of morbidity and mortality in the United States. In 1900, the leading causes of death were tuberculosis, pneumonia, and enteritis. Today these diseases are of secondary importance as causes of death; their former places are now occupied by cardiovascular diseases and cancer.

Table 19-1 indicates the remarkable change which has occurred in the principal causes of death. The decrease in the communicable diseases and increase in importance of the chronic diseases represents both a tribute and a challenge to preventive medicine. Improvements in diagnosis and treatment, sanitation, nutrition, housing, and conditions of labor, as well as the more specific preventive measures such as immunization, have played important roles in the conquest of the communicable diseases. Most recently chemotherapy has hastened their decrease. These measures have already virtually eliminated many previously important diseases, and opened the path to eradication of others.

The relative and absolute increase of the chronic diseases has been due in large part to the survival of more persons into the later decades of life when these diseases are more prevalent. During the first half of the twentieth century, the average expectancy of life at birth (for white males) increased from 48 to 67 years.

**Aging of the Population.** Figure 19-1 indicates the steadily increasing proportion of persons in the older age groups in the United States. In just 100 years—from 1860 to 1960—the proportion of persons under 20 years of age will have dropped from one half to less than one third of the total population. In this same period the proportion in the age group 45 to 64 will have doubled, and in the age group 65 years and over the proportion will have tripled.

The changing age composition of the population (i.e., the increasing proportions of persons in the older age groups) is changing the orientation of preventive medicine. Whereas previous efforts have been directed largely to the control of the communicable diseases of early life, efforts are now being focused to an increasing extent on the diseases common in middle and later life—the chronic diseases.

**Age Relationship.** Aging and chronic disease are closely related by separate phenomena. Increasing interest is being shown in the problems of an aging population not only by physicians but also by other professional groups. At this point it is appropriate to differentiate several concepts used in this field, i.e., senescence (the

Table 19-1. Death rates for leading causes of death, Death Registration States, United States,<sup>1</sup> 1900 and 1950

Rank Order	1900 <sup>a</sup> Cause of Death	Rate per 100,000	Rank Order	1950 <sup>b</sup> Cause of Death	Rate per 100,000
	All causes (343,217 deaths)	1719.1		All causes (1,452,454 deaths)	963.8
1	Pneumonia (all forms) and influenza	202.2	1	Diseases of the heart	355.5
2	Tuberculosis (all forms)	194.4	2	Malignant neoplasms, including neoplasms of lymphatic and hematopoietic tissues	139.8
3	Diarrhea, enteritis, and ulceration of the intestines	142.7	3	Vascular lesions affecting central nervous system	104.0
4	Diseases of the heart	137.4	4	All accidents	60.6
5	Senility, ill-defined, and unknown	117.5	5	Certain diseases of early infancy	40.5
6	Intracranial lesions of vascular origin	106.9	6	Influenza and pneumonia except pneumonia of newborn	31.3
7	Nephritis	88.6	7	Tuberculosis (all forms)	22.5
8	All accidents	72.3	8	General arteriosclerosis	20.4
9	Cancer and other malignant tumors	64.0	9	Chronic and unspecified nephritis and other renal sclerosis	16.4
10	Diphtheria	40.3	10	Diabetes mellitus	16.2

<sup>1</sup> The Death Registration Area did not include all states until 1933. Therefore, data for 1900 do not represent mortality for total United States.

<sup>a</sup> First Revision, International Statistical Classification of Diseases, Injuries and Causes of Death, 1900.

process of growing old); gerontology (the science of the physical and psychological changes which are incident to old age); and geriatrics (the treatment of problems peculiar to old age). Senescence is an inevitable, normal biological phenomenon. In the case of some conditions we are now quite limited in ability to differentiate

Fig. 19-1. Per cent distribution of total population by age; United States, 1860 to 1960.

senescence in its pure sense, from pathological changes occurring in old age as a result of environmental factors in earlier life. However, the leading chronic diseases represent well recognized pathologic processes and should not be confused with senescence.

Although more prevalent in the older age groups, these diseases occur at any age. The National Health Survey (1935-1936) revealed that fully one half of the chronically ill persons in the United States are under the age of 45 years. More than three fourths are in the productive years from 15 to 64. Hence, preventive and other measures for the control of chronic disease should be directed toward the whole age span of the population.

**Associated Factors.** Many persons view the chronic diseases—frequently referred to as the “degenerative” diseases—as inevitable concomitants of the aging process. This way of thinking, which has no scientific basis, leads to defeatism in control and rehabilitation efforts. It attempts to conceal our ignorance of these diseases and tends to discourage inquiry into their etiology. Within the medical and allied professions there is increasing dissatisfaction with the concept of the inevitability of many of these diseases—the concept that little if anything can be done to prevent, arrest or cure them. This shift in thinking is not based on the mere desire to substitute optimism for pessimism. Rather it is based on mounting evidence that

environmental factors rather than a mysterious "aging process" play the decisive role in the etiology of at least some of the diseases misnamed "degenerative." There is considerable evidence supporting the concept that conditions of life—the physical and social environment—are basic factors in the development of chronic disease.

**INFECTION.** It has been known for many years that pathogenic organisms are the causative agents in certain chronic diseases, e.g., syphilitic aortitis, diphtheritic heart disease, rheumatic heart disease, neuromuscular residuals of poliomyelitis, neurological sequelae of encephalitis, and gonorrheal arthritis. Within the last few years the occurrence of some cases of congenital heart disease—formerly considered to be a nonpreventable disease—has been shown to be related to rubella infection in the mother during pregnancy, particularly during the first trimester.

The control of the infectious diseases, which are responsible for organic impairment of the heart and other organs of the body, is an important phase of chronic disease prevention.

**OCCUPATIONAL EXPOSURES.** The influence of specific environmental factors in causation of cancer is well established (Hueper, 1950). Carcinogenic agents have been identified in a number of occupations. Men employed in certain chromate and uranium ore operations have vastly higher mortality rates from lung cancer than is usual for men of their age. Cancer of the bladder is much more common among amine dye workers than among the general population. Radiologists show a mortality from leukemia (due to exposure to x-radiation) which is much higher than expected. Exploration of the effect of conditions of work on the development of cancer and other chronic diseases has only begun.

**NUTRITION DEFICIENCIES AND EXCESSES.** Nutritional deficiency is well known as an etiologic factor in several chronic disease processes. Insufficient iodine in food results in thyroid disease. In some instances of iodine deficiency heart disease results, either myxedema or thyrotoxicosis. Severe deficiency of thiamine may lead to cardiac decompensation in the form of beriberi heart. Recent studies indicate that lipotropic factors in the vitamin B complex (choline, inositol) may be related to the deposition of fat in the intima of blood vessels (atherosclerosis).

Table 19-2. Standardized death rates<sup>1</sup> for specified causes of death, all ages combined, by weight class<sup>2</sup>

Cause of Death	Standardized Death Rate per 100,000					
	Underweight		Normal Weight	Overweight		
	15-34%	5-14%		5-14%	15-24%	25%+
All causes	913	833	844	1,027	1,215	1,472
Organic heart diseases	63	66	80	115	135	129
Angina pectoris	12	14	16	32	39	37
Diseases of the arteries	15	17	23	34	46	41
Acute and chronic nephritis	56	64	82	108	202	224
Cerebral hemorrhage and apoplexy	46	50	70	101	115	170
Diabetes	9	9	14	22	45	117

<sup>1</sup> Rates are per 100,000 population.

<sup>2</sup> Based on mortality experience of about 200,000 insured lives.

Abstracted from Table 48, page 195, L. I. Dublin, A. J. Lotka, M. Spiegelman, *Length of Life*, The Ronald Press Co., New York, 1949.

Not only undernutrition but also overnutrition is related to chronic disease. General caloric overnutrition (obesity) is closely associated with excessive mortality from several chronic diseases. Table 19-2 reveals that the greater the degree of obesity, the higher the death rate from the following: organic heart disease; other vascular diseases, including cerebral hemorrhage; nephritis; and diabetes. Persons with marked obesity (more than 25 per cent above normal) have more than 12 times the mortality rate from diabetes than persons slightly underweight. For cerebral hemorrhage and apoplexy the differential is three times, for nephritis almost four times and for organic heart disease approximately two times. Even a slight degree of obesity, 5 to 14 per cent above normal, has a considerable effect. In fact, it will be noted that the so-called "normal weight" persons have a higher mortality from these diseases than those who are "underweight." This fact naturally raises the question as to whether "normal" weights—which merely represent arithmetic means—should be considered optimum weight. So far as mortality from chronic disease is concerned Americans are on the average overweight. Reduction of obesity and the maintenance of optimum weight is a major element in the prevention of chronic disease in the United States.

**EMOTIONAL DISORDERS.** Emotional patterns resulting from social maladjustments are being given increasing recognition as possible etiologic factors in chronic disease. One cannot consider the problem of obesity, for example, without noting that it is often a manifestation of emotional disturbance. The role of the emotions in the causation of vascular and other diseases is now being intensively explored.

**SOCIO-ECONOMIC STATUS AND CHRONIC DISEASE.** Available data show marked variations in mortality rates among different socio-economic groups. In point are the studies by the Registrar General for England and Wales in which standardized mortality rates were computed for the population classified into five socio-economic groups (see Table 19-3). For cancer of the stomach and esophagus among males aged 20-65, the professional workers (Group I) have the lowest mortality rates and the unskilled workers (Group V) have the highest rates. The rates for cancer of these sites in unskilled workers are approximately twice that in professional workers.

Similar mortality rate patterns are found for pulmonary tuberculosis. In contrast, for coronary heart disease significant differences in the opposite direction are shown among the socio-economic groups, with Group I having the highest rates and Groups IV and V the lowest.

A study by J. S. Whitney of death rates by occupation in 10 selected states of the United States in 1930 also revealed marked variation in mortality among different occupational groups. Standardized death rates from specified causes per 100,000 gainfully occupied males 15 to 64 years of age are shown in Table 19-4.

The fact that socio-economic status is related to the prevalence of chronic disease has been demonstrated not only in mortality statistics but also in disability statistics. In the National Health Survey reports data are presented (U. S. Pub. Health Service, 1938) on the number of days of disability per person per year (per capita volume of disability) for certain diseases, by income status. The per capita volume of disability from rheumatism among persons aged 20-64 was more than four times as great among the lowest income group (persons on relief) as among the highest (persons with incomes of \$5,000 and over). A similar comparison for the

cardiovascular diseases shows three times as much disability among those in the lowest income level.

In seeking interpretation of the relation of socio-economic status to chronic disease it is evident that socio-economic status embraces a complex array of factors—occupation, nutrition, housing, medical care, education, habits of living, personal hygiene, etc. The relation of these factors to chronic disease merits further investigation.

**Prevention.** As yet our knowledge of the etiology of the chronic diseases is only fragmentary. This basic fact must not obscure other equally significant facts. With the existing though limited knowledge of etiologic agents and of factors associated with chronic disease we can prevent the occurrence of a significant number of cases of some of these diseases; we can prevent an appreciable amount of disability; and we can postpone, if not prevent, death from certain of these diseases. Through the application of existing knowledge about specific carcinogenic agents, infective processes and nutritional factors, the occurrence of a certain amount of chronic disease can be prevented. After onset—in diseases such as cancer, diabetes, several forms of cardiovascular disease, neuromuscular and other chronic diseases—much can be done to prevent illness and disability through early diagnosis and adequate treatment, including intensive rehabilitation.

Prevention of chronic disease is not solely a responsibility of the physician. Rather it is the responsibility of society as a whole. However, the physician should elucidate the relationship between chronic disease and the conditions of life and modes of living. By directing public attention to the importance of changing those conditions which give rise to disease, he can fulfill an important part of his social obligation to prevent disease.

## CARDIOVASCULAR DISEASES

Diseases of the heart and blood vessels—the cardiovascular diseases—are a group of conditions of diverse etiology linked together because they affect principally one organ system. They constitute the leading causes of death and of disabling illness in the United States.

**Mortality Trends.** In statistical grouping of causes of death, it is customary to combine chronic nephritis with the cardiovascular diseases. In 1950, deaths attributed to the cardiovascular-renal diseases totalled 769,751 in the United States (U. S. Dept. H. E. W., 1955). Of this number, 70 per cent were ascribed to diseases of the heart, 20 per cent to intracranial lesions, 3 per cent to nephritis, and 7 per cent to other forms of vascular disease.

As a cause of death the cardiovascular diseases appear to have advanced sharply in recent years. It is difficult to interpret this trend for the separate diseases because of the numerous changes in nomenclature and classification. A case which three decades ago might have been called chronic nephritis is now labeled hypertensive heart disease. Advances in diagnostic standards have also altered the picture. Hence in considering the *trend* of mortality over the years, it is necessary to lump the cardiovascular and renal diseases together.

At present approximately one out of every 200 persons in the United States dies each year as the result of a cardiovascular-renal disease. These diseases now account for one half of all deaths; in 1900 only one fifth of all deaths were due to these diseases. However, this significant change in proportional mortality (Table 19-5)

Table 19-5. Cardiovascular-renal diseases—crude death rates, proportionate mortality, and age-adjusted death rates, United States Death Registration States, 1900-1950 <sup>1</sup>

Year	Crude Death Rate per 100,000	Proportionate Mortality (percentage of all causes of death)	Age-adjusted Death Rate per 100,000 <sup>2</sup>
1950	511	53.0	439
1940	487	45.4	487
1930	420	37.2	502
1920	371	28.6	485
1910	382	26.0	504
1900	353	20.5	453

<sup>1</sup> The Death Registration Area did not include all states until 1933. Therefore, data for previous years do not represent mortality for total United States.

<sup>2</sup> Adjusted by the indirect method on the basis of the age distribution of the United States population, 1940.

Source: Office of Biometric Research, National Heart Institute, *Statistics of the Cardiovascular Diseases*, January, 1950, Tables 1 and 2, pp. 1 and 2. Public Health Service, Publication No. 429, *Cardiovascular Diseases*, 1955, Tables 14 and 15, pp. 27 and 28.

during the past 50 years is attributable largely to the increasing percentage of older persons in the population.

When correction is made for the age changes in the population it is evident that the death rate from the cardiovascular-renal diseases (age adjusted) is actually declining. There has been a downward trend since 1930. Whereas the risk of dying

from these diseases in any one year remained relatively constant from 1910 to 1930, there has been a 12 per cent decline in the past two decades.

The downward trend in the cardiovascular-renal disease death rate has not been uniform among the various age groups of the population. Table 19-6 reveals that

Table 19-6. Cardiovascular-renal diseases—deaths and age-specific death rates, United States  
Death Registration States, 1920-1950 <sup>1</sup>

Age (in years)	1920	1930	1940	1950

Source: Public Health Service Publication No. 429, *Cardiovascular Diseases, 1955*, Table 2, p. 5. Office of Biometric Research, National Heart Institute (mimeo.), *Statistics of the Cardiovascular Diseases*, Jan. 1950, Table I, p. 1.

for persons under 45 years of age the death rate has been decreasing sharply; for middle-aged and older persons it has been stationary.

The types of heart diseases most common in the early decades of life result from infectious processes, especially rheumatic fever. In the older age groups, the effects of arteriosclerosis are relatively more frequent. The decreasing mortality from cardiovascular-renal diseases among younger persons is probably due in large part to a decrease in the frequency and severity of the bacterial diseases affecting the heart, e.g., the streptococcal infections. The incidence of these bacterial diseases has been decreasing over a long period extending back to the latter part of the nineteenth century. Improved standards of living, as well as specific control measures, may account for this long-term trend. With the recent developments in chemotherapy even greater control of these disease processes can be expected.

Comparable progress has not been made with respect to the cardiovascular diseases common in later life. However, medical research has recently demonstrated significant relationships between metabolic factors and some of these diseases, suggesting the possibility of further reduction in mortality from this cause.

**Morbidity.** Current data on cardiovascular disease morbidity are not available. From the National Health Survey (1935-1936) data, it has been estimated that there were 9,200,000 persons in the United States with cardiovascular-renal diseases as of July 1, 1949. Estimates indicate that more than 100,000,000 days are lost from work or other usual pursuits each year by reason of cardiovascular disease (U. S. Public Health Service, 1939).

Only limited information is available on the relative prevalence of the major types of heart disease. Data, from a study made in 1939 of 4,547 cases seen in 19 cardiac clinics in Philadelphia, are shown in Table 19-7. As found in this study,

Table 19-7. Heart disease (all forms)—percentage distribution of etiological types of heart disease among 4,547 cases <sup>1</sup> in 19 Philadelphia heart clinics, spring of 1939

Etiological Type <sup>2</sup>	Percentage of All Cases
Total—all types	100.0
Rheumatic heart disease	35.0
Arteriosclerotic heart disease	20.1
Hypertensive heart disease	12.5
Syphilis of aorta and heart	4.4
Congenital heart disease	4.3
Thyroid heart disease	0.6
Other organic heart disease	8.2
Functional cardiac conditions	0.4
Potential and possible heart disease	14.5

<sup>1</sup> Consists of 3,869 cases of organic heart disease and 678 cases with functional cardiac conditions or possible heart disease.

<sup>2</sup> Listed according to primary etiological type.

Abstracted from Table 4, pp. 7 and 8, in Hedley, O. F., "Heart Disease in Philadelphia Cardiac Clinics," *Public Health Bulletin*, No. 268, U. S. Public Health Service, 1941.

rheumatic heart disease accounted for about one third of all cases, arteriosclerotic and hypertensive heart disease for another third, and miscellaneous conditions, including potential and possible heart disease, for the rest.

**Prevention of Occurrence. CONGENITAL HEART DISEASE.** Until very recently, congenital heart disease was regarded as nonpreventable. A certain number of pregnancies resulted in "blue babies" or infants with other manifestations of cardiac defects. The cause of these malformations was not known. However, research in the last few years has revealed that many cases of congenital heart disease, and other congenital defects such as blindness and deafness, are due to antepartum rubella infection (see section on rubella, Chapter 1) in the mother, particularly during the first trimester of pregnancy.

Just a few years ago the diagnosis of severe congenital heart disease meant, in most cases, a fatal prognosis. Modern surgery has changed this outlook. Diagnostic and surgical technics recently developed now permit the saving of many children whose hearts and large blood vessels are congenitally defective.

For maximum utilization of these new technics, active case-finding programs are necessary. Parents, teachers, public health nurses, and others should be made aware of the advances in this field, and be assisted to recognize the early signs of congenital heart disease in children. These include cyanosis, breathlessness, chest

deformity, and clubbing of the fingers. Children with these symptoms should be referred to their own physician. Final diagnosis and treatment of such children often require highly competent teams composed of physicians who see enough cases of heart disease in children to maintain their skills at a high level. In many parts of the country, centers are being established to which physicians may refer cases of suspected congenital heart disease for adequate study and treatment. In view of the highly specialized nature of resources necessary for handling congenital heart disease and the relatively small number of cases, the development of such centers appears to be the best way of meeting the problem.

**INFECTIOUS FORMS OF HEART DISEASE.** A variety of infections may damage the heart, as noted in the section on mortality trends. However, these are becoming less common as causative agents. Diphtheritic heart disease, once a fairly frequent complication of diphtheria, is now a rarity.

Syphilitic heart disease has declined in importance as the frequency and severity of this disease has decreased and better methods of treatment have been made generally available (see section on syphilis, Chapter 4).

Bacterial endocarditis is a fairly frequent complication of rheumatic valvular disease and congenital heart disease. It may follow dental surgery and surgery of the nose or throat. To protect against this infection which formerly was fatal in almost all cases, antibiotics are administered before and immediately after such surgery in the presence of valvular or congenital heart disease. In this manner the occurrence of bacterial endocarditis is prevented in many instances. Patients with valvular or congenital heart disease should be carefully instructed that their disease requires special precautionary measures before any such surgery is undertaken.

Rheumatic fever (see streptococcal infections and rheumatic fever, Chapter 1) is the most prevalent type of infectious heart disease. It is a repetitive disease, recurring again and again in the same child with increasingly serious damage to the heart muscles and valves. Rheumatic fever attacks or recrudescences are usually associated with recent streptococcal infections. This relationship has been obscured by the fact that the onset of rheumatic fever is often insidious. It may follow the streptococcal infection by two to six weeks or longer. From several recent studies, it appears that prompt and adequate treatment of acute streptococcal infections with penicillin is effective in reducing the risk of subsequent rheumatic fever.

Once rheumatic fever has occurred, patients are often placed on continuing chemotherapy or antibiotic therapy to prevent recrudescences. Daily doses of sulfa compounds have been commonly used. However, this regimen necessitates very close medical observation, including laboratory studies so as to minimize the danger of reactions to these drugs. Oral penicillin has been proved equally effective and is much safer. It has come into increasing use as the cost declined and better means of administration worked out, until it is now the drug of choice for rheumatic fever prophylaxis.

Not only is the rheumatic child himself likely to suffer recurring attacks of the disease, but his siblings are also subject to a much higher attack rate than are children in nonrheumatic families. Hence, once rheumatic fever has struck any member of a family, preventive care should be directed toward the entire family.

Environmental factors play a significant, though not precisely defined, role in initiating rheumatic fever and in the perpetuation of the disease. Overcrowding and other manifestations of poor economic status have been clearly linked with high

incidence and repetitiveness of rheumatic fever. Serious attention should, therefore, be given to improving the housing, nutritional and emotional aspects of the patient's environment. The medical social worker can contribute a great deal in these respects toward preventive care in rheumatic fever. For example, the physician in recommending a single bed, or a room alone, for the rheumatic child will often find that the medical social worker can provide assistance to the family in carrying out such advice.

The full classical picture of rheumatic fever with obvious signs of acute infection, severe joint pain, and carditis is not often seen. Much more frequently the onset of the disease is vague. It may escape attention for months or even years. Yet damage to the heart valves in these "mild" cases may be profound. Hence, active case-finding endeavors, aimed at bringing all suspicious cases to medical attention, are an essential feature of the prevention of disability and death from rheumatic fever. Awareness by physicians of the possible significance of even vague symptoms is an important aspect of early case finding. But the medical profession is not alone in this responsibility. Parents, teachers, and public health nurses should be alert to the potential danger of such signs as nontraumatic epistaxis, abdominal and precordial pain, joint pain, pallor, anorexia, lassitude, and failure to gain weight. The schoolroom provides an excellent opportunity to detect such symptoms. Adequate referral arrangements for diagnosis and care should, of course, be available and used.

In conclusion, for the prevention of rheumatic fever, prompt chemotherapy or antibiotic therapy of streptococcal infection, especially in siblings of known cases, is recommended. And, after onset, vigorous early case finding by physicians, continuing chemoprophylaxis or antibiotic prophylaxis of known cases, and attention to socio-environmental factors are recommended to reduce disability and death from this disease.

The effectiveness of ACTH and cortisone in rheumatic fever is now being studied. Prompt suppression of the clinical manifestations of the disease has been achieved. So great is the promise of this new form of therapy that the possibility of a fundamental change in our entire approach to the problem of rheumatic fever must be considered.

In a summary review of heart disease due to infectious agents, it is appropriate to emphasize these points. During recent decades there has been a sharp drop in this type of cardiovascular disease. Present knowledge if effectively applied should lead to a virtual disappearance within the next decade of heart disease resulting from diphtheria, syphilis, rheumatic fever, and other infective agents. In the United States, such an accomplishment would largely eliminate cardiovascular disease as a cause of death and disability in the first half of life.

**HYPERTENSIVE AND ARTERIOSCLEROTIC CARDIOVASCULAR DISEASE.** In general, it must be said that the etiology of hypertension is little understood, even though some mechanisms in the pathogenesis of hypertension have been discovered, e.g., the humoral mechanism associated with renal ischemia.

Three factors known to be associated with the hypertensive disease process offer the physician some possibility of dealing with the problem on preventive basis. These factors are: a definite familial tendency, the relationship of obesity to hypertension, and the personality pattern of hypertensive patients.

When hypertension has occurred in one or several members of a family, addi-

tional cases among siblings and children of patients may be anticipated. Whether this is due to hereditary factors or to patterns of living is not clear. In any event, the physician, especially if he serves the entire family, should be alert to early manifestations of the disease in all members of the family.

Obesity is highly correlated both with morbidity and mortality from hypertension. Reduction of weight in the obese-hypertensive patient has been shown to result in a lowering of blood pressure. It may reasonably be assumed that maintenance of optimum weight, especially where a familial tendency to hypertension is known, will assist in keeping the blood pressure at more normal levels. Achievement of this aim often requires personality adjustment, since overeating may be a manifestation of an emotional disorder.

The fact that psychic factors sharply affect the cardiovascular system, including the blood pressure, has been clearly demonstrated. Sharp but temporary increases in blood pressure occur with anxiety, fear, or anger. From this fact and the fact that the pressure is often labile during the early phases of hypertension, it has been hypothesized that long-continued psychic trauma to the cardiovascular system results eventually in sustained hypertension and its structural concomitants. Psychological studies of hypertensive patients suggest that personality disorders, characterized by suppressed hostility, are associated with the disease. The avoidance or correction of such personality defects through good mental health may prevent the development of hypertension. Interesting case studies have been published illustrating the apparent reversal of early hypertension through psychotherapy. However, much more work in this field must be carried out on large series of cases before the role of this factor in the prevention of hypertension can be evaluated.

As in the case of hypertension, our knowledge of the etiology of arteriosclerosis is quite meager. It has long been known that the intimal thickening in arteriosclerosis is due to deposits of fat, including cholesterol. Recent studies in this field offer convincing evidence that this condition is closely associated with specific disorders of metabolism. There is strong hope now that arteriosclerosis may be prevented or corrected when metabolic factors are better understood. This new optimism contrasts sharply with the old fatalistic view that arteriosclerosis represented an uncontrollable "degeneration" of aging.

The most promising of these recent studies are exploring the relationship between coronary artery disease and abnormal cholesterol metabolism, especially hypercholesterolemia. Patients with coronary thrombosis have, on the average, substantially higher blood cholesterol levels than persons without evidence of coronary disease. It has been demonstrated that lowering of blood cholesterol levels exerts a favorable effect on arteriosclerosis in animals. Numerous studies now in progress are designed to elucidate the relationship of cholesterol to the occurrence of arteriosclerotic disease in humans, and the possibility of preventing the disease through control of fat metabolism.

Whether hypercholesterolemia can be reduced through dietary control is still unsettled. It is known that the body synthesizes some cholesterol through ordinary processes of metabolism even though no foods high in cholesterol value are ingested. Some studies on apparently normal human populations have revealed no significant relationship between consumption of cholesterol and blood levels. Other studies,

especially of patients with coronary disease, have indicated that lower blood cholesterol levels may be attained on low cholesterol diets.

According to recent work (Boas and others, 1948), a hereditary disorder in the metabolism of cholesterol (resulting in hypercholesterolemia) is associated with coronary artery disease. Siblings of patients with coronary artery disease show a high incidence of hypercholesterolemia and of coronary artery disease, especially at the younger age levels.

Another recent finding is that coronary arteriosclerosis is associated with a particular fraction of the blood cholesterol (Gofman and others, 1950). This fraction may be amenable to dietary control through low cholesterol foods, but more investigation of this question is required before final judgment can be made.

In summary, recent data suggest the possibility of preventing arteriosclerotic cardiovascular disease through maintenance of low blood cholesterol levels. Low cholesterol diets may be important in this regard. Administration of substances which reduce cholesterolemia is another possibility, especially where coronary artery disease is impending or exists. These measures have been proposed particularly in the presence of obesity or familial history of arteriosclerotic disorder. Critical evaluation of these measures is needed.

**Prevention of Disability and Death.** Since our knowledge of how to prevent the occurrence of hypertensive and arteriosclerotic heart disease is still quite limited, cases of these diseases will continue to occur. However, even after their onset, prevention of disability and premature death is possible in many instances.

Early diagnosis of these conditions by the physician creates the best opportunity for minimizing their progress toward disability and death. Although these diseases are ordinarily first discovered in the physician's office, many cases can now be detected in mass screening programs. The 70 mm. chest x-ray film usually taken for the discovery of tuberculosis can also be interpreted for abnormal size or contour of the heart shadow. About 2 per cent of the general population over the age of 15 years screened in one chest x-ray survey showed suspicious cardiac findings. Intensive follow-up of these persons revealed that about one half of them (1 per cent of the total group screened) had previously unknown, clinically significant heart disease (Thompson and Jellen, 1948). In other surveys, the percentage with suspicious findings on the screening film has varied from 0.5 to 3.5 per cent.

Mass chest x-ray screening programs offer an excellent opportunity for finding heart disease. Up to the present such programs have been insufficiently utilized for the detection of heart disease.

Proper management of patients with hypertensive and arteriosclerotic heart disease will not only prolong their lives but make them happier and more productive. Several approaches should be used, including proper diet, reduction of excess weight, emotional re-education, and occupational adjustment. Recent successes with salt-restriction, anticoagulant therapy and drugs such as methonium, hydralazine and reserpine offer a considerably improved prognosis even to the patient with severe disease.

The place of emotional re-education in preventing disease and premature death from hypertensive and arteriosclerotic cardiovascular disease is not adequately defined. Certainly the personality pattern must be considered in correcting obesity. Excessive eating often reflects underlying emotional needs which should be met in

some other manner. The cultivation of serenity is especially important for persons with cardiovascular disease. Merely telling the patient "be calm" or "stop worrying" is of little avail. The patient must be assisted in developing insight into his emotional problems if any effect is to be expected. A noteworthy point in psychologically supportive therapy is that not all patients with hypertension or with definite arteriosclerotic disease die quickly under ordinary conditions of stress. Some live many years of practically normal life with apparently no further manifestation of disease, a fact insufficiently stressed in the education of the patient. Further evaluation of the role of psychotherapy in cardiovascular disease is needed.

A frequently important aspect of prolonging useful life of patients with cardiovascular disease is occupational adjustment (Goldwater, 1947). Balance must be maintained between unnecessarily condemning the individual to invalidism on the one hand and ignoring the need to lighten his labor on the other. The ideal solution is selective job placement, consistent with the physical capacity of the patient. The problem of adequate job placement for persons with cardiovascular disease is complicated by employment policies which preclude the hiring of handicapped persons and discourage the retention of such persons in employment. Restrictive employment policies were adopted originally on the theory that the quality and output of work by physically handicapped persons is inferior to that of nonhandicapped persons. Although mounting evidence indicates this theory to be untenable, restrictive employment policies persist because of other considerations. Workmen's compensation rulings, conditions in employer liability insurance, and plans for disability retirement in industry militate against the employment of persons with cardiovascular disease. Here is another illustration of the effect of social conditions on the management of disease. The physician in caring for the patient with cardiovascular disease must extend his interest beyond the patient and his individual pathology.

Maintenance of optimum weight, emotional adjustment, and suitable job placement are important in the reduction of disability and premature death from hypertensive and arteriosclerotic heart disease.

## CANCER

Cancer may be defined as a group of diseases characterized by an abnormal growth of cells which spread through the tissues of the body. It is synonymous with the terms malignant neoplasm. Its properties of invasiveness and metastasis differentiate cancer from benign neoplasms which do not have such properties. However the dividing line between malignant and benign neoplasms is not sharp.

Malignant neoplasms may originate in practically any tissue or site of the body. A variety of cellular types is involved, including epithelial cells (carcinoma), connective tissue cells (sarcoma), and blood cells (leukemia). Ultimately, it may be demonstrated that these are different diseases.

**Mortality.** Cancer is now second among the leading causes of death in the United States, accounting for approximately 200,000 deaths (one eighth of all deaths) each year. The number of cancer deaths and the corresponding crude death rate have been increasing sharply in recent years, as indicated in Table 19-8. The crude death rate has just about doubled in the period 1900 to 1950.

Examination of the rates for the two sexes reveals a striking difference in trend.

Table 19-8. Cancer—deaths, crude death rates, proportionate mortality and age-adjusted death rates by sex, United States Death Registration States, 1900-1950 <sup>1</sup>

Year	Deaths	Crude Death Rate per 100,000	Proportionate Mortality (Percentage of All Causes of Death)	Age-Adjusted Death Rate per 100,000 <sup>2</sup>		
				Total	Male	Female
1950	193,977 <sup>3</sup>	128.7	13.4	115.0	117.1	113.2
1940	158,335	120.0	11.2	119.6	114.8	124.9
1930	114,186	97.4	8.6	113.4	101.6	126.2
1920	71,756	83.4	6.4	104.9	88.8	122.5
1910	36,193	76.2	5.2	97.0	77.3	118.2
1900	12,769	64.0	3.7	79.6	60.1	99.2

<sup>1</sup> The Death Registration Area did not include all states until 1933. Therefore, data for previous years do not represent mortality for total United States.

<sup>2</sup> Adjusted on the basis of the age distribution of the population enumerated as of April 1, 1940.

<sup>3</sup> Leukemias and cancers of lymphatic and hematopoietic tissues (International List Numbers 200-205) are excluded from 1950 deaths and death rates to make the rates comparable with earlier years. The Sixth Revision of International List of Causes of Death, 1948, made these diseases a part of the neoplasm classification for the first time.

Source: Public Health Service, *Vital Statistics of the United States, 1950*, Table 8:43, p. 210. Federal Security Agency, *Cancer Mortality in the United States*, "Trend of Cancer Mortality in the United States, 1900-1945," Vol. 32, No. 1, December 28, 1949, Tables 1, 2, 3, pp. 11, 12, 13.

The age-adjusted cancer mortality rate for females in the United States reached a peak about 1930 and since that time has been steadily dropping. The rate for males, on the other hand, continued to climb at least until the 1940's.

**Factors in Mortality Trends.** Two major factors must be considered in interpreting the rapid increase in the total number of cancer deaths. One is the aging of the population, for which accurate correction can be made in the rates. However, even when correction is made for age, there remains a substantial increase—more than 50 per cent during the same period—not attributable to changes in the age composition of the population. The other element is the improvement in diagnostic standards, a factor which does not lend itself to precise measurement. However, because our ability to diagnose cancer has improved considerably during recent decades, it is reasonable to assume that some part of the rise in age-adjusted cancer death rates is due to this factor.

The decline in cancer mortality among females (Table 19-8) may be attributed in part to earlier diagnosis and more effective treatment of cancer of the accessible sites, which comprise a substantial proportion of cancer in women. This decline represents a significant sign of progress in cancer control.

Among males, part of the steady rise in cancer mortality is due to the rapid increase in cancer of the respiratory tract during recent years, especially cancer of the lung. Although it is true that some of this increase is due to improved methods of diagnosis, autopsy records of several leading hospitals reveal that the proportion of lung cancer diagnoses to all diagnoses has risen sharply in recent years. This finding suggests that there has been an absolute increase in cancer of the lung. Figure 19-2 shows trends of mortality from pulmonary cancer and pulmonary tuberculosis in males in the United States. It is evident that there has been a crossing of the curves; more persons in this country now die from respiratory cancer than from respiratory tuberculosis.

Deaths from cancer of the skin, lip, and buccal cavity—all accessible sites, and more common as sites of cancer among males—have been decreasing in recent years. Earlier recognition and more adequate treatment of cancer of these accessible sites are responsible in some degree for this downward trend. Improved oral hygiene, such as elimination of jagged teeth through better dental care, may also have played a role.

\* 10 per cent sample.

**Morbidity.** Data on the prevalence of cancer in the United States are limited. Dorn and Cutler (1955) on the basis of surveys during 1948-1949 in 9 metropolitan areas in various parts of the country, found a prevalence rate of 430 per 100,000. From the same study it was estimated that 319 new cases per 100,000 persons are diagnosed for the first time during each year (incidence rate).

Distribution of cancer by site is indicated in Table 19-9. Cancer of the digestive tract accounts for about one third of all cancer among males, but less than one fourth among females. Cancer of the respiratory tract, urinary system and buccal cavity is much more prevalent among males than females. Almost one half of all cancer in females develops in the breast or genital system, sites which in most instances are accessible to early recognition—a fact of particular significance in cancer control.

**Distribution in Population Groups.** Significant age, sex, geographic, race, and socio-environmental differences in cancer mortality have been noted.

In general, cancer prevalence increases with age. Cancer of the prostate occurs most commonly in men past the age of 65 years. The prevalence of cancer of the breast rises sharply during the late middle years of life and continues to rise in the later years of life. However, cancer of the brain is much more likely to develop in

Table 19-9. Primary site of development of cancer among white males and females <sup>1</sup>

Primary Site <sup>2</sup>	Male	Female
Trachea, bronchus and lung	9	2
Urinary system	7	3
Buccal cavity	5	2
Skin	15	11
Digestive Tract	32	23
Breast and genital system	12	45
All other sites	20	14
Total	100	100

the early years of life, and cancer of the bone and leukemia are found in infants and children.

For sites common to both sexes, there is more cancer among males than among females. Cancer of the stomach causes almost twice as many deaths among men as it does among women. In cancer of the lung, the ratio of male to female deaths is four to one. These differences may reflect varying degrees of exposure to carcinogenic agents rather than biological sex differences. The fact that deaths due to cancer of the esophagus and stomach are more common among persons of low economic status (see Table 19-3) also suggests some extrinsic (socio-environmental) factor.

In the southern part of the United States cancer of the skin occurs much more commonly than it does in the northern states. This difference has been attributed to heavier solar radiation in the south. Solar radiation, in the 2,900 to 3,200 Å range, is an experimentally demonstrated carcinogen (Blum, 1940).

Negroes in the United States have far less cancer of the skin but considerably more cancer of the uterine cervix than do Caucasians. The difference in skin cancer probably reflects biological variation in amount of skin pigment. Among Caucasians themselves, those with darker skin show less skin cancer than fair-skinned persons.

In the case of cervical cancer, however, all available evidence indicates that extrinsic factors, rather than biological variations, are responsible for the "racial" differences. Cervical cancer is known to occur more frequently among women who have experienced several pregnancies than among those who have had none. It also appears that pregnancy early in life may predispose to the development of cervical cancer. Many studies show a higher mortality from cervical cancer among persons of lower economic status than among the higher income groups. To such factors—multiple pregnancies especially early in life and low income status—we can probably attribute the higher incidence of cervical cancer among Negroes than among whites.

Apparent "racial" and "geographic" differences in the occurrence of cancer deserve careful scrutiny. They may conceal underlying socio-environmental variations among groups of people, including differences in the amount and quality of medical care.

Socio-environmental factors in the development of cancer have only recently

begun to receive the attention they merit. According to British statistics cancer of the esophagus and stomach causes twice as many deaths among persons in the lowest economic group as among the highest. Skin cancer is highly correlated not only with certain occupations but also with social status and exposure to soot and grime. Similarly, in cervical cancer as noted above, environmental conditions may be responsible factors.

A relatively new approach—the epidemiologic investigation of cancer, with emphasis on social causation—offers much promise of providing information useful in the prevention of cancer. It may lead to isolation of more specific etiologic agents.

**Etiology.** In spite of the vastly increased research into the nature of cancer during the recent years, our understanding of the specific etiology of cancer is advancing slowly. This is perhaps due to the fact that cancer is not a single clear-cut disease entity. Rather, it appears to be a group of diseases characterized by abnormal cellular growth. Hence, research is necessary both into the cell (and its various types) and into the factors that precipitate the cellular abnormality.

Three general categories of etiologic factors have received the greatest attention—genetic, endogenous, and exogenous. Although individual studies are usually designed to isolate one or another specific factor in these groups, the possibility that they are interrelated must be constantly kept in mind.

The genetic theory received its greatest support from the fact that strains of small animals have been developed with proneness to cancer of certain sites. In one strain cancer occurs in a very high proportion of offspring. Another strain of the same species, apparently living under the same conditions, shows cancer only occasionally. The genetic theory has been challenged recently by the discovery that excessive incidence of breast cancer in a certain strain of mice was due to an ultra-microscopic factor transmitted through the milk. Formerly this strain was considered one of the classical demonstrations of the operation of some chromosomal mechanism. However, Bittner demonstrated that “cancer prone” mice, when foster-nursed by mothers of a low cancer-incidence-strain, did not develop the disease. On the other hand mice from so-called noncancer strains, when suckled at the breasts of mothers from a cancer strain, did show a high incidence of breast cancer. The development of cancer was apparently due to some ingested factor.

Endogenous changes, i.e., alterations in physiology, have also been suggested as factors in the development of cancer. It has recently been demonstrated that administration of female sex hormones to men with cancer of the prostate results in substantial improvement and prolongation of life—though not cure. Likewise, male sex hormones given to women with breast cancer often produce significant but temporary improvement. Comparable results are obtained through castration. From such evidence, it appears that hormonal balances are concerned in perpetuation and extension of these two types of cancer. Possibly, changes in secretion of the sex glands during middle and later life are responsible for the original neoplasm itself. It is conceivable that other endocrine glands play some role.

That exogenous factors directly cause some cancers has been known for many years. For example, cancer of the scrotum among chimney sweeps—noted in England during the days of the Industrial Revolution—was caused by long-continued exposure to soot. Protection against such exposure prevented cancers in this occupational group.

Since that time a great variety of agents have been demonstrated to be carcinogenic. Several types of carcinogenic agents are listed below:

1. Mechanical (cancer of the buccal cavity and lip due to jagged teeth and pipe stems).
2. Chemical (cancer of the bladder due to certain aniline dyes; leukemia due to benzol poisoning; cancer of the lung due to chromate ores).
3. Thermal (cancer originating on the site of old burns).
4. Radiation:
  - A. Solar (cancer arising on the exposed parts of the skin among outdoor workers).
  - B. X-radiation (cancer of the lung among Schneeberg miners due to contact with radioactive ores; cancer in x-ray burns; and leukemias among radiologists).
5. Parasitic (cancer of the bladder due to infection with *Schistosoma hematobium*).

A tremendous variety of agents, therefore, possess the property of stimulating malignant growths. However, the total proportion of cancer cases which have been clearly demonstrated as due to specific carcinogens, is not great. One difficulty in establishing such a relationship is that it is often concealed by a long latent period, even 10 to 30 years. Occupational and other exposures at the time the cancer is diagnosed may be irrelevant. It is not customary in the United States to obtain and record carefully socio-environmental information in connection with morbidity and mortality. Detailed epidemiological studies of cancer patients, with particular attention to their exposures throughout life, would be likely to yield valuable information. The discovery of carcinogenic agents and other factors associated with cancer incidence, prepares the way for prevention of at least certain types of cancer.

**Prevention of Occurrence.** When specific carcinogens have been identified (as in certain occupations) every effort should be made to eliminate the exposure or at least to reduce such exposure to the minimum. In industry, this requires knowledge of toxic materials; design of machinery and organization of processes so as to prevent access of the carcinogen to workers; good housekeeping; and adequate disposal of carcinogenic wastes. During periods of rapid expansion of chemical industries, as in wartime, insufficient attention is given to such problems.

Education for individual responsibility in avoiding exposure to known carcinogenic agents is also of considerable importance. Numerous illustrations of this type of cancer prevention could be cited; self-protection of radiologists against leukemia and skin cancer; avoidance of excessive exposure to solar radiation, especially by fair-skinned persons who are more likely to develop cancer of the skin; improvement of oral hygiene, including attention to jagged teeth and to other forms of chronic irritation.

The discovery and treatment of precancerous lesions constitute a second important realm of cancer prevention. Keratoses of the skin; warts subject to chronic irritation, e.g., plantar warts; solitary thyroid adenomata; fibroadenomata of the breast in young women; chronic cervicitis; leukoplakia; and chronic gastritis (pernicious anemia type) are examples of lesions and chronic processes known to be associated with subsequent cancer development. Physicians may prevent a substantial amount of cancer mortality by noting such lesions, explaining their potential

significance to the patient, and taking whatever corrective action is indicated. Individuals known to have exposure to carcinogens, such as workers in certain industrial operations, should have periodic examinations for the purpose of discovering any precancerous changes. In the case of the aniline dye industry, for example, cystoscopic examinations at six-month intervals have been used to reveal alterations in the bladder mucosa. If abnormalities are found removal from further exposure and continued observations are ordered so as to minimize the danger of cancer morbidity and mortality.

Improvement of general standards of living and health may be expected to reduce the incidence of cancer of some sites. A relationship has been noted between cancer of the skin and occupation; cancer of the cervix and low economic status; cancer of the buccal cavity and poor dental care; and cancer of the stomach and low economic status. Better working conditions and more adequate medical and dental care would contribute to the reduction of cancer.

The occurrence of cancer may, therefore, be prevented through: (1) identification and avoidance of carcinogenic agents; (2) systematic discovery and treatment of precancerous lesions; and (3) improvement of the general standards of living.

**Prevention of Disability and Deaths.** Since our knowledge of how to prevent the occurrence of cancer is so incomplete, major efforts in cancer control must continue to focus on early diagnosis and adequate treatment of the case. After the onset of cancer, a substantial number of patients' lives are being saved and more could be saved.

Approximately one fourth of all patients admitted to hospitals in the United States for the diagnosis and treatment of cancer are being "cured," i.e., they survive at least five years following treatment, without evidence of recurrence. It is recognized that even after the five-year mark has been passed some patients develop recurrences of the original disease. Such instances are frequent enough to justify indefinitely continued follow-up examinations.

A wide range of rates of cure have been published. These rates vary depending on the types of treatment used, the nature of the cases comprising the series, and other factors. The over-all approximate figure of 25 per cent survival from cancer, given above, is based upon the recent experience of several states which have maintained a follow-up of patients treated in a variety of types of hospitals.

The over-all cancer survival rate masks wide differences in survival rates for cancer of different sites and different stages. Table 19-10 shows the extent of this variation among four sites, in California experience.

Table 19-10. Cancer--five-year survival rates by site, according to stage at first admission, 1942-1946

STAGE	NUMBER IN EACH GROUP					PER CENT 5-YEAR SURVIVAL				
	Total	Prostate	Lung	Ovary	Breast	Total	Prostate	Lung	Ovary	Breast
Localized	1,139	25	6	17	153	51	36	0	52	73
Regional	2,553	120	110	57	426	18	18	0	25	31
Metastasis	3,541	236	290	162	377	8	8	0	1	25
Unknown	6,186	482	272	100	305	28	26	7	45	50
Total	13,419	863	678	336	1,261	23	20	3	21	39

Source: State of California Department of Public Health, Tumor Registry

Since the time when the patients represented in these survival percentages were actually treated, considerable progress has been made in diagnosis, and in radiation and surgical technics. It is likely, therefore, that survival of cancer patients is steadily improving. For example (Symposium, 1948), among patients treated for cancer of the breast in 1938 at Memorial Hospital in New York City, 28.8 per cent survived five years. Of those admitted during 1942, the corresponding survival percentage was 39.8. A report (Symposium, 1948) from Washington University School of Medicine, St. Louis, reveals that since the first pneumonectomy for lung cancer was performed in 1933, this type of surgery has been performed on 311 patients. Of these, 52 were operated on before 1942 with a five-year survival rate of 28 per cent. In the early days of this surgical procedure for lung cancer, operative mortality was 53 per cent. It has subsequently been reduced to 7 per cent. Thus, in less than 20 years, a formerly hopeless disease is now being treated successfully in a significant percentage of cases.

So rapid have been the advances in cancer diagnosis and treatment that—according to most authorities—an estimated one third of the present deaths from cancer could be avoided through application of present knowledge. In the United States this would mean saving approximately 70,000 lives annually. Accomplishment of this goal depends primarily upon two factors: (1) early detection and diagnosis; (2) prompt and adequate treatment.

In the promotion of early diagnosis and treatment of cancer public education is a most important element. A recent nation-wide survey (University of Michigan, 1948) showed that although 80 per cent of the population considered cancer one of the most dangerous diseases, only 60 per cent knew that it was curable and only 49 per cent could name a single symptom of cancer. Acquaintance of the public with the common symptoms of cancer should be encouraged. This can be accomplished by individual education of patients by physicians as well as by public campaigns. Even after suspecting the presence of cancer, some persons delay seeking medical attention because they fear having their suspicion confirmed, or because they do not know or believe that cancer is curable in the early stages. Both recognition by the patient and motivation are therefore needed.

Besides public education several other specific methods have been suggested and tried for the early detection of cancer. These include: various forms of periodic examinations by physicians, and mass screening tests carried out by technicians.

A complete physical examination including a careful history every year or even every six months has been advocated as one means of detecting cancer. Special examinations can be carried out in physicians' offices or in cancer detection centers where apparently well people report periodically for check-ups. These examinations have two well-recognized values: (1) the discovery of cancer in from 0.2 to 1.0 per cent of the population examined, depending upon the nature of the population and the completeness of the investigation; and (2) the discovery of a significant amount of other disease which had not been recognized previously. (From some detection centers as many as 50 per cent of the persons examined have been referred to physicians for necessary attention for a variety of conditions.)

Detection centers have served one other important purpose, i.e., to stimulate public and professional interest in the idea of periodic examinations. The popularity of detection centers is attested by the fact that applicants have had to wait weeks

or months for appointments at many of the centers. The popularity of these centers probably reflects, to some extent, the difficulties experienced by people in finding physicians who will do comparable examinations in their own offices. Recognition of this situation by the medical profession has led to the recent proposal to "make every doctor's office a cancer detection center."

The fact that complete examinations are quite expensive in terms of physician time and laboratory services has led to certain modifications. One is to limit the investigations to a few accessible sites such as the skin, buccal cavity, breast, cervix, and rectum. A check of these areas can be performed rapidly and—it will be recalled—these sites account for more than one half of all female cancer and a substantial amount of male cancer. These sites are also the ones most amenable to cure in the present state of our knowledge.

Another approach to the problem of early cancer detection has been the application of cytology and radiography in mass screening programs.

Since many cancers originate in epithelial tissues (carcinoma) they begin at an early stage to exfoliate cells with the morphologic characteristics of malignancy. If recovered, such cells may constitute the earliest manifestation of cancer. They are present in many cases before any detectable lesion appears. The technic of recovering, staining, and examining such cells is known as the cytologic test for cancer.

This test was developed and has been applied most extensively for cancer of the cervix. Many reports indicate a discovery rate of two to four cervical cancers per 1,000 apparently well women screened with the cytologic test. It should be emphasized that these were women with no signs or symptoms of cancer. Often the final diagnosis was carcinoma in situ, i.e., cancer confined to the normal boundaries of the tissue in which it originated.

The cytologic technic is also used in the detection and diagnosis of pulmonary cancer. For this site, sputum specimens have been found to be approximately as reliable as bronchial washings (Farber and others, 1950)—an important factor in the use of the test on a mass scale for detection of pulmonary cancer. Its use is advocated in all pulmonary disease not obviously due to some other cause. Some institutions use the test routinely in tuberculosis wards. It would also appear useful in follow-up of persons screened by mass chest x-ray surveys and found to have suspected pulmonary disease. Attention is again drawn to the fact that in the recent years mortality from lung cancer has increased to the point that it now exceeds mortality from pulmonary tuberculosis in the United States.

Application of the cytologic test of cancer to gastric, prostatic, and other specimens is now being studied.

The miniature films taken in mass x-ray surveys may disclose pulmonary cancer as well as tuberculosis and heart disease. Intensive follow-up of neoplasm suspects from such surveys, including adequate arrangements for diagnosis and treatment would result in the saving of a considerable number of lives. Increasing attention is being given to this aspect of mass x-ray surveys.

Mass application of radiographic techniques for the discovery of cancer of the upper gastro-intestinal tract is now being evaluated. One proposal has been to carry out a preliminary screening of older age males by determining the presence of achlorhydria, occult blood in the stool, or pernicious anemia. Those who show positive findings are given radiographic examinations. Work is also in progress in

the development of a technic suitable for mass use for making quick but permanent records of the radiographic appearance of certain parts of the gastro-intestinal tract.

In the fight against needless deaths from cancer, many forces are now being joined. Patients are seeking medical attention earlier in the course of this disease. Growing numbers of persons are availing themselves of health examinations in physicians' offices and cancer detection centers. Physicians have become increasingly alert to the early signs of cancer and great progress is being made in diagnosis and treatment. To assist in the early detection of cancer, physicians, voluntary and official health agencies, and other groups are cooperating in programs of public and professional education and in the development of mass screening services, incorporating such procedures as photofluorography and cytology. Research workers, although concentrating on the etiology of malignant growths and on ways to prevent the occurrence of cancer, are also deeply concerned with prevention of disability and death following the occurrence of cancer. Extensive research is under way to find new diagnostic and therapeutic technics, e.g., serologic tests for the diagnosis of cancer and the use of radioactive substances in diagnosis and therapy.

The forces arrayed against needless deaths from cancer share this common motivation—existing knowledge and technics can save the lives of tens of thousands of cancer patients each year.

## DIABETES

Diabetes is a constitutional, hereditary, metabolic disease characterized by high blood sugar levels and excretion of sugar in the urine. It is associated with a relative insulin insufficiency. It is not clear whether this insufficiency is due to deficient production or diminished effectiveness of the hormone secreted by the islands of Langerhans in the pancreas. Insulin insufficiency is closely related to abnormal activity of other glands of internal secretion, especially the pituitary.

Diabetes is important not only for its acute derangements of body chemistry which may lead to fatal acidosis and coma, but also, because it predisposes to the development of arteriosclerosis, neuritis, and cataract.

**Mortality.** The number of deaths attributed to diabetes has risen sharply since 1900, as has the crude mortality rate (Table 19-11). During the period 1900 to 1950, the proportion of all deaths charged to diabetes increased severalfold, and the disease advanced to appear among the 10 leading causes of death. For 1950, the mortality rate from diabetes was 16.2 per 100,000, according to the revised method of coding causes of death. However, the rates are much higher among older age persons (Iskrant and Kurlander, 1955)—over 100 per 100,000 for persons 65 years of age and older, 25 per 100,000 for those in 45-64 year age group, and less than 1 per 100,000 among children. Females are affected more frequently than males.

One may wonder why the discovery of insulin in 1921 and its widespread use has not resulted in a reduction in diabetes mortality. Insulin does not cure diabetes; it merely helps to control the disease. When the patient ultimately dies from some other cause, diabetes is usually still present and is listed on the death certificate, even though it may be well controlled. Until 1949, the statistical allocation of causes of death was based on arbitrary coding rules. One effect of such rules was that if diabetes was mentioned on the death certificate, it took a high priority for assignment

Table 19-11. Diabetes—deaths, crude death rates, proportionate mortality, and age-adjusted death rates, United States Death Registration States, 1900-1950<sup>1</sup>

Year	Deaths	Crude Death Rate per 100,000	Proportionate Mortality (Percentage of All Causes of Death)	Age-Adjusted Death Rate per 100,000 <sup>2</sup>
1950 <sup>3</sup>	24,419	16.2	1.7	14.3
1950 <sup>4</sup>	(42,102)	(27.9)	(2.9)	(24.7)
1940	35,015	26.6	2.5	26.6
1930	22,345	19.1	1.7	22.2
1920	13,898	16.1	1.2	19.8
1910	7,252	15.3	1.0	18.9
1900	2,187	11.0	0.6	13.0

<sup>1</sup> The Death Registration Area did not include all states until 1933. Therefore, data for previous years do not represent mortality for total United States.

<sup>2</sup> Adjusted on the basis of the age distribution of the United States population, 1940.

<sup>3</sup> Actual number of deaths as coded by Sixth Revision, International List of Causes of Death, 1948. This revision in coding changed the death rate markedly and requires an adjustment before comparing with earlier years.

<sup>4</sup> Estimated number of deaths and death rates in 1950 if coded by the Fifth Revision of the International List. See Vital Statistics of the United States, 1950, Vol. I, p. 182.

Source: Public Health Service, Vital Statistics of the United States, 1950, Vol. I, Table 8:43, p. 212; Bureau of Census, *Vital Statistics—Special Reports*, Vol. 23, June 26, 1945, p. 26; Vol. 16, August 4, 1942, p. 65; *Ibid.*, *Vital Statistics Rates in the United States*, 1900-1942, p. 872.

as the primary cause of death. Thus, many persons who died with diabetes had their deaths attributed to diabetes, although the actual cause of death may have been quite unrelated to it.

In 1949, a new method of coding death certificates was adopted in the United States. According to this new method, the death is charged to whatever disease the physician indicates is the primary cause. Diabetes is thus not arbitrarily selected. It appears that there will be an almost 50 per cent drop in the diabetes mortality rate due to the change in method of coding death certificates. The new method will reflect the true cause of death more accurately. However, its adoption means that caution must be exercised in comparing current figures on diabetes mortality with those of previous years.

Because of these difficulties, diabetes mortality statistics are not as significant as similar statistics for cancer and for cardiovascular-renal disease.

Another and more meaningful view of the trend of death from diabetes may be obtained by comparing the expectation of life for known diabetics who were under care at different periods during the past 50 years. Figure 19-3, based upon data from the George F. Baker Clinic for Diabetics in Boston, Massachusetts, reveal that a diabetic 10 years of age in the period 1897-1914 had a life expectancy of only 1.3 years; in 1939-1945 a 10-year-old diabetic had a life expectancy of 4 years. This phenomenal improvement in the outlook for a child with diabetes may be attributed largely to the use of insulin. Even at the age of 50 years, there has been a doubling of life expectancy during the past half century. In fact, such excellent means have been developed for controlling diabetes that the expectation of life for persons with the disease is rapidly approximating that for the general population.

**Morbidity.** Field studies of the prevalence of diabetes during the past few years have radically changed our concept of the amount of diabetes in the American popu-

From Joslin, Elliot P., and others, *Postgrad. Med.*, 5:2:139, 149.

Fig. 19-3. Expectation of life in years for diabetics,\* and for white persons in the general population. Selected ages and periods.

\* Seen at the George F. Baker Clinic, Boston.

lation. As recently as 1946, Marks estimated on the basis of extensive studies that there were 700,000 diabetics in the United States, with 55,000 new cases occurring each year (Marks, 1947). A year later (1947), a survey was made in Oxford, Massachusetts, by the U. S. Public Health Service (Wilkerson and Krall, 1947). This survey, which included blood sugar and urine sugar tests for 70.6 per cent of the entire population of Oxford (4,983 persons), disclosed 70 cases of diabetes. Of these, 40 were previously known cases and 30 were previously unknown, i.e., were discovered in the survey. If the percentage of cases discovered in the surveyed population is projected to the entire population, the resulting prevalence rate would be 1.7 per cent. Assuming that this rate is applicable to the country as a whole, it can be estimated that more than two million persons in the United States have diabetes, and about one million of them are unaware of the disease.

**Factors in Occurrence.** That there is an hereditary susceptibility to diabetes has been known for many centuries. The incidence of diabetes is several times higher among the parents and siblings of diabetics than among the parents and siblings of nondiabetics. In part, this higher incidence may be attributed to familial patterns of living, such as excessive eating. However, from studies of twins convincing evidence is available as to the hereditary factor in the disease. For homozygous (identical) twins, where one of the pair has diabetes the incidence of diabetes among the paired siblings ranges from 49 to 100 per cent, depending upon the age of the subjects at the time of the study (White and Pincus, 1946). This may be compared with an incidence, among heterozygous (fraternal) twins of diabetics and among nontwin siblings, of 5 to 10 per cent.

While heredity determines susceptibility to diabetes, the actual occurrence of the disease among adults is correlated with obesity. According to Joslin more than one half of the diabetics in his series at some time during their life were 20 per cent or more above average weight. Table 19-2 in the introduction to this chapter indicates the excessive mortality from diabetes which is associated with obesity. Obesity

may be the basis for the higher incidence of diabetes among upper income groups. Conversely, the lower incidence among persons engaged in heavy manual labor may be associated with relative undernutrition.

**Experimental Diabetes.** Animal experimentation has not only yielded an effective treatment for diabetes but may yet lead to methods of prevention. Diabetes has been produced in animals by several techniques, including injection of alloxan; pancreatectomy; prolonged administration of glucose-in-saline solution intraperitoneally; and partial pancreatectomy plus injection of anterior pituitary extract. Diabetes produced in cats by the latter method can be cured if treated with insulin during the first three months after onset of the disease (Lukens and Dohan, 1942). Functional recovery of animals is maintained after insulin therapy is discontinued. These experiments are consistent with the theories that diabetes may result from overtaxing the insulin-producing mechanism and that it may under certain conditions be reversible. The restoration of function to the islands of Langerhans in animals apparently depends upon the initiation of treatment early in the course of the disease.

**Prevention of Occurrence.** Since heredity is involved in the development of diabetes, consideration must be given to the possibility of preventing it through the restriction of marriage among diabetics. The marriage of known diabetics to one another should be avoided since the disease would probably appear in their offspring (Joslin and others, 1946). Marriage of diabetics into families where diabetes is common may result in a high proportion of offspring with diabetes. However, the marriage of a diabetic to a nondiabetic whose family is free of the disease apparently does not predispose to diabetes in their children. Among diabetics, birth control as well as restriction of marriage should be considered for the prevention of diabetes in children.

The achievement and maintenance of optimum weight is a significant factor in preventing diabetes. Dietary control is especially important in families where diabetes is common. Frequently, glycosuria and hyperglycemia are reduced and even eliminated when there is a significant reduction of weight in obese middle-aged persons. In one study (Paul, 1941), 127 obese females over the age of 45 years with slightly to strongly positive sugar tolerance tests were advised to stay on reduction diets. Among 10 patients who did not reduce their weight, five subsequently showed signs that the disease process had progressed, i.e., two "potential" diabetics became true diabetics, and in three diabetics the disease became severe enough to require insulin. Among the 117 patients who did succeed in lowering their weight, 94 per cent showed improvement in sugar tolerance.

For the prevention of diabetes, especially if the disease is present in the family the following measures are recommended: (1) avoid obesity; (2) if already overweight, reduce weight to optimum; (3) have periodic examinations for the presence of urine sugar and high blood sugar levels; (4) avoid intermarriage of diabetics.

**Prevention of Disability and Death.** The considerable extension of life expectancy for diabetics in recent years has been due largely to better patient management including the use of insulin. The earlier treatment is started, the more likely it is to be effective.

The detection of diabetes in its earliest stages—before the onset of typical symptoms which often reflect advanced disease—and continuing good care are basic elements in the prevention of disability and death from diabetes. The preventive

significance of early detection of diabetes is twofold. Discovery of the disease in its presymptomatic state, if followed by adequate treatment, minimizes the danger of complications such as coma and infection. In addition, from laboratory and clinical evidence it appears that early therapy reduces the progress of the disease process itself and may even reverse the pathologic changes. Diabetics with no or minimal complications at the time of diagnosis have a death rate less than one-third that of patients with serious complications at the time of diagnosis (Metropolitan Life Ins. Co., 1949). Another indication of the fact that good care saves diabetics is the fact that physicians with diabetes show a lower mortality than nonphysicians with the disease, especially in the younger age groups.

Since the disease occurs more commonly in families where one member is known to have it, emphasis in case finding should be placed on detecting the disease in parents, siblings and the children of known cases. Periodic examinations of members of families where diabetes exists constitute an important element in the control of the disease.

Until 1947, the principal method for the early discovery of diabetes was urinalysis. Reliance was placed on this technic because it was believed that substantially all early diabetics showed glycosuria. Also, the Folin-Wu method of blood sugar determination, requiring venous blood, was too cumbersome and expensive.

Wilkerson, Heftmann, and their associates in the U. S. Public Health Service have developed and popularized a new method of detecting diabetes. It is based upon use of 0.1 ml. capillary blood from the finger tip or ear lobe for a simple inexpensive blood sugar test. The specimen is collected within two hours after a meal containing at least 50 grams of carbohydrate. The test can be completed within five minutes. It reveals only whether the blood sugar is above or below a certain level. Community-wide surveys utilizing this test and urinalysis have demonstrated the feasibility of the blood sugar screening method. They have also shown that about one out of three diabetics escape detection if dependence is placed upon a single urine specimen. Both blood and urine sugar tests should be used for maximum results.

Screening examinations, using blood and urine sugar tests, may be carried out on a routine basis in physicians' offices, hospitals, and in community-wide surveys. Concentration on members of diabetic families will yield the greatest return per 1,000 persons examined. However, application of this procedure to large population groups is required if a substantial proportion of the million undiscovered diabetics in the United States today are to be found.

Once diabetes is diagnosed, it becomes important that a close and friendly relationship between the patient and his physician be maintained. Diet, and the use of insulin if necessary, must be regulated. Special emphasis must be placed upon the avoidance of infections which may precipitate a crisis in the disease. Good hygiene of the feet, including cleanliness and avoidance of pressure, is important because of the vascular changes which so frequently occur. Since the giving of detailed instructions in hygiene and diet for diabetics is so time consuming, efforts have been made to organize such teaching in group classes. In one community such classes have achieved considerable success (Wilkerson, 1949).

As in the case of other diseases, a successful attack on diabetes will require the wholehearted cooperation of the public, medical and allied professions, voluntary health agencies, such as the American Diabetes Association, and health depart-

ments. The focal point of this attack should be the discovery of diabetes in its early stages. Treatment is now often delayed until symptoms of advanced disease have appeared. Intensive management of diabetes from its incipency not only reduces disability but also offers hope for restoration of pancreatic island function.

### NEUROMUSCULAR DISABILITY

Neuromuscular disability is a general term embracing a wide variety of conditions which limit the voluntary muscular capacities. Some of these defects are congenital, e.g., cerebral palsy. Others are residual effects of neutropic virus infections such as poliomyelitis. Trauma accounts for a large group including amputees and paraplegics. Probably the largest number result from diseases of obscure etiology such as rheumatism, multiple sclerosis, and epilepsy. Among older age persons a common disability is hemiplegia arising from intracranial lesions of vascular origin.

**Mortality and Morbidity.** Although the primary condition—such as virus infection or cerebral vascular lesion—may result in death, the neuromuscular conditions themselves are not significant causes of mortality. Rheumatism, for example, is rarely mentioned on the death certificate as a contributing cause of death.

However, these diseases account for a large amount of disability. Rheumatism alone, according to the National Health Survey (1935-1936) in the United States, affected almost 7,000,000 persons and caused approximately 100,000,000 days lost from usual employment; it is by far the most prevalent pathological condition. Other diseases in the neuromuscular group, while not as common as rheumatism, often result in long-term disability and even permanent invalidism when they occur. Any period of life may be affected: infancy (cerebral palsy); childhood (poliomyelitis); young adult life (multiple sclerosis and rheumatoid arthritis); and old age (cerebral vascular lesions).

Neuromuscular disability is an important cause of economic as well as physical dependency. It often requires long-term medical and institutional care so that the personal and family resources are exhausted. A substantial proportion of persons receiving governmental financial assistance in the United States, especially during periods of favorable economic circumstances, consists of families where one or more members suffer from a neuromuscular handicap.

**Prevention of Occurrence.** Aside from accident prevention and vaccination for poliomyelitis, knowledge of specific measures for the prevention of occurrence of the diseases and conditions which cause neuromuscular disabilities is quite limited.

**Prevention of Disability.** During the past decade there has begun an important shift in public and professional attitudes toward treatment of this handicapped group. Previously, they were among the most neglected of health problems. Three influences have contributed to the development of more aggressive and optimistic viewpoints. The first was the pressure for manpower during the war years which led to the large-scale introduction of handicapped persons into industry. Although they had heretofore been largely cast aside by industry, these handicapped individuals proved their worth in production and their records showed an absentee rate no greater than that of normal persons. Second, physical medicine—encouraged by opportunities in the armed forces and in civilian life—demonstrated its ability to improve significantly the physical capacities of persons formerly considered helpless.

Finally, clinical investigation has led to the use of drugs which offer great promise in controlling such diseases as rheumatoid arthritis and epilepsy.

During the war years, 1941-1945, industry was forced to expand even though the labor reservoir was diminished due to simultaneous expansion of the armed forces. Employment of handicapped persons became a necessity. Experience with such persons dispelled many misconceptions about their work performance, e.g., false beliefs that they have a higher accident rate or that their work performance is poor. In a study by the U. S. Department of Labor, Bureau of Labor Statistics (1948), the records of matched handicapped and nonhandicapped workers exposed to the same work hazards were compared. There were no significant differences between the two groups in rates of absenteeism and frequency of nondisabling injuries. The handicapped, given reasonable job placement, had a lower rate of disabling injuries and their production rate was better than that of normal workers.

Data such as the above led the Association of Casualty and Surety Executives, composed of 65 major companies, to adopt a policy that no higher rate for workmen's compensation insurance is charged because of employment of disabled workers (Wilbur, 1946). Not only large industry, but small plants also have found the employment of physically impaired workers to be economically sound. In fact, several successful small plants have been established largely on the basis of utilizing handicapped persons.

Expanding employment opportunity for persons with neuromuscular disabilities has been a major factor stimulating rehabilitation efforts. There had been some interest in rehabilitation following World War I. However, major emphasis was on vocational training and guidance, and little attention was given to physical restoration until the past decade.

During and since World War II, the success of physical medicine in dealing with the problems of the disabled has been a second important influence toward an improved outlook for those with neuromuscular handicaps. A dynamic approach—stimulation of patient activity—has replaced passive care and proved the value of vigorous attack on these problems. An example of the results of aggressive treatment of patients with such disorders by physical medicine at a Veterans' Administration hospital is quoted in a report of the Council on Physical Medicine and Rehabilitation of the American Medical Association (1949). Of 130 patients all except two were World War I veterans and many had not been out of bed in 10 years. After nine months of a rehabilitation program 65 of the patients had been discharged to their homes, and 25 of these were employed. Of those remaining in the hospital 30 were ambulatory and undergoing advanced rehabilitation, and 25 were capable of some self-care. All but 10 of the original group of 130 had shown significant improvement.

A report (Federal Security Agency, 1947) of the first fiscal year (1945) of operation of the expanded Federal-State Vocational Rehabilitation Program for civilians disclosed that services were provided for 161,047 persons of whom 41,925 completed their services and obtained jobs. Many of the others were still in process of rehabilitation at the end of the year. Of the group rehabilitated into jobs, 79 per cent were unemployed at the time of applying for services, and 18 per cent had never worked previously. Their income, including wages and subsistence, before rehabilitation was approximately \$12,000,000 per year. After rehabilitation they earned at the rate of \$73,855,700 per year. They returned through income taxes to

the Federal Government in the first year after rehabilitation about two thirds of the cost of their rehabilitation services.

Both technical and organizational advances in physical medicine have helped to make possible such excellent results. Technical advances include emphasis on active motion by the patient against resistance, instead of assisted motion and massage; improved prostheses which are designed primarily for function rather than appearance (e.g., "hooks" instead of "hands"); training equipment and programs which stress self-care and independence as the first steps in rehabilitation, thus minimizing an attitude of dependence upon others. Organizationally, it has been recognized that centers for rehabilitation offer the best prospects for successful efforts. In such centers can be concentrated the specialized medical and auxiliary personnel as well as equipment. After diagnosis and evaluation a planned program for each patient can be undertaken with medical direction and including participation by physical therapists, occupational therapists, medical social workers, and other professional workers.

The recent development of several drugs has also improved the outlook for those with certain types of neuromuscular disabilities. Probably the most striking advance has been the use of ACTH and cortisone in rheumatoid arthritis. Dramatic, though temporary, improvements occur regularly in persons with this disease when either substance is used. When the drug is discontinued relapses ensue. How to maintain improvement and yet avoid undesirable side effects with these drugs is a problem still to be solved.

The control of epilepsy has been greatly enhanced by such drugs as dilantin, mesantoin, and tridione. Skillful use of these substances, singly or in combination with phenobarbital, greatly reduces both grand mal and petit mal seizures in most persons with epilepsy.

In summary, neuromuscular disability can be prevented or significantly reduced in many instances through physical medicine and drug therapy. Employment opportunities for individuals with such diseases have expanded and should be encouraged.

### EARLY DETECTION OF DISEASE BY HEALTH EXAMINATIONS AND BY MASS SCREENING TECHNIQUES

Early detection is a basic element in the reduction of disability and premature death from the chronic diseases. When these diseases are discovered in their early stages, the most effective use can be made of existing knowledge and techniques of treatment, patient management, and rehabilitation. Specific procedures are available for the early discovery of many of the chronic diseases. Numerous opportunities are available for applying these detection devices. Yet a vast amount of chronic illness is well advanced before it is diagnosed for the first time. The time interval between onset of the disease and adequate medical attention must be reduced if substantial progress is to be made.

Opportunities and procedures for the detection of incipient chronic diseases are discussed below. It will be noted that no single or simple solution is offered to the problem of assuring their early discovery. Health examinations are helpful, but they offer only a partial solution to the problem. Similarly, educational campaigns—early symptoms of disease and on the need of seeking medical attention early—are

useful measures, but they too reach only part of the problem. These measures require extensive supplementation. Other approaches must also be employed, particularly the recently developed plan of multiphasic screening of large population groups.

**Adult Health Examinations.** In most instances at present, chronic diseases are discovered by the patient's physician after the patient becomes aware of symptoms, and his physician carries out diagnostic studies which may require laboratory, x-ray, and consultant services. Educational campaigns designed to motivate the public to seek medical attention at the first signs of illness increase the opportunity to detect disease early. However, in many cases symptoms do not appear until the disease is well advanced. Also, early symptoms of many of these diseases are not unlike those of minor transient complaints. Many persons are inclined to ignore them. When medical attention is sought, physicians must weigh the probabilities of serious disease against the inconvenience and expense of extensive diagnostic studies. Thus, attention to symptoms does not necessarily assure the *early* detection of disease.

Recognizing the fact that many diseases are insidious in their onset, life insurance companies and medical and public health agencies began several decades ago to recommend periodic health examinations for the early detection of disease. As greater numbers of people take such examinations, there is increased opportunity to discover incipient chronic disease. The combination of a carefully taken history, complete physical examination, and routine laboratory and x-ray studies, plus special studies which may be indicated by the history and physical examination—these elements comprise the ideal method.

The advantages of health examinations are not limited to the early detection of disease. Such examinations also serve the purpose of establishing and reinforcing good patient-physician relationships. From an interpretation of the health history, the physician may gain insight into social and environmental factors important to the patient's health. The physician is given the opportunity to review health habits and give advice concerning them. For example, the importance of oral hygiene can be stressed; women can be taught how to make self-examinations of the breast; the significance of obesity can be explained; and fallacies about health can be detected and corrected. Work capacities, both physical and psychic, can be estimated and adjustments recommended.

However desirable as an ideal, health examinations represent only a partial solution to the problem of early detection of disease. At least one hour of a physician's time is required for an adequate single examination and much more time is considered necessary by many physicians. If the review is limited to a briefer history and physical examination (as is often the case), a considerable amount of incipient disease is overlooked. Multiple routine laboratory and x-ray studies on an individual basis are very expensive. It is significant that, although the importance of health examinations has been stressed in educational campaigns and programs over the past several decades, only a relatively small proportion of the adult population has sought them.

The ideal health examination is seldom achieved. Most so-called "check-ups" are skimpy. One reason is the fact that the cost of a complete examination on an individual basis is high. Also, examinations are frequently superficial because most physicians today are oriented more toward caring for the sick than toward main-

taining health. The pressure of caring for the sick in the home, office, clinic and hospital precludes any substantial amount of time being devoted to health maintenance examinations. Obstetricians and pediatricians have succeeded to a considerable extent in directing their efforts toward health maintenance. However, it will probably be many years before this is typical of medical practice as a whole. Even though all other difficulties were overcome, at the present time there are not enough physicians in the United States to provide this type of examination for the majority of the American people. Hence, the discovery of chronic disease in the general population through health examinations has distinct limitations.

Another opportunity for the early detection of chronic disease is provided in the millions of health examinations taken for special purposes. Among these are the examinations for employment, life insurance, military service, the school health examinations, cancer detection examinations, and many others. A considerable amount of time is spent by physicians on these examinations and on completing examination forms. In most instances the examination is not performed by the examinee's family or personal physician; the people examined are not always apprised of the findings or of the need for follow-up diagnostic studies or treatment; and the examinations vary widely in scope—from the superficial "once over lightly" type of review to the extensive examination, including history, physical examination, and multiple laboratory and x-ray studies. Large segments of the population are not included in the special purpose examinations. Here again we have a valuable but limited opportunity to detect chronic disease in its early stages.

**Mass Screening Surveys.** The limitations of the "individual-examination-by-a-physician" type of approach have led workers in the fields of medicine and public health to develop supplementary measures for the early detection of significant disease in large population groups. Among these measures, the most widely known are the mass screening surveys. Millions of persons have been screened for tuberculosis in mass chest x-ray surveys and for syphilis in mass serologic surveys.

As a case-finding technic, the mass screening survey has numerous advantages. The x-ray or laboratory test can be performed by technicians. Physicians are not required to administer the tests. Physicians' services are needed only for interpretation of positive or suspicious findings and for follow-up diagnostic study of "suspects." The cost per person screened is very low; little time is required for the test and large population groups can be screened within a relatively short time. It is no surprising that these surveys have met with widespread acceptance by the medical and allied professions and by the public.

Recently, the mass screening technic has been modified significantly in demonstration programs in several areas of the country. The modification is a relatively simple one. In these demonstration programs, survey procedures are arranged to screen a population group for several diseases at one time, rather than for a single disease. Instead of a single test, a battery of tests is used in this new type of survey which is called "multiphasic screening." For example, in one multiphasic screening survey (Canelo and others, 1949), conducted jointly by a county medical society, a city health department, and a state health department, a combination of tests was used to screen for a number of diseases including tuberculosis, syphilis, certain forms of heart disease, and diabetes.

A considerable number of simple tests are now available for use in multiphasic

screening programs. The 70 mm. photofluorographic technic for detecting tuberculosis and the serologic test for syphilis are well known. Recently, there have been advances in the application of these two technics. The chest x-ray is now being interpreted not only for tuberculosis, but also for cardiac abnormalities and for pulmonary neoplasms. Where chest x-rays are so read, a considerable amount of previously undiscovered heart disease is being brought to treatment and pulmonary neoplasms are being detected in a significant number of cases, at a stage when lifesaving measures can be carried out. Further applications of the photofluorographic technic are now being evaluated, e.g., using it in combination with the Schmidt camera and contrast media for discovery of lesions of the gastro-intestinal tract.

In a recent modification of the serologic test for syphilis the specimen is collected by saturating a small amount of filter paper with capillary blood. This technic—the filter paper microscopic test for syphilis—eliminates the necessity for venipuncture. At the laboratory, only a slight alteration in the usual serologic technic is needed for the examination of the filter paper specimen.

The Wilkerson-Heftmann micro blood sugar screening test for diabetes likewise requires only a drop of capillary blood and has now been adapted to an instrument which processes automatically as many as 120 specimens per hour.

The copper sulphate method has proved satisfactory for the early detection of anemias. In this hemoglobin screening test, a drop of blood is placed in a solution and the reading is based on whether the drop rises or falls. It is thus possible from a few drops of capillary blood to screen an individual for syphilis, diabetes, and the anemias.

Urine tests for glycosuria and albuminuria are, of course, quite simple. There is no difficulty in incorporating them into a multiphasic screening procedure.

To the above tests might well be added the determination of weight and height, vision, and hearing.

Great advances have been made in the cytologic technic for the early detection of cancer. The test is now applicable on a mass scale to uterine cancer and, in combination with chest x-rays, to pulmonary cancer. Studies are being made of its applicability to gastric and other cancers. Current efforts to develop a serologic test for cancer show considerable promise.

Although it is true that no combination of x-ray and laboratory tests can take the place of a careful evaluation by a physician, it is equally true that a skillful combination of tests will lead to the discovery of a considerable number of cases of incipient disease; in many instances, cases which might be overlooked in routine "check-ups." Not only is a significant amount of early disease discovered through multiphasic screening programs, but also the physician's concern with "preclinical medicine" is greatly increased. As more persons with incipient disease are referred to him for diagnostic study and treatment, there is greater opportunity for effective guidance, treatment, and rehabilitation.

It has been pointed out that multiphasic screening is not a substitute for comprehensive health examinations and is not intended as such. It is designed specifically for the early detection of significant diseases in large population groups. In screening simultaneously for several diseases, economies are effected in the organization and administration of community-wide, industrial, and other mass case-find-

ing programs. Follow-up services—an all-important phase of case-finding programs—can also be organized and conducted more economically.

In summary, a number of opportunities for the early detection of the chronic diseases are now available. It has been noted that the "individual-examination-by-a-physician" approach requires supplementation. Mass screening surveys, and particularly those using multiple screening procedures, are valuable and economical measures for the early detection of disease (Journal of Chronic Diseases, 1955).

Multiphasic screening surveys—using various combinations of tests—are being carried on in many sections of the United States. These surveys, for the most part, are conducted jointly by the medical profession, health departments and voluntary health agencies. Their objectives include, as a main item, the evaluation of the technic itself in terms of cost factors, characteristics of population groups to be screened, screening levels for referral purposes, and essentials of organization and administration. In one area, a multiphasic screening procedure combined with a modified health examination by physicians is being studied with a view toward incorporating features of both in a community-wide health maintenance program.

Further application and critical evaluation of multiphasic screening and other technics for the early detection of chronic diseases are essential for the prevention of disability and premature death from these major health hazards in adult life.

## MENTAL HYGIENE

PAUL V. LEMKAU, M.D.

### THE PLACE OF MENTAL HYGIENE IN PUBLIC HEALTH

When public health was principally concerned with the reduction of mortality, the promotion of mental health and the prevention of mental disease could hardly be considered public health responsibilities. Aside from general paresis, few mental diseases shorten life markedly. When the reduction of morbidity was added to the aims of public health practice, however, mental illness perforce became an important concern. Patients with mental illnesses severe enough to require hospitalization occupy beds; approximately one half of the hospital beds in the United States are occupied by the mentally ill. These patients are completely unproductive for long periods of time; the half of the hospital beds occupied by the mentally ill admit only one-one-hundredth the number of patients admitted to the other half. According to the National Health Survey of 1936, mental illness was exceeded in the production of morbidity only by the arthritides. Less exact data suggest that perhaps 10 per cent of the total population is continuously ill with more or less severe types of mental illness which causes losses in social productivity and adds to the cost of medical care. Because of the size of the problem and the cost of the medical care the patients need, there is no question that mental diseases constitute a major public health problem.

The care of the mentally ill has been a governmental responsibility for centuries (Deutsch, 1949). That it did not earlier become a problem for health department is probably explained by the fact that it is such a large burden in its own right, and that it was recognized as a problem before the state began to realize its responsibility in other health areas. The hospitalization of the mentally ill is so great a problem that it has appeared to require a separate administrative department to manage it; its long tradition of separate administration makes it difficult to include it in the smaller, newer health departments, even though the latter have heavy medical care responsibilities in the case of other diseases, notably tuberculosis.

On the other hand, mental diseases have, in a limited sense, been the concern of public health since its inception. Deliria accompanying the infectious diseases were public health problems during the now fading era of the isolation hospitals. Paresis rapidly became the concern of public health when its relation to syphilis was discovered and prophylaxis against it became theoretically possible; indeed this is one of the few mental illnesses in which effective prophylaxis can be statistically demonstrated (Lemkau, 1949). Public health has recognized less responsibility for

long-term effects of complicated infectious processes. Thus, the public health officer has been concerned with the acute case of meningococcus meningitis or encephalitis but has shown less interest in the long-term behavior disorders following brain destruction or damage by these diseases. When such damage has been severe, the patients have traditionally been sent to the psychiatric hospital for care.

**The Concept of the Multiple Etiology of Disease.** When disease could be considered simply as an acute, critical battle between a host and an invading organism, ending soon in victory over the invader or in death, the explanation of the outcome could usually be made in the somewhat mechanical terms of immunology. In the more chronic diseases, however, other types of factors were found to be important. In tuberculosis, for example, there is the invasion of the host by bacteria, but the battle is not a short one and the course of the disease is not completely explained on this basis alone. Older theories of hereditary predisposition do not withstand modern critical evaluation. The course of the host-invader battle is not only a matter of the pathogenic power of the invader, but also of the "state of health" of the host. This "state of health" is not measured entirely in terms of specific immune reactions but is found to be related to more general health conditions. An important factor appears to be the psychological adjustment, the mental health, of the host. It appears that this factor in some cases, at least, determines whether or not the patient gets the disease, whether he remains under treatment once he has it, and the quality of recovery and length of time necessary for recovery. Tuberculosis is the example used here, but other chronic infectious diseases such as brucellosis, virus pneumonias and others also appear to be markedly influenced by the factor of the mental health of the host. These concepts are the subject of intensive and productive research at the present time, usually designated by the term "psychosomatics."

The occurrence of psychoses secondary to arteriosclerosis or senile degeneration of the brain does not appear to be determined by the severity of the brain damage alone, but also by the mental and social health of the whole person. This issue and its relation to the prevention of psychoses in the aged is discussed more fully below. The principle of multiple etiology, that psychological or social stress is a factor in the etiology of the psychoses as well as the brain damage, may be applied to other situations as well; for example, some of the blood dyscrasias, as well as conditions in which the brain and its nutrition do not appear directly involved. Examples of such conditions are gastro-intestinal ulceration, in either the upper or lower parts of the tract, some allergic conditions and some skin affections.

The two mental illnesses that are numerically and therapeutically the greatest problems are schizophrenia and the manic-depressive psychoses. In neither of these is any "primary" etiological factor, such as infection or brain damage, known. Both are presumed to appear because of factors of inborn vulnerability plus some other factors which place stress on the individual so that the characteristic symptoms appear. The stresses are believed to be due to life situations which are not to be defined in general terms as common to all individuals, but rather that they are specific to the particular individual affected. In other words, these two illnesses are believed to depend primarily on "host" factors, individual factors; to a large degree. It should be noted that these considerations are primarily theoretical; the hypothesis appears to serve better than any other now extant to explain the occurrence of these illnesses and to furnish a basis for the therapy, and perhaps, the prevention of them.

The situation is at present much the same in the large group of mental illnesses not requiring hospitalization. The most important group of these are the neuroses. Cause and effect relationships between factors of accumulated vulnerability and precipitating "cause" were greatly clarified through military psychiatry in World War I and II so that the multiple, nonspecific character of etiological factors in these illnesses is quite clear at the present time; so clear that few any longer question the prevailing psychogenic hypothesis in this area, a fact not so true in the case of the two major "psychogenic psychoses" discussed above.

It is quite clear that the recognition of emotion and experience factors affecting the vulnerability of the individual human being to disease excludes very few illnesses, even the acute ones. Fundamentally, the psychogenic hypothesis can be stated very simply. The health of the individual depends upon his satisfaction in living which is, in turn, dependent upon his social situation and interpersonal relationships and upon his attitudes and feelings, the latter having been determined by inborn factors to some extent, but more significantly by previous social situations and interpersonal relationships. It is against this background of state of health that the drama of all illness takes place, whether it be the determinant between life and death in pneumococcus pneumonia, the length of convalescence after an appendectomy, or the extent of disability following a transection of the spinal cord by trauma or destruction of cell groups by poliomyelitis.

The promotion of the personal and interpersonal health of the individual is not entirely a medical problem, in the narrow sense of that term. It involves all those forces having to do with how people live and feel. Thus, it includes sociology, economics, anthropology, psychology, philosophy, theology, and many other areas of investigation and learning. It comprises, in short, all human biology. Within the profession of medicine, this tremendous area of research and treatment has become one of the primary interests of the specialty of psychiatry. The sub-specialty of mental hygiene is primarily concerned with efforts and research toward the promotion of maximum health and with the prevention of disease due wholly or partly to individual or host factors, rather than to specific external, invasive etiological factors. These concepts are brilliantly discussed by Holliday (1943).

The mental health of the human being is dependent on far more than attitudes and interpersonal relationships. Mental health is impossible for the individual whose basic state of health is such that the central nervous system is hampered in its metabolism. Typical conditions of this type would be malnutrition, interferences with blood supply and various toxic states including excessive fatigue, acute or chronic. The avoidance of conditions of life which tend to lower the level of "support" received by the central nervous system is obviously mental hygiene, but mental hygiene of a very obvious and elemental sort, though by no means have all the problems of the type been solved. The problems with which the mental hygienist is principally concerned are those which are effective in conditioning toward mental ill health even in the absence of any interference with the general metabolic state of the individual.

The use of the name "mental hygiene" to designate the area of the promotion of health and the prevention of disease due to attitudinal, social and emotional factors requires some comment (Beers, 1948; Deutsch, 1949). Historically, the term has been used as an euphemism for almost all of psychiatric care and treat-

ment; indeed, when it was introduced there was little thinking beyond the reform of inadequate psychiatric hospital care and the extension of early treatment. With more modern psychodynamic concepts, the misuse of the term by confounding it with psychiatric treatment is less excusable. There are those who would like to drop the term entirely because of its historic misuse, substituting "mental health" in its stead. This is being done in many places. It is perhaps well to recognize that a proper, more restricted definition might be the object of public education rather than the merely substituting another term which, without public education as to its real meaning, will shortly become contaminated with the same issues which presently surround "mental hygiene." The prefix word "mental" could be dispensed with if medicine and the social sciences could come to a more complete realization that human biology is the basic problem, that the behavioral sciences are as much a part of the study of man as are the so-called "basic" or "pure" sciences.

**The Development of Mental Hygiene in Public Health.** When psychiatry had developed the psychodynamic hypothesis discussed above there became immediately apparent the possibility for prevention. If the life experiences of an individual so conditioned him that he became ill when further stresses impinged upon him, then it became reasonable that this early conditioning or structuring of the personality might be undone through therapy. Furthermore, the early conditioning toward liability to mental illness might be prevented by preventing some of the traumatic experiences which appear to have weakened the personality structures seen in cases requiring treatment. The experiences to be dealt with are believed to be interpersonal in character for the most part, with the parent-child relationship the most fundamental. Other conditioning factors are found in the larger social sphere beyond the family, such as the school, the church, and other community organizations. All these relationships take place in a larger sociological and cultural setting which also affects the individual's personality strength. This may happen directly as when poverty or ignorance prevents proper nutrition, or indirectly, as when the social and cultural pattern controls the kinds of persons with whom the individual comes in contact. In general, the psychogenic hypothesis holds that those experiences which take place during the periods of life marked by rapid development, infancy, childhood, and adolescence, are more influential in affecting personality structures than those occurring later.

This theory offered for the first time a practicable means of approaching the problem of the prevention of the psychogenic mental illnesses. The psychiatrist began to look for the administrative organization to reach the developing personalities in order to see whether practices could be devised which might produce a smaller number of vulnerable structures. The most pressing and immediate opportunity at the beginning appeared to be in the area of juvenile delinquency. When this problem was attacked, it was found that the cases had enormous ramifications in the community, particularly in the school. There followed a period of intense interest in pupil-teacher relationships which is still continuing, with new insights and methods in mental hygiene in the schools being developed.

Mental illness as a public health problem is no novelty in Europe, where the treatment function of public health was never so markedly separated from the preventive one as in this country, and where organized public health early took responsibility in this field. Just when and to whom the idea occurred that mental hygiene

was a public health problem in the United States is hard to determine; it was prevalent enough at the time of the first edition of the present text, in 1913, to have been given a place in it. During and immediately after World War I, the idea possessed Dr. Thomas W. Salmon (Bond, 1950), probably because he was both a psychiatrist and a medical officer in the U. S. Public Health Service and was restless enough in his thinking not to be able to keep the two aspects of his position separate. At any rate, by 1918, Welch, Howell, Rose, and others concerned with public health education considered that mental hygiene was an appropriate subject for the health officer to study, following the steps of the Harvard School of Public Health where Salmon had given courses as early as 1913.

The first state health department to establish a division of mental hygiene was, appropriately enough since this state also organized the first mental hygiene society, in Connecticut. This division was established in 1920, and in 1934 became a bureau. Not many states followed the pattern, however, until the passage of the National Mental Health Act in 1946, followed by appropriations in 1947. The "Mental Health Authority," required to be designated for each state under this act, became the health department in all but 12 of the 53 states and territories. Under the careful and creative planning and consultation service established by the Division of Mental Hygiene of the U. S. Public Health Service, later the National Institute of Mental Health, programs in states and territories have grown with exceeding rapidity (Lemkau, 1949). In 1950, all the states are working in one way or another toward the development of a program for mental hygiene and the promotion of mental health.

The first report of the Committee on Mental Health, World Health Organization, 1950, stated the importance, indeed the inevitability, of organized public health mental hygiene if there is to be any hope of controlling the tremendous cost in money and human productiveness that results from mental illness. In the words of the report: "The committee therefore considers that the most important single long term principle for the future work of WHO in the fostering of mental health is the encouragement of the incorporation into public health work of the responsibility for promoting the mental as well as the physical health of the community."

## BASIC TECHNICS IN MENTAL HYGIENE

Mental hygiene fundamentally is the effort to prevent or to change attitudes which are or are believed to be inimicable to the best possible state of health for the individual or group concerned. Attitudes are recognized to be the result of two general factors: first, the emotional experiences that have taken place in the course of a life and, second, the thinking and learning that has been done by the individual because of, or in spite of, those emotional experiences. Learning and thinking alone are easily seen to be not enough to change attitudes, viz., the deeply prejudices thinking of the learned men of the Nazi regime in Germany. These functions take place only through a screen of attitudes, what Plant (1950) has called an "envelope," a sort of semipermeable membrane which selects and colors the things learned and thought. Attitudes are, for the most part, extremely difficult to analyze by the individual who holds them, or for that matter by others, since such analysis involves prejudices and biases which are difficult to put aside. They come, some

them, from periods of life no longer within the range of memory, from the period covered by the amnesia the human has for the earliest years of his existence. The person holds certain attitudes to be axiomatic, not subject to proving, but right just because they are right; he rejects any suggestion that they are capable of interpretation on the basis of past personal experience and argues about them on some falsely logical ground, a phenomenon the psychologist calls rationalization.

A corollary to the principle that all attitudes have an emotional component, is that attitudes can be changed most effectively only when emotional forces are used in the procedure of change. An analogy to this principle might be drawn from the treatment of diabetes mellitus; the abnormal thirst is caused by a disordered metabolism which is due to lack of insulin. Giving water may quench the thirst temporarily, but to correct the disease, the disordered metabolism must be corrected by the administration of insulin. Ill health due to attitudinal derangement may be temporarily corrected by authoritarian advice and logic, but to correct the basic issues, the emotional factors underlying the attitudes will have to be dealt with. There will have to be some sort of corrective emotional experience along with logical explanation if fundamental changes in attitudes are to be accomplished.

If this be true, then the physician will have to give greater scientific place to the art and skill of medicine than has usually been his wont during the recent decades of rapid advance in the physiological and parasitological aspects of disease. The art of using the emotional experience in therapy must be recognized as a part of the science of medicine; the art must, so far as possible, be reduced to principles, and the principles to a useful science which the physician may use with the same pride and satisfaction he now has in the exactness of the hematocrit or the serological tests for syphilis.

It has been one of the most important findings of psychoanalytic research that the emotional experiences necessary to change attitudes cannot or do not take place unilaterally, that in every case the emotional situation necessary for attitude changing involves the physician as well as the patient. The statement of this principle has required some courage in the past, for a profession has been told, and to a surprising extent the telling has been accepted, that it could not deal with human patients without becoming humanly-emotionally-involved. The profession has long recognized the art of medicine; it has more recently realized that this art is not practiced *on* a patient, but *with* a patient, the physician participating in the interaction.

Boiled down to its very essence and applied to the field problem, these concepts have been stated by Ginsberg (1950).

Mental hygiene is concerned with public health programs at every point, since practically all programs have an element of attitude-changing about them. The details of the place of mental hygiene in programs will be discussed more fully in a later section. Suffice it to say here that no person in the health department is free of the necessity to realize that his job has to do with attitudes, his own and those of others. The top administrator will be concerned with attitudes of employees, knowing that the quality of their contacts with the clientele of the department will be affected by them. The clinic physician cannot help but affect attitudes and will need to recognize his own as well as those the patient exhibits if the best promotion of health is to be achieved. The sanitarian will need to recognize that his ability to listen to the explosive protests of the man selling milk without a license is frequently

an unavoidable by-product of the changing of attitude necessary to lead to submission to the regulation. Recognition that the process of attitude-changing which is necessary to lead to a desirable action as a mutual experience, is also a recognition of the all-pervasive character, the "horizontal function," of mental hygiene in the health department.

When it can be granted that attitude changing is not something done *to* people, but rather that it is a mutual experience lived through *with* people, the client gains in stature. He is no longer a body to be managed, but a person with whom an experience is shared. As such, he deserves greater consideration as a person. A two-minute interview with the mother of an infant in child health conference is seen not to be enough; the experience cannot but be incomplete and frustrating for both participants, physician and patient. Authoritarianism with the tuberculosis patient resistant to hospitalization becomes unsatisfactory as a means of management in many cases, not only because it frequently fails, but because the physician or nurse feels he has failed in his part of the process of attitude-changing to lead to the health-promising action. The clinic practices will require more attention to the patients' views, and the time it takes for attitude-changing will be taken into consideration in scheduling and planning. Clinics will be planned with the patients' as well as the physicians' comfort in view, since the process of treatment is not imposed *on*, but rather, worked out *with* the patient. The health educator can hardly be bored with the uninformed question when he catches the scent of the attitudes it reveals and the need to work them through with the group to which he is speaking.

The discussion of technics of mental hygiene has thus far dealt exclusively with the implications of the interpersonal relationships in the development of the personality and the determination of its mental health. There is no intention to neglect the personality-forming forces that lie in the cultural, sociological, economic and other areas. It is probable, however, that these forces are not felt directly until personality has developed considerably, until the child comes into contact with a wider environment than his home and immediate community. It is probable that such forces become directly formative only after the child starts school, and are not very strongly effective until the adolescent period of development when the tendency to make comparisons becomes acute. Prior to this time, and continuing in and beyond it, forces such as poverty, poor housing, low cultural standards in the community, lack of recreational facilities, etc., are felt not directly, but through their effect on the personalities surrounding and guiding the child and from whom he gets his interpretation of the culture and the environment. The child is likely to feel poverty in such ways as the pain in his mother's back which is the result of her being unable to afford a washing machine and which makes the mother very irritable, than in any more direct way. Improper nutrition may result from poverty, but the impact on the child of the situation is more likely to come through the parents' frustration and guilt than from its own realization of lack of money in the family.

There are many aims in mental hygiene which are identical with those for most other diseases. Good housing is as much to be desired as a preventive for mental ill health as it is to prevent tuberculosis. Good nutrition is a preventive for mental illness as it is for pellagra. The interpersonal factor of attitude formation and manipulation has been stressed, however, because it is more specifically related to mental hygiene than these more impersonal forces.

## MENTAL HYGIENE IN PUBLIC HEALTH PROGRAMS

There are few agencies in modern social structure which direct their services to all individuals in the entire population. Two stand out immediately which do, public health departments and public schools. In actual practice, public health programs are, as far as the more personal clinical services are concerned, largely confined to the lower socio-economic levels of the population, though this pattern is changing rapidly as more and more methods for the preservation of health are learned and are recognized as separate from the practice of curative medicine. The health promoting possibilities of the science of nutrition are a case in point; mental hygiene is another.

The argument as to what is treatment and whether it is ever a proper part of public health programs is nowadays largely an academic one. Treatment, it can be argued, is always preventive in nature, preventive of progress of disease, preventive of death, preventive of chronicity and long morbidity. This is largely a specious argument as are most of those so often made in the case. Actually, the questions are usually settled pragmatically. Syphilis treatment became a part of public health programs when it became treatable but the treatment was so long that it required a follow-up system not available to the practitioner and too expensive to be borne by any large segment of the population. Pneumonia in the days of serum treatment became a public health problem for a short period because too few physicians had the necessary technical skill to make a diagnosis of type of organism, and, again, because of the cost of the treatment. When a new treatment was discovered which was less costly and did not require a new, specialized diagnostic skill, pneumonia was returned almost at once to the physician for handling; syphilis treatment appears to be going the same way with the rapid reduction of cost and the greater simplicity of treatment procedure, only the epidemiology being retained as the health department function. Full medical care for the indigent has been a part of public health practice since the origin of public health in ancient times. It is perhaps a reasonable pragmatic conclusion that when any medical problem is too expensive or requires special technics not available to the general practitioner or which the physician does not care to handle, then public health will become responsible in that area. It is on this sort of pragmatic basis that public health programs are usually constructed, and it is from this viewpoint that the place of mental hygiene in representative programs will be discussed.

**Hereditary Factors.** The promotion of health in any individual begins with the moment of conception. Mental hygiene in the prenatal clinic attempts to see to it that the family into which a child is born is as healthful a place as possible for its optimum development. That there are vast differences in the quality of the new individual that comes into being at the moment of conception is quite obvious. Variation runs the full gamut from the extraordinary potential for genius in all lines of human endeavor to the almost complete absence of potentialities in any direction other than ability to maintain a purely animal existence; in the most unsuccessful conceptions even this potentiality is exhausted before the period of gestation is over and abortion or miscarriage occurs. This variation may be due to one of two factors: first, a predictable one based on characteristics of the histories of the father and

mother, second, an "accident" occurring in the complicated cellular mechanics of the merging of the chromosomes of egg and sperm.

It is a curious fact in the history of medicine that heredity is likely to be used to explain the presence of incurable disease, whereas the diseases which can be successfully treated are rarely regarded as hereditary. Phthisis was thought to be hereditary until the etiological agents became known, and racial (hereditary) susceptibility was long used to explain the differences in death rates in white and colored people. As the multiple etiology, the host factor, in the etiology of the disease gained recognition as well as the bacterial agent, the racial difference was recognized as not solely, at least, due to hereditary differences between Negro and white, but due to differences in socio-economic factors and in other conditions of living. The same depreciation of the importance of hereditary factors has taken place in diabetes and, perhaps, also in cancer.

The complexities of the etiology of many mental diseases are still not by any means completely worked out, and definitive and directly specific treatment methods are unknown. For this reason, perhaps, heredity is seized upon as a very important factor in the etiology of them. It is quite possible that eventually it may be found that some of the conditions now ascribed to hereditary causes will eventually be proved to be of other origin. In any case, the easy blaming of hereditary etiology is frequently a deterrent to the research necessary to prove hereditary origin, as well as to continuing therapeutic efforts. Sterilization and birth control, as mental hygiene measures for the prevention of the birth of children in whom mental deficiency of severe degree and certain neurological diseases can be definitely predicted, is certainly defensible. Perhaps equally often, these procedures may be defended not on the ground of heredity but on the ground that a given set of parents is not capable of rearing children properly and will produce exaggerated susceptibility to disease in them. It is rare that the local health department can be active in the area of mental hygiene that has to do with the prevention of births, even though the problem is clearly recognized, because of the complications involved with some religious sects which treat this area of biology as a moral rather than a scientific issue. With increasing population pressures over the world, it is possible that the selective planning of the number and spacing of births may eventually be a public health issue on other grounds than those of hereditary disease.

**Prenatal Clinics.** The health of the fetus can be interfered with by a list of factors that is becoming longer as knowledge is gained. The effect on the fetus of rubella infection in the mother, particularly if the disease occurs in the early months of the pregnancy, is one of the most startling of these factors. [It should be a part of the mental hygiene program of every health department to have a plan for such protection of the pregnant woman as is possible ready to put into effect when an epidemic of rubella should appear. The newspaper releases, the radio spots, the movie trailers should be ready for the emergency so that as far as we are able cataracts, mental deficiency, and congenital malformations of the heart in the unborn child may be prevented (Ober and others, 1947). There is, of course, also work to be done in research to find ways of immunizing females to the disease before the childbearing period. This problem has many points of similarity with that of the treatment of syphilis in the pregnant woman.]

Another factor influencing the health of the unborn child is nutrition, which

discussed elsewhere in this volume. Certain drugs are known to affect the unborn infant; perhaps the most important are sedatives, which, when given in too large doses to the mother during labor, reduce the capacity of the newborn to obtain sufficient oxygen as soon as it is born, thus subjecting the nervous system, which is extremely sensitive to anoxia, to the risk of damage. There are many other factors which may be capable of damaging the unborn infant, such as toxemia of pregnancy and metabolic diseases in the mother.

For the most part, the factors dealt with thus far are at the level of the organic development of the infant; there are other factors also to be considered during the prenatal period which have to do with the emotional setting in which the child is to mature.

The most obvious of these has to do with the attitude of the prospective parents toward the child. The foibles and fears of the pregnant woman are well recognized as important elements of her life during pregnancy (Blass, 1950). Many have felt that some, at least, of the usual symptoms occurring during pregnancy are related to the mother's attitude toward the pregnancy. Research indicates that the emotionally well-adjusted mother delivers with fewer complications than the emotionally unhealthy mother (Wooten, 1950). Psychotherapeutic relief of hyperemesis is an acceptable method of treatment by most obstetricians, even though too often it is the crude psychotherapy of a very dull needle used in intravenous feeding. It is believed by some that pre-eclampsia occurs more frequently in pregnant women under severe emotional stress than in those not so burdened, though this remains to be statistically demonstrated.

The common emotional stresses occurring in pregnancy appear to lie in three general areas. First, the prospective mother shows concern about her capacity for bearing and mothering a child. Second, she shows increased concern about sexual anatomy and physiology and about the effect of childbirth upon her body and her personality. Third, there appears a concern about her relation to her husband during the pregnancy and the period to follow it. In line with the earlier discussion of basic techniques in mental hygiene, it will be recognized that these stresses may be dealt with by educational efforts taking place in a situation in which the emotional component is clearly recognized and used in a relationship with the patient. The successful use of mothers' classes in prenatal clinics indicates that the fears concerning the process of childbirth itself are readily dispersed by frank discussion and by teaching the physiological anatomy of pregnancy and delivery. This is largely the basis of the "natural childbirth" movement of Read (1944) and Jackson (1948). Even without the open recognition of the deeper basis of fears associated with pregnancy having to do with the almost universal association of a feeling of guilt with sexual activity, such methods, whether carried out with individuals or with groups, relieve many of the anxieties. Classes in baby care similarly tend to relieve the fears of the normal woman that she does not have the capacity to be a "good" mother.

It is apparently a part of the normal psychology of pregnancy, at least in our culture, that the woman should become more self-centered than is her usual wont. Her husband is less important to her, her concern is upon herself and her infant. There is perhaps some guilt associated with this which makes itself apparent as a fear that her husband will desert her, something that occurs often enough, especially in the lower socio-economic groups, to justify the concern. This is a matter that can

be discussed both in interviews with the mother, and with the father, who has been too much neglected in the prenatal clinics.

Not infrequently, pregnancies are not welcomed, sometimes for exquisitely realistic reasons having to do with inability to feed and clothe another child. In other cases, the pregnancy may be rejected because it is felt to be a threat to the beauty of the mother, and of the freedom of the parental couple. It has been observed that feelings of rejection normally become less as a pregnancy progresses; the girl who never even wants to see her baby in the first trimester is waiting happily for its appearance by the time delivery comes or as soon as delivery is over (Wootten, 1950); Klein and others, 1950). This phenomenon occurs frequently in pregnancy; recognition of it may relieve the physician and the nurse who worry about what is to become of the child early in the pregnancy only to find their worries useless in the majority of cases because of the change of maternal attitude. Acceptance can undoubtedly be favored through interview and group teaching during pregnancy.

A topic of importance in the prenatal care of the multiparous patient, particularly of the mother in her second pregnancy, is the introduction of the new baby into the life of the child or children already in the family. Children tend to want the exclusive attention of their parents, particularly their mothers, and they resent the intrusion of the helpless infant that so successfully gets first attention. This problem is the more acute because the succeeding child appears frequently when the previous one is in the period of negativism to be discussed later. This problem is most suitable to be discussed in the prenatal clinics. The sex education of the children already in the home is also likely to be a matter of question by the mother during her pregnancy.

The introduction of the issue of sibling rivalry as a topic to be discussed even before the rival appears on the scene is an example of a principle of mental hygiene that deserves discussion as a general technic. A situation which is known to give rise to emotional conflict in a significant percentage of families is dealt with in discussion before the situation actually arises. The aim is to lessen the emotional impact of the situation and, consequently, its potential as a source of conflict. To use a humble analogy, if one is watching an open door and sees it begin to close as a result of a draught, sees it speed up as it nears being closed, he is not likely to jump when the slam, seen to be inevitable as soon as the door began closing, actually comes. If, however, the door is at one's back, and the stages of its closing are not seen before-hand, the slam comes as a sudden shock and results in an involuntary, violent "jump." Sibling rivalry can be a great shock if one does not know that, at least in our competitive culture, it is almost inevitable. The shock of its appearance may lead to ill-advised handling such as punishment, shaming, and withdrawal of affection from the child. It should be expected to occur in some degree and appreciated as a justifiable defensive reaction of a child who sees affectional sustenance being withdrawn from him by an intruder in the family circle. When the parents understand the needs of the older child, provide the affection he is striving for, and give him an opportunity to participate in the care and affection given the new baby, healthy responses are encouraged. This concept of "anticipatory guidance" (Levy, 1946) will appear again and again as a basic technic in mental hygiene in public health, from the situation in prenatal care, to the preparation for retirement in old age.

**Prematurity.** The great increase of public health programs to preserve the life of premature infants has raised some new problems in mental hygiene. In the first place there is the fact that the birth and the child are not "normal," a situation that makes the parents feel different from others. There is also the common fear that the premature infant will not develop properly, a fear not entirely without foundation since blindness due to retrolental fibroplasia does occur. Cerebral injury during the birth process is a greater risk for these children than for the more mature infant at term because of underdevelopment of the protective tissues about the brain. The prevention of prematurity is good mental hygiene in the light of these facts.

The "abnormal" condition of the child and the birth may lead to feelings of isolation and self-blame, frequently associated with feelings of guilt and of unworthiness in that the parents have failed to produce a normal child in a normal way. It is easy for this self-blame to be projected upon the child so that it is somehow disliked for having inflicted the anxiety and, not infrequently, shame on the parents. There may be disappointed grandparents and other relatives who do not hesitate to blame one or the other marital partners for the mishap, thus throwing additional strain on the husband-wife relationship. There is also the very real anxiety concerning the viability of the child which is a stress the medical attendants may share with, but too frequently falsely deny to, the parents. These factors all add up to explain why telephone calls are so frequent to the premature ward; they also indicate the need to treat the frequently bothersome caller sympathetically and with understanding.

The fact that the precarious condition of the premature infant requires hospital care interrupts the mother's taking over the care of the child immediately after its birth. Instead she must put off the practice of motherhood for weeks or months, until the child is ready to come home. The expected sequence of pregnancy-delivery-care of the infant, looked forward to for months, does not come off on schedule; adjustments have to be made. Babies are often referred to colloquially as "little strangers"; a period of hospitalization for the child tends to accentuate its strangeness when it does come home. There are no data to support the supposition but it has been suggested that more premature babies are abandoned by their parents than is the case with term babies. If true, such a fact might have many explanations, but an important one might be the delay which makes possible the setting up of living habits which do not for weeks or months after delivery include the baby, with resultant failure to develop the sacrificial quality of love which appears when the infant needs immediate care.

As will be the case throughout this discussion of the place of mental hygiene in public health programs, these do not exhaust the factors involved. It is merely an attempt to indicate the types of feelings, some of which are emotional stresses of some magnitude, which demand recognition as significant features to be considered and dealt with on a premature service. In general, they are factors of emotional stress and must be dealt with through the technic of interpersonal emotional exchange, through sensitive interviewing or group technics.

**The Well-Baby Clinic.** (Child Health Conference, Baby-Keep-Well Clinics, etc.) In general, the work of the well-baby clinics includes the period of life from birth until the child begins to attend school. These five or six years are usually divided into two periods: that from birth until about two, designated infancy, and that from three until five, called the preschool period. Physiologically, this is a period

of momentous changes, perhaps best illustrated by the fact that the newborn infant grows about eight times as fast as the child at three. Nutritionally, feeding changes from the exclusively liquid diet of the infant to the pattern of eating common to the group in which the child is nurtured. Culturally, the child changes from the completely dependent infant to the relatively self-reliant school child, and from the accepting infant to the individual willing to defend his place in his culture. Neurologically, the child changes from one who can make only random movements to one who can plan and act in a relatively accurate way, from one with no sphincter control to one who can adjust elimination to some extent to the rules of the people with whom he lives. It is not remarkable that a period showing such enormous growth should be considered important in mental health. Attitudes which affect the essential soundness or weakness of personality structure are forming with as great rapidity as are myelin, bone, and muscle, perhaps with even greater rapidity.

Once the basic physiological demands are met, the primary ingredient in the life of the child which is necessary for optimum growth and development is an appreciative, accepting and loving attitude on the part of the parents. Such an attitude has already been fostered in the prenatal clinic through discussions of attitudes with the parents and helping the parents reach this emotional state. Anxieties have been relieved so far as possible, resentments toward the infant have been frankly recognized in so far as possible, and hopefully, the home is ready to receive the baby.

The initial experience with the child is rarely completely under the control of the health department but is in the hands of the obstetrician or midwife, or a hospital. Nevertheless, rooming-in and breast feeding will be discussed because of their mental health significance according to current thought.

The new baby has since the earliest times been the companion of its mother. Since the discovery of asepsis, however, this time-honored relationship has been interfered with, and the child is relegated to a nursery, the mother seeing it only at feeding time, if then. While this is probably less of a problem than it was a few years ago when obstetrical hospitalizations were 10 to 14 days long, it is nevertheless a matter which is at present receiving a good deal of attention as a factor in the mental health of the mother, and through her, of her infant (Maloney and others, 1946). It is known that mothers have considerable anxiety about their infants when they are separated from them and that they are more comfortable when the infant is at hand, can be seen, and can be attended to when it needs care. Mothers are fully aware that hospital nurseries are usually understaffed and that infants are allowed to cry unattended in them longer than would be the case if the child had its mother's care (Aldrich and others, 1945). Crying in the newborn infant is an indication that it is not under optimal conditions for its growth and development; crying in nurseries can be greatly reduced by increasing the amount of nursing care per infant, and can be still further reduced by placing the child where its mother, with such help as may be needed, can attend to its needs when they are demonstrated by crying. Rooming-in of the child with its mother makes this possible. Rooming-in can provide relief from some of the mother's anxieties about her baby and can actually afford more optimal conditions for the child than can be given in the hospital nursery.

The period of rooming-in can also be used to allay some of the anxiety of the mother about her competence as a mother. She can learn under experienced guidance

ance the hows and whys of infant care over some days, not through the seeing of a single bath performed by someone else as was hospital practice until recently. Another factor in the mental health situation is related to the modern movement toward early ambulation. It appears clinically that there are fewer marked depressive reactions in women returning home after childbirth since hospitalizations have been shortened and it is the impression of workers in this field that this is even more the case when the mother has charge of the infant in the hospital.

In most rooming-in programs, the father is able to become acquainted with his infant directly and not through plate glass. This cements the family group earlier than is the case if father learns only of the difficulties of infant care after the child is at home. Rooming-in probably fosters breast feeding, though this is difficult to demonstrate since the programs now in operation tend to select mothers for this type of care partly because they wish to nurse their children.

Quite aside from the advantages of breast feeding from a narrow organic viewpoint and the convenience of it, there appear to be advantages to the mental health of the child and the mother. In the first place, the infant cannot be breast fed unless it is held closely to the mother in a cuddling manner; at least the *forms* of giving affection and security are insured.

The infant will cry when support is suddenly withdrawn; from this the assumption may be made that the optimum conditions for growth and development include such pleasantly firm cuddling as is unavoidable in the nursing position. The establishment of attitudes toward food and eating have their first opportunity to develop when feeding first takes place. While it is true that the whole experience is lost in the infantile amnesia, it is not unlikely that attitudes which so often cannot be explained on the basis of remembered experiences are actually preserved from these original feeding experiences. Until quite recently there has been considerable fear of "spoiling" infants by holding them during artificial feeding. We have seen cases in which the mother denied herself the satisfaction of holding the child during bottle feeding because of this fear, quite overlooking the fact that were the child breast fed she would perforce have to hold him. These mothers frequently are very grateful when encouraged to enjoy cuddling the child during feeding.

The care of the infant is a difficult, time-consuming, and tiring task which would probably be unbearable except for the satisfactions that accrue from it. Unless the mother can feel the deep thrill of her love for and joy in serving her infant, she is likely to resent its intrusion upon her. A part of the satisfaction arises out of cultural and developmental factors. She is proud before the community of the accomplishment of childbearing. She may see in the child a sort of fulfillment of her destiny, a recurrence of a feeling commonly appearing at the onset of menstruation. The infant is also a product of her sexual life, and where this sphere is satisfying, the care of the child has a certain sexual significance, giving satisfaction on a sensual-emotional level. Breast feeding binds itself to all three of these areas of satisfaction and thus contributes to the mental health of the well-adjusted mother. It is hardly necessary to add that there are mothers whose cultural and sensual-emotional lives are so restricted and barren that they cannot accept the satisfaction of breast feeding; when such situations are severe, the infant may be protected from the mother who is made tense and irritable because of this intrusion on her privacy of body and be better served by artificial feeding (Fries, 1937). It is perhaps worth while to

mention that, while perhaps above 90 per cent of women could breast feed if they chose, there are those who cannot; these need to be protected from feelings of guilt about their failure.

Attitudes toward feeding are set up not only through contacts with the mother, but also through the timing of feeding in relation to hunger. The theory that the infant is a metabolizing machine running on schedule, which grew up during the highly mechanistic period of medical practice and psychological research just past, led to the establishment of fixed interval feeding schedules unrelated to the occurrence of hunger in the individual child. To be sure, the interval was determined basically from the average time between feedings demanded by infants, but it disregarded two factors: first, that there is wide variation in infants, and second, that patterns vary at varying ages. Gesell (1945) has shown that hunger occurs in a rather random pattern for the first few weeks of life, later settling down into a reasonably regular one. In the individual infant, sticking to an imposed clock schedule results either in frustrating waits or feeding when not hungry, thus serving to contaminate the feeding activity with attitudes deriving from anger at frustration or from ennui. It is to avoid this association of negative attitudes with feeding that has given rise to the concept of self-scheduling, which means feeding the child when it is hungry. It is quite clear that the public at large never accepted rigidly scheduled feeding; recently in a well-baby clinic several mothers admitted in interviews that they fed their infants when they were hungry, but quickly added that they didn't tell their pediatricians since the latter didn't approve!

The introduction of solid food is an event of some significance, again because attitudes in process of formation are associated with it. Solid food is a new sensual experience and requires new muscle movements of face, tongue and pharynx for its management. Furthermore, it runs counter to an important protective reflex present in all healthy infants, the reaction of extrusion which takes place when objects get into the buccal cavity. These and other factors frequently make the child awkward in handling solid foods at first, and if feeding is insisted upon, make it angry so that as much willful resistance as the child is capable of is added to the basic lack of skill. The mother's frustration, if there has not been anticipatory guidance on the point, is likely to be reflected in the infant's reactions, leading to loss of satisfaction on the part of both mother and child. The primary issue is the preservation of appreciation of and satisfaction in the infant by the parents, particularly in this early period by the mother.

A factor in this promotion of appreciation will be satisfaction gained through noticing the development of the child in many spheres such as emotional reactivity, language, locomotion, sensory appreciation of the world about him, and others. Instruction in observing these activities is a mental hygiene function of the well-baby clinic. For the most part, in the past these developmental factors have been used primarily for diagnosis of retarded or accelerated development. While this is a legitimate medical use of such data, it is hardly justifiable for use by parents except in special cases. The competitive character of our culture presses strongly to make all parents strive to make their children better than others. Developmental averages are prostituted to this end, frequently interfering with the satisfaction of the parent in the child. It is justifiable to demonstrate the unfolding growth of a particular

child, stressing its individuality rather than its place in some percentile scale of development.

Locomotor development poses some particular problems, for as soon as a child learns to walk it also learns to climb and explore. This is again an opportunity for anticipatory guidance. Appreciation of the child's development will not be interfered with by too much broken bric-a-brac since such articles have been put out of reach in anticipation of the climbing.

Immunizations have received a good deal of attention as mental hygiene factors (Huschka, 1944) since children frequently respond violently to them. Usually, violent reactions are traced to the parents, the parent being accused of frightening the child and of being frightened themselves so that the child mimics their attitudes. (Later, after speech is established, the doctor may be used as a threat.) Physicians are accused of falsely acting as though there were to be no pain and then suddenly giving a good deal of pain. In the prelanguage period of development it is possible that attitudes are established toward necessary medical procedures which may persist even though specific memory is not present. There is some evidence that medical procedures completed before the age of eight months are not remembered to affect future actions; on this basis it would appear wise to complete as many such procedures before this age as possible (Levy, 1950). A discussion of the impending immunization procedures with the mother before they are to take place, perhaps allowing her to observe the procedure in children other than her own, may help to relieve her anxiety and to allow her to be more helpful to the infant when its turn comes. The physician's attitude will be sympathetic, but matter-of-factly accepting that some helpful medical procedures are unavoidably painful and must be endured by both mother and child. This is undoubtedly more successful than insincere declaration that "it won't hurt a bit" which the doctor's conscience usually forces him to shade with "just a little needle prick."

Associated with the rapid decrease in rate of growth from birth to the middle of the preschool period, and with the change in types of food eaten, there is usually a marked decrease in appetite. It has been amply demonstrated (Davis, 1928) that the child allowed to eat only as much as it wants of a variety of foodstuffs will eat a diet which results in satisfactory growth and development. The difficulty is that the diet selected by the child is likely not to be one fitting the habits of the family in which it lives and, also, that the family is likely to be dissatisfied with the amount the child eats and the time taken to eat it, as well as the way the food is eaten.\* A discussion of the difficult mechanism of handling eating utensils for an organism just learning the extent of its own body, of the balance of muscles necessary for smooth movement, may avoid the irritation that arrives when expectations exceed possible performance, thus protecting the child-parent relationship.

The issue of toilet training brings out very similar problems. It is probable that sensitivity to the fullness of the bladder cannot reach consciousness until well after the child is walking and that about the same time relative control of the sphincters becomes possible for the child. Because of this, there would appear to be little gained from trying to "train" the child earlier, though on an unconscious, conditional

\* The feeding sequence in the film "Preface to a Life" (Mental Health Film Board, Inc.) is sometimes criticized as overdrawn. Clinical experience will, however, show it to be a reasonably accurate representation of the situation in many American middle-class homes.

reflex basis, it is probably possible to achieve bowel movement and even urinary voiding at a convenient time and place. This is aided by the fact that mothers become quite adept at recognizing the early signs of voiding reflexes and "catch" the movement, generously giving the child credit for his interpretation of its activity. Too frequently it is not recognized that the child is unable to exercise any conscious control, however, and failure is likely to be blamed on the child, thus making him an undeserving culprit and putting stress on the home relationships.

Emotional control is, in a somewhat similar way, likely to be expected before the child is able to exercise it. After the child is walking well and begins to have some language, it also begins to develop the notion that it is an individual in its own right and there begins the first struggle for independence from the parent. This is a struggle that will be repeated in adolescence when it will be associated with a great deal of anxiety because of the difficulty of determining just how much independence the child actually needs for his optimum growth and development. At two or three, however, assertion of independence in the period of negativism appears a little ludicrous, and the parent, unless pushed to anger by embarrassment before friends, is likely to look upon the incessant "I won't," "No, No," and "I don't want to," with tolerant amusement. When insistence on action leads to the violent temper tantrum the parent is likely to lose patience completely and fall into punishing procedures almost as preposterous as the child's resistance. Such reactions which leave both child and parent exhausted and frustrated and damage the relation between the two are, to some extent, forestalled if the parent has learned before the first reaction of negativism to expect it and to see it in perspective as the budding maturation of a new and individual person.

Similar reasoning and experience shows its pertinence (Cooper, 1948) may be brought to bear on most of the problems of the preschool child's life. The qualities of possessiveness and sharing, of being able to dress, of delaying washing before meals, of hitting other children, of denying love for the parent, etc., may be handled in the well-baby clinic by foreseeing their probable occurrence in a child and giving the parents a basis for appreciating them as evidence of growth and development, rather than evidence of moral depravity based on devilish disregard of the Fourth Commandment. Preparation may be done individually or in groups in which the more experienced parents can share their experience with the parents going through the difficulties for the first time.

The central theme of mental hygiene as it appears throughout the program of the health department, but particularly in child health programs, is that the physical and emotional development of the child should be appreciated and furthered rather than thwarted and restricted; that development of the person be guided under the attitude that Senn has described as "permissive with limits" rather than confined to some preconceived, rigid path which could not be adaptable to the individual child in question in the light of the known wide variations in children's personalities and rates of development. The aim of mental hygiene is to see to it that each person develops its individual potentialities as fully as possible so that the resulting adult will present maximal health and strength of personality. This is believed to be the best possible basis for the prevention of mental illness as well as all other types of disease in which there is any personality involvement. Furthermore, such a concept is the only one tenable in a democratic society which has as its aim the development

of the individual to his highest capacity in order that the society itself may be borne on the shoulders of strong, healthy-minded individual citizens.

The concepts presented thus far have little apparent relation to the rather complicated psychoanalytic picture of family relationships typified in the Oedipus theory. Such difficult and often not too well substantiated theories are probably not suitable for use by the health officer or nurse. While all the concepts thus far dealt with can be taught only in the setting of warm interpersonal relationship, it is in all probability only in a setting of a much deeper "transference" type of relationship that these drives can be dealt with because they involve such basic emotional values of the parent and child. Deep rejection, serious jealousy of the child or of its relationship with one parent by the other, persistent and exaggerated behavior difficulties which are seen to be symptomatic of the preceding types of parental reactions, are cases for referral to the psychiatrist or child guidance clinic. These more pathological reactions can be spotted early, though too often they are referred late when the reactions are not only present but fixed by habituation.

As the child reaches five or six, both he and the parent will be facing the fact that it will shortly be spending five or six hours a day out of the home. The child, particularly if it has older brothers and sisters in school, will not infrequently hurt its parents' feelings by its obvious wish to get into school and away from home. The mother who has had to live through the difficult stresses of the preschool negativism for more hours a day than the father, may also look forward to the child's being away, though she may feel rather guilty about her conscious partial rejection.

Even though the child who has been allowed to grow into an individual usually looks forward to going to school and is familiar with much of school routine through conversation about the house, it is still likely to feel awed by the enormity of the new adventure—the big buildings, the strange, separate-sex toilets, eating away from home, frequently a bus ride with strangers, a new adult to deal with. Anticipating and recognizing these reactions is the aim of the "preschool roundup," a gathering of children to start school in the fall, the spring before, and their mothers. Mother and child meet the teacher, and learn about the building and become desensitized to it. Discussion of the mother's attitude toward starting a child in school has not been very highly developed, though in many programs, there is obvious tacit recognition of its importance. The physical examination and immunizations that are the usual reasons given for the preschool roundup tend to overlook these basic mental hygiene gains, a more conscious development of them would probably contribute to the family's interest and cooperation in the roundup. It is hardly necessary to point out that the issues of the preschool roundup will have been faced earlier by the mother who has sent her child to a nursery school or day-care center.

These latter two institutions are of real importance to the health department. Usually it is responsible at least for the licensing of the building and grounds to be used by the school or center, and not infrequently it is also responsible for health inspections of the children, at least for the nonproprietary schools and centers. In cooperation with the department of education there is not infrequently some control over types of educational program, selection of equipment, etc., and this trend is likely to be extended in the future as nursery schools more frequently are incorporated into systems of public education. Ideally, the day-care center and the nursery school should have very similar programs, though the former usually cares

for the child for a longer period of time, the mother's working day. Too frequently, for economic reasons mainly, the day-care center will be manned by a less well trained staff and have poorer equipment and housing. The aim of the nursery school is to provide optimum stimulation for the growth of the child from the ages two or three until five. The small families now the fashion in many groups in our culture do not offer sufficient contact with contemporaries during the period when basic attitudes toward sharing, taking turns, respect for the opinions of others, etc., are laid down. Furthermore, many toys that are advantageous for the development of muscles and coordination are too bulky and too expensive for the individual family to own; they can be provided for groups. In addition to these advantages for the child, the nursery school offers an excellent opportunity for the teaching of parent-craft. This is an important part of the work of the better nursery schools. The alert health officer will find the trained nursery school teacher an excellent resource for staff education, particularly of nurses and physicians working in the well-child conference. Though not designed as a treatment agency, the nursery school may offer therapeutic possibilities for particularly severe feeding and relationship problems in selected cases (Blatz and others, 1935).

**School Health Programs.** Throughout the first years of its life the child has spent most of its time in the family circle and has been measured by standards that vary widely. When he starts school he is measured against a large group of his contemporaries, and by methods far more standardized than any used in homes. He is measured against tasks not heretofore encountered and tasks designed to fit the abilities of the majority of the children, though not all. Furthermore, he is measured by persons not related to him and not responsible for his whole life; the teacher may not be objective in judgment, but the prejudices introduced in judging the child are not the same as those of parents. It is perhaps for these and other reasons that most new cases arriving at child psychiatric clinics are older than school starting age, though the problems needing treatment are found to be of several years duration when investigated. Careful work in well-baby clinics in the future will, hopefully, make the sudden increase in recognized problems as the beginning of school life arrives less acute.

The principal problem of school systems is the maintaining of the concept that each child is an individual with unique experiences even though millions of children must be educated. The mental hygiene opportunities in the school are two: first, to safeguard the rights of the child who is "different" and does not fit the educational "production line," however much understanding of variability and appreciation of it the teacher may have, and this understanding and appreciation are major concerns of teacher education. The second opportunity for mental hygiene in the schools is the inclusion in the life of the child of experiences and knowledge that will lead to strong personality structure. Of the two tasks, the first is, at the present time, by far the more easily defined and executed. The second is very much still a matter of experiment and, to be sure, of controversy.

Although it has by no means been accomplished, it is logical to assume that psychiatric diagnosis at least, and perhaps psychiatric treatment, should be a part of the school health program. The school health program, as soon as it leaves the very narrow standard of recurrent, cursory physical examinations for each child and begins to look more widely into the child's life through the nurse-teacher con-

ference and the inclusion of the parent in the physical examination and history taking, inevitably finds mental health problems. For example, in a suburban school it was found that no less than 80 per cent of first graders were considered to be feeding problems by their parents. It is very well known that many illnesses show themselves by changes in behavior before physical signs appear; the teacher frequently sees these phenomena first and when they are recalled to her through the teacher-nurse conference they can be studied. Thus, the school physician will have many more difficult diagnostic problems to solve, and he will find that a good many of them will be behavior difficulties of emotional origin.

Having made the diagnosis, there will immediately arise the problem of treatment. With the improvement of psychiatric training in medical schools and in hospital residencies, both general and pediatric, more and more of this treatment will come within the ability of the nonspecialized physician. We may even hope that with increased skill, the school physician will find sufficient confidence in dealing with mild psychiatric problems that he will not so constantly have to defend himself against accepting any responsibility for them by crying that he has not sufficient time to treat. There will be found to be many cases which require only short treatment to give very rewarding improvement.

There will, however, be a remainder of cases in which more extensive treatment is needed, both of parents and of the child. There is almost nowhere in the world where the cry does not arise that there are insufficient treatment facilities and this is likely to continue for a long time yet to come due to shortages of psychiatric and auxiliary treatment personnel, and also to the fact that treatment remains a slow and therefore expensive procedure when the illness is severe. The advantages of early treatment, before school age is reached, have already been mentioned, and there is no dearth of patients needing treatment beyond school age. For these reasons, it is believed that clinics to treat cases exclusively recognized in the school, are probably not ideally to be made a part of school health programs. Clinics are probably best established independent of the school and free to accept cases from other sources as well. In some cases, they may receive support from the educational system proportionate to the part of the case load originating in the schools. A subtle advantage of the separation of the treatment agency from the school is that medical treatment, particularly psychiatric treatment, is not best performed under authoritarian powers, and, however much the school may seek to keep its standards flexible and pupil centered, the fact remains that there is the ultimate legal authority that children shall go to school, which can hardly help but influence the clinic atmosphere in the minds of the parents and children, if not in the staff itself. On the other hand, it can be easily demonstrated that a clinic under school auspices generally makes more pertinent and easily followed recommendations to the teacher and principal for treatment of children in the school system. It must also be noted that what is probably the largest single organization of child psychiatric clinics in the world is that operated in the New York City schools, and operated rather independently of the school health program. While no objective measure of its success is available, its survival over many years in a budget with strained resources may be interpreted as indicative that it has been successful.

It is probable that almost 1 per cent of all school children need psychiatric treatment because of relatively severe symptoms; perhaps 10 to 20 per cent will

require careful diagnostic survey and treatment of lesser symptoms at some time during their school careers.

Aside from the usual symptomatology of childhood neurotic and conduct disorders, two other issues need to be singled out for special attention: these are the reading and speech disorders, and mental defect. In both cases, diagnosis is usually the function of the psychiatric team of psychiatrist, psychologist and social worker, but in both also, treatment and management are likely to be in the hands of specialized teachers who have the advantages of psychiatric understanding of the child in the therapeutic and teaching endeavor. With speech and reading disabilities, improvement through special teaching methods, combined when necessary with psychiatric treatment, may be expected to result in real improvement in symptoms.

With mental deficiency, improvement in capacity is not to be expected; the goal is rather to make maximum use of the abilities that are present and avoid stresses that make for conduct disorder and other forms of poor mental health. To accomplish this, mental deficiency will need to be diagnosed early during the preschool period for several reasons. In the first place, it is a matter of anticipatory guidance for the parents to make sure that they do not expect too rapid development of the child and that they obtain maximal satisfaction from the advances that are made. Second, the mentally deficient child requires care in the "dosage" of stimulation it receives so that it will not be inundated by massive doses that it cannot use profitably. The stimulation must be adjusted to promote maximal development within the range of the child's capacity. Obviously, planning for the mentally deficient child's schooling will also depend upon early diagnosis; the conclusion that the child cannot handle ordinary classroom work can and should be made before long series of frustrating failures have added behavior disorder to what might have been a healthy though intellectually limited personality.

The second aim of mental hygiene in the schools is that of helping each child gain the strongest personality structure possible for it. This is the broad aim of all education, educational theory having gone far beyond the more narrow ideal of simply teaching a child certain facts and methods, however much this older ideal is still seen in actual practice. The newer ideal in education means that in the education of the child the facts of actual living will have to be dealt with as well as the three R's and their elaborations. The problems presented are by no means easy to solve.

Very broadly they are attacked by two major methods: first, the selection of teachers whose sound mental health will serve as an example and set the ideals of the child; second, by training these teachers to have an understanding of the emotional and developmental life of the child so that she can lead it toward the soundest development. The methods by which these tasks are to be accomplished are by no means fully known or standardized (Prescott, 1938; Ryan, 1938; Pyle, 1939).

Certain specific schemes have been developed for promoting mental health which must be mentioned briefly since they are resources to which the school health officer may turn. The first of these is counselling. Begun as vocational counselling for adolescents about to leave school, the system has spread to include persons specially trained for dealing with individuals even at the elementary grade level. The visiting teacher system has developed to make personnel available for attitude-changing through their education and experience in social work. The truant officer has changed

from an attendance enforcement officer to a person who attempts to discover and change those attitudes which make school attendance difficult for the child.

The idea that there are certain generalizations about emotional life than can be taught and certain experiences which are helpful to any child has been incorporated in teaching to some degree. Homemaking courses for both boys and girls attempt to teach principles of family living as well as methods of budgeting, how to clean a house, and how to bathe a baby. Marriage courses, begun in colleges where they were found to be highly successful when conducted in an informal, frank and friendly manner, have begun to appear in some senior high schools. Vocational training has begun to consider not only technics of handling materials and machines, but also how to get along with fellow workmen and the boss.

The human relations class (Bullis and O'Malley, 1947, 1948) is a specially arranged series involving discussions of emotionally charged situations with which the child can identify and yet see objectively enough to make a reasonable analysis of them. It offers opportunity for the child to set attitudes toward similar situations that may arise for him in the future. He may also get the habit of understanding and being tolerant of views divergent from his own, and can come to the realization that emotional isolation is largely a matter of not knowing how other people feel rather than that they do not have feelings similar to those troubling the individual himself. There are other schemes in which the general idea that sharing emotional experiences is helpful is worked out in classroom procedure specifically set aside for it.

A second method with the same aim is the incorporation of living emotional material in classroom material (Ojemann, 1946). Although there are many other levels at which this may be done, a convenient example is the study of Shakespeare's plays. Lear and Polonius are examples of old men—they could be discussed in terms of attitudes toward older people in the population. Othello's paranoid thinking and feeling can be the basis for a discussion of jealousy and its effects on family life. The passion of Romeo and Juliet is a topic difficult to deal with but very real to adolescents and very near to experiences that may be deeply disturbing; perhaps they would be less so if completely discussed. Racial prejudice is very much available for discussion in Shylock, the rights of women in Portia. Examples are legion and need to be elaborated no further, nor is it necessary to indicate that if such discussions are to be held, the teacher must be prepared for them. It is not unlikely that the teacher will need the help of the nurse and physician, perhaps the psychiatrist occasionally, in such ventures.

Sex education is a special problem of teaching that is frequently referred to both public and psychiatric personnel. While still a very controversial issue, there appears to be a growing sentiment that the school shall have some responsibility in sex education, either directly, by teaching the child the biology of sex and attitudes toward its functioning, or indirectly, by teaching parents and thus making the material available to the child. There would appear no good reason why the anatomy and physiology of the reproductive system in the human should not be taught as a set of facts on the same level of importance as the anatomy and physiology of the gastro-intestinal tract. The difficulty is, of course, in the area of emotion and attitudes; perhaps the basic difficulty is that most teachers, indeed most parents, are so unused to facing issues in this field directly that they are totally unprepared to face them with children. The motion picture films in the field of sex education

(National Institute of Mental Health) are very helpful in preparing adults for this task, and when these are prepared, for beginning discussions with children. The emotional concerns associated with the pubertal growth spurt offer a field in which knowledge of the developmental pattern can relieve the anxiety and feeling of isolation normally aroused in the child who is much larger or much smaller than his contemporaries at a particular time.

The mental hygiene aspects of the school health program comprise two problems: first, that of the "case" and its treatment; second, the teaching of as yet not clearly defined mental health principles to all children and their teachers. The technics for the former, although subject to improvement, particularly in attaining less costly and time-consuming treatment methods, are well known. Whether the therapeutic service should be a part of the school itself or a community service used by the school once diagnosis is made is a moot point, in general, best resolved in favor of the latter type of organization. Mental health education consists in helping the child gain certain knowledge and to undergo certain emotional experiences shared with others. The technics for this sort of work are not standardized, but invite responsible research.

Mental hygiene in education is actually broader than indicated above. It includes concern about the size of classes, the condition and quality of books, the freedom of the teacher from coercive, undemocratic administration which robs him of satisfaction in his work, the inclusion of the creative arts in the educational program, as well as many other issues with which educators themselves are primarily concerned. In the presentation above, these issues have not been discussed, not because they are not important, but rather because they are implied as extensions of the attitudes set forth as more specifically defined mental hygiene.

**Industrial Mental Hygiene.** Industrial hygiene has, for the most part, not included any mental hygiene in its program. What development there has been in this field has been too often separated from programs of industrial health or medical services initiated by the industry with the cooperation of individual psychiatrists or personnel experts. It is typical of the mental hygiene in industry that it flourishes in times of labor shortage, when the objective is to keep every possible worker producing at his highest possible level, and that it tends to lag whenever the labor market is easy. This situation brings to the fore some interesting ethical problems, not properly discussed here.

The principal problems mental hygiene in industry attempts to relieve are absenteeism, labor turnover, and high accident rates. Usually high rates in any of these factors indicates low "morale" in the industry. Since standards are extremely difficult to establish for any of the factors, it is quite frequently difficult to define exact aims for a mental hygiene program in industry; too often programs are begun and proceed for years without knowing the base line from which they began, thus excluding the possibility of evaluation. A notable exception to this is the "Hawthorne Experiment" reported by Mayo and his co-workers (1933), and Roethlisberger and Dickson (1942). Perhaps the most important problem in the field is the establishment of relatively standardized methods of reporting the three basic factors so that they reflect sensitively the known changes that take place under various social conditions within the plant and also of various recruitment methods.

The fact that increased production by the individual worker is the indirect aim

of mental hygiene in industry brings up some difficult problems. It makes the mental hygienist the ally of the industry, and from a rather narrow point of view, the enemy of the laborer whose production is to be increased. The fact that increased production is the indirect result of better health may be missed and must constantly be stressed if direct opposition from unions is to be avoided. Attempts to solve this problem by promoting programs of mental health in the unions themselves have been made, but so far as is known have not achieved broad adoption. Ideally, of course, mental hygiene per se should be independent of both management and labor and apply equally in practice to both; practically, since management foots the bills, this is difficult to achieve though not impossible for those industries in which management is able to take a genuinely long-term view of its place in society.

Low morale in industry is usually found to be dependent upon two factors: first, a lack of understanding on the part of the workmen of the constructive aims and objectives of management; and second, on the personal interrelationships within the industry and in the workman's personal life. The first problem is one of communication. This problem hardly exists in very small industries when the owner is actually a fellow workman, but it presents a difficulty in large industries where there must be a hierarchy standing between the workman in the plant which may be thousands of miles away from the executive officers which control its aims and objectives. There is the foreman, the departmental supervisor, the plant superintendent, the vice-president, and frequently many others through whom communications with the "top management" must be carried out.

This issue has been attacked primarily by setting up management discussion groups which cross executive levels. In these groups the agenda do not include exclusively problems of the mechanics of production, but also include issues of employee-management relations. The rates of absenteeism and of accidents become subjects for concern as indicators of the condition of the industry's health, and as indicators of ill health in particular areas. There can then be a diagnosis of the problem and relief of it; this usually takes the form of better relationship between management as represented by the foreman, and the man at the bench. The scheme was most clearly worked out under the stress of wartime conditions and reported by the War Manpower Commission (1945). The Army furnished very numerous examples in World War II of the importance of the ordinary soldier knowing the aims of his superiors whenever possible. A special case in this area is the removal for treatment of the executive who has become psychiatrically ill or emotionally disturbed to the extent that he forms a focus for the epidemic production of low morale or actual emotional illness on the part of the workers (Giberson, 1940). Psychiatric treatment of an individual in this situation becomes an issue of prevention of disease for the group; indeed the treatment of psychiatric illness in the industrial setting has this as one of the important goals, the other being of course, the restoration of the worker to full productivity as rapidly as possible.

The second area of concern of mental hygiene in industry is low morale due to difficulties in personal interrelationships within the industry or in the family life of the individual. It is well known that family strains frequently have their origins in financial stress and it is to avoid such stresses that there are loan funds and other social services available through many industries; these are not usually identified as mental hygiene efforts though they act to relieve acute stresses on the individual.

The Hawthorne experiment demonstrated a clear relationship between the personal situation of the individual workman and variations in productivity, and developed a counselling system whereby the workman could, through interviews, share his problems with a neutral person and come to some solution of them more rapidly than would have been the case otherwise. Within the industry itself, improvement in personnel management by foremen appears to be the primary issue. The foreman is taught to judge situations in terms of the man rather than the mechanic, of the laborer rather than the labor, of the worker rather than the work. This is a more practical method of dealing with the problem for any but the largest industries. Foreman education in dealing with personnel has received considerable study and the methodology in this field is reasonably well standardized (War Manpower Commission, 1945).

Mental hygiene in industry offers some relief from the problems of labor turnover, of absenteeism and of excessive use of sick leave. It offers the possibility of control of epidemics of emotional distress traceable to a psychiatrically ill executive at whatever level. It offers the possibility of cutting down on accident rates by correcting some of the tensions which make for random rather than planned and coordinated movements and for inattention on the job which appears to be responsible for many industrial accidents.

Selection for jobs is not usually a matter of psychiatric concern in industry except on rare occasions where it may be involved in executive selection. Generally, selection is in the hands of psychologically trained personnel who use the techniques of their profession for placing workers according to intellectual and aptitude qualifications. There is increasing concern about fitting people to jobs which can afford not only satisfaction in pay, but emotional satisfaction as well, of placing people according to personality qualifications broader than those inherent in intelligence and aptitude. Thus, the gregarious person is placed in a team operation, the person who wishes to work alone is given an individual operation to perform. For the most part, this latter type of personnel selection is not well standardized. The mental hygiene aspects of personnel selection are obvious and need hardly to be discussed further.

**Mental Hygiene in Housing.** The relationship between family life and mental health has already been indicated, though far from exhaustively discussed. The opportunity for premarital counseling in connection with the serological test for syphilis mandatory before marriage in many states, cooperation with the courts in the study of threatened marital disruption, the counseling of couples who wish to adopt children or who wish advice regarding hereditary stigmata they hesitate to pass on to their children, are all areas that invite service or at least experimentation as possible services of official health agencies. As medical care programs are extended and the health department extends its cooperation in the health problems of many families, further opportunities for counseling, case finding, and in some cases psychiatric treatment will become apparent and pressing. Inasmuch as the mental health of the child is so largely a problem of the healthy living of the family, concern for the family will probably be extended in the years ahead. Inasmuch as housing so markedly affects family life, and is already a subject of concern to public health, it is appropriate to include a brief discussion of the mental hygiene of housing here.

In general, it may be said that housing ideals from the standpoint of physical

health will also, in all probability, be quite satisfactory to the mental hygienist as well. Such housing will afford maximum convenience as a means of avoiding excessive fatigue. It will provide sufficient space to offer privacy. It will be planned to include recreational space for physical exercise and allow creative activity. It will be clean, the basis for attractiveness, and be inviting, offering a place for family association. These are basic elements for healthful living for the whole man; mental hygiene has few suggestions to add.

It is a moot point whether slums are the result of poor economic conditions which are in turn due to the low quality of the people who inhabit them, or whether illness, mental or physical, acute or chronic, personal or having to do with the general economic structure, leads people to subside to a frustrated condition so that their homes become slums because of their lack of care. It is not difficult to understand how a family forced into substandard living conditions by acute adversity might find unbearable the eternal frustrations of trying to make a slum house livable and would eventually become apathetic and cease to try to improve. It is easy also to understand that children raised in slum dwellings might well reach adulthood with no other ideal for living than that in which they spent their childhood, or with no understanding of another type except in the fanciful, unavailable luxury palaces of Hollywood, or the almost equally ideal model house and kitchens used for teaching home economics in many schools. Whatever the eventual solution of the dilemma, it is clear that efforts must be made both in the direction of improving housing and of improving the quality of the people who live in the houses.

Ideally, homes should be varied enough so that they can satisfy the wishes and needs of particular families. Thus, some homes will be separate houses, others apartments or multiple dwellings. It is, of course, economically impossible to allow for such selectivity at this time. Cheap production dictates that houses shall be practically identical. It is fair perhaps to point out that the difficulty may be in economics and not in people, that changes may be indicated in the economic situation so that the satisfaction of human needs may come within the range of economic possibility. To some extent this is already happening in the programs of government housing. It is a remarkable fact that almost every ship built, except under the stress of war-time production, is designed for a particular job, whereas houses have relation to the particular family they are to house only for a very small proportion of the population living very high on the economic scale. As one looks at the seas of two and three bedroom houses now being built, and the skyscraping apartments with a thousand identical living spaces, one can sympathize with the definition given by a biologist. Riding past a development, he poked his thumb out the window and exclaimed, "Breeding pens!"

There are things to be done, however, even within the limits of the present economic setting. When it is uneconomic for each house to have space for the husband's workshop, it is possible to have shared space operated along the lines already established in communal laundries in apartment houses. This has advantages not only in furnishing a place where creativity frustrated in production line work can have a place to flower, but also makes possible the development of friendships between families and an opportunity to avoid expensive commercialized recreation. Playgrounds too expensive for single families can be established for larger housing units; at times the situation will even support a supervisor for them; this is

likely to be necessary where the mother can see her child only by looking out of a tenth story window and cannot afford the time to stay at the playground with her youngster. Nursery schools provide opportunities not available for individual families and should be an integral part of large housing units. The human animal has remarkable powers of adaptation, but it seems logical to expect that it will need some reminders of its former terrestrial life during its adaptation to living on concrete and terrazzo. These suggestions are designed to aid the adaptation.

Furniture is, of course, to be designed for durability, ease of cleaning, comfort, and beauty; but a study of any home will show furnishings that are uncomfortable, ugly, and full of dust-catching crevices because the family has become attached to them. They have become personalized in some way. This factor is receiving more recognition constantly in cases in which people must leave their own homes and go to institutions to live; they are being allowed more and more to bring with them favorite chairs and other items of furniture. Similarly, children entering hospitals are encouraged to bring a few favorite toys with them—this is extended in some pediatric hospitals to where one parent is invited to stay with the child during a short hospital stay. Planning for housing must recognize these essentially irrational patterns of behavior in human beings if people are to have homes rather than mere houses.

The attachment to a house itself is a major problem that invites a great deal of careful research. How widespread the phenomenon is has not been determined, but psychiatrists see cases in which distinct emotional depression follows moving, even though the move be to better rather than worse quarters. Moving is apparently a traumatic experience, probably symbolizing the tearing of ties in which places have been associated with experiences. Such ties are probably as strong in a slum setting as they are in higher grade housing and this sort of factor as well as the economic ones usually cited may account for the surprising finding that people may have poorer health when living in good houses than they had before they moved. Another subject for research in this field lies in what appears may be a higher rate of mental disease in children of families which live in various foreign cultures when the children are young.

**Mental Hygiene in Special Programs.** The multiplication of categorical programs in public health practice has introduced new problems of mental health that are not yet fully understood and which are difficult to discuss in a general way. In the first place, the programs which are most successful in capturing public interest and support are those which have tremendous symbolic as well as realistic significance. The heart is not only the primary organ necessary for life to continue, but it is also the word used to convey many of the deepest human feelings. It is the symbol of love; in the expression "my heart was in my mouth" it conveys fear and apprehension; through its association with blood it expresses rage in "I saw red." Poliomyelitis appeals not only to pity for the crippled, but capitalizes as well on the guilty satisfaction one has that "Thank God, I am not so deformed." That cancer is pictured as a crab, a word with multiple meanings, with all the age old symbolism that attached to that crustacean, probably accounts for some of the success in arousing public interest in the illness quite apart from its position as a statistically important cause of death. The exact mechanisms through which these factors bear on preventive and curative programs in these and other categorical programs are not

fully known. It is, however, clear that they deserve attention since such programs will certainly arouse a great deal more feeling than simple willingness to be certain of health status. Very few programs have achieved the note of victory shown in the tuberculosis poster of the girl waving the clear x-ray and happily shouting "It's great to be healthy." Most still rely on the negative predictions of disaster such as the "Tenth Man" of mental illness or the "One in Eight" of heart disease. One of the most difficult problems of health education is to balance the anxieties aroused by publicity about disease by the reassurance that follows examination or the satisfaction that comes from giving money for a cause.

Cardiac programs for children demand consideration from the mental hygiene standpoint. The child is made to act differently from its contemporaries and, unless particular care is taken, it may be denied stimuli necessary for its personality growth and development. Such stimuli will come from home teaching, occupational therapy, and care that family contacts are numerous and easy. While the ideal is that the child shall be afforded the same opportunity for social life as normal, it must be noted that this will require special effort on behalf of the child, since the illness and its treatment isolate the child from many ordinary stimuli. On the other hand, the best mental hygiene for the person in some cases of severe crippling which will likely be chronic, may be to deprive him of some stimuli in order to leave aspects of the personality undeveloped. It has been demonstrated that this happens in some instances, whether by design or accident. It would certainly appear wiser, for example, to avoid development to the level of the adolescent drive for independence in the individual for whom economic and personal independence is not imaginable. This is a special case of vocational guidance.

In the diseases affecting the young adult, of which the prototype is tuberculosis, the question will not be one of insuring or guiding personality development so much as helping an already formed personality to adapt to new circumstances and a new concept of itself (Coleman and others, 1947). The independence and feeling of self-competence won during the period of adolescence must be exchanged for an attitude of acceptance of dependency for a period, and the vanity of pride in health and self-sufficiency must be sacrificed for the period of cure and modified for a long period of years. The recognition of such factors in the clinic, together with the social and economic factors, will probably aid in recovery and make rehabilitation less difficult. It is probably wise to work out as many of the "reality problems," of how the dependents are to live with the patient so that as little independence as possible is lost. In most democratic governments treatment and restoration of health for the person contracting tuberculosis is not only a right of the citizen, but it is also the citizen's responsibility to exercise his right.

Leaving a tuberculosis hospital presents almost as many problems as entering it, and many of these have mental health components. Discharges against advice make up from 40 to 60 per cent of all discharges from such hospitals. The reasons for this high percentage of cases in which treatment is interrupted probably lie in too little attention to personality factors and environmental problems upon admission, as mentioned above, but also in inadequate medical care for the whole person in most hospital programs. This may be supplied through better occupational and educational therapy in hospitals, by better social work and by more extensive use of psychiatric consultation both with regard to individual patients and in the design of

the hospitals' general program. On the other hand, there are patients who fail in the attempt to leave the hospital, including those whose disease relapses when cure and return home is approached. The need for psychosomatic care in such cases is particularly clear (Hartz, 1944).

For a disease where the modification of mode of living is not only for a period of months but for life, the problem is not of preserving ambition to recover but rather for the modification of existence so that disability will be as little as possible, considering the pathological process underway. In diabetes, the modification will be permanent, but will affect few of the activities of the person. It is quite clear, however, that the modifications that are necessary may be a heavy burden for the person, and that abandoning treatment is a constant temptation, perhaps to be compared to the recurrent yearnings of the alcoholic to drink (Rosen and Lidz, 1949). Beyond this restless tendency to abandon treatment there is to be considered the modification of metabolism that takes place under emotional stress, modifications which may tend to make the prescribed, standardized treatment for the patient recurrently ineffective. These factors can only be approached through the method of dealing with the person through the methods described under the section above on the basic technics of mental hygiene.

In cardiac disease of older persons, as, indeed, in all aging processes, the issue is not one in which some relatively simple procedure may restore health completely, but rather one of a permanent modification in way of life and, perhaps, adjusting to the idea of death in a more intimate way than is necessary for the population as a whole. Again it is necessary for a radical readjustment of the patient's picture of himself to take place if he is not continually to be kicking against the brick wall of the restrictions placed upon him. The cardiologist would be delighted if he could achieve the sense of resignation to the impossibility of physical exertion that was so apparent in some of the soldiers seen in World War II. Many of these men had been raised on the idea that they needed to protect themselves from exertion from early childhood. The fact that study showed the early diagnosis of severe heart disability was false failed to shake their conviction that they must not exercise. Too often the concept contaminated all their lives and they were unable to do anything except care for their nonexistent heart disease and cherish their very useful neurosis.

When the problem is cancer, the issue is much different since, when the diagnosis is made, some action is necessary and is usually willingly carried out. If the curative action is not effective, there is no problem of rehabilitation, but rather one of making death as comfortable as possible and the intervening period of life as productive and satisfying as possible. The problem of the patient's knowing when an illness is a terminal one is an ancient one; many psychiatrists are beginning to feel that many more humans are heroic souls than used to be thought, and that most patients might well face death rather than be hypocritically shielded from the fact of its approach. This is a question of practice each physician has to deal with for himself and for his patient; the judgment certainly lies in the area of the mental health of both.

If the disease is cured, the rehabilitation problems will be relatively easy unless the patient has been maimed as a result of treatment. Then the issue will, of course, be the same as for the crippled or the plastic surgery patient, an area which has been extensively investigated since the war.

It may appear odd to speak of the mental hygiene problems of psychiatric illness but there are many, both for the patient and his family (Stern, 1942). The patient who has recovered from a psychiatric illness requires a great deal of rehabilitative effort, for his self-confidence is extremely severely shaken. He cannot blame an impersonal organ such as lungs or pancreas for his illness; it is a loss of compensation of his very self, his personality, that he must face. Nonpsychiatric efforts at the rehabilitation of such patients is very new and, while promising reports have appeared (Rennie and others, 1950) much further experimental work is necessary. For the family the problem is also a difficult one, because psychiatric illness frequently gives the impression of purposiveness which results in the blame of the patient for his illness. It is perhaps this factor which keeps the stigma of mental illness so strong in popular thinking. The patient is blamed for his symptoms and the family also feels some guilty responsibility for it as well. Dealing with such issues is not impossible, but since it is the personality itself which is the seat of the pathology, the problem is more complicated than in diseases on simpler levels of function.

One of the most common problems encountered by the psychiatric consultant to a health department is how to deal with the announcement that a repeat x-ray is required of a suspicious condition picked up in a survey. Is it possible to write a letter that will bring the patient in for the check-up but not alarm him unnecessarily and in a way that is not medically warranted? People, although they should know better after centuries of experience, do not expect physicians to make mistakes, and they have little tolerance for the fact that the mechanical aids to medical practice do not result in absolutely reliable findings. This being the case, there appears to be no way to avoid their anxieties when they are informed of the necessity for recheck. The problem is simply to keep this anxiety to as small a group as possible, and reduce it to a basis for action as soon as possible. Thus, every effort should be made to get the question settled quickly. As short a time as possible should elapse between the survey x-ray and the recheck—the patient's anxiety and resentment will be the greater if he thinks he has been allowed to carry his suspected disease for weeks during the red tape of processing the survey films. He will probably have little patience with personnel shortages that dictate this delay and may quite correctly come to the conclusion that a better administrative procedure ought to be worked out. When the announcement that recheck is necessary is made, it would probably be better to make an early appointment or suggest two definite alternate dates and hours rather than simply give the days and hours when the recheck can be done. This will give the impression that the patient himself is being considered, and that he is no longer one of a horde being x-rayed, but an individual selected for special study for definite reasons. The recheck should also be read as soon as possible and the information it reveals shared with the patient. If he is to get this from his private physician, a system should be worked out so that a definite appointment for this also is made at the time the plate is taken. It is necessary to arouse anxiety in order to get the diagnostic action necessary. Inasmuch as this may be useless anxiety, it should be relieved as soon as possible, and it should be tied to action designed to relieve it when it is aroused, so that if it is unjustified, the patient may be relieved completely, and if justified, further action can be taken.

The issues drawn from experience in tuberculosis surveys are applicable to other diseases as well. In diabetes surveys based on the determination of reducing

substances in the urine it has been suggested that the rate of false positives is so high that the anxiety aroused is of greater detriment than the advantage of the actual cases found. Whether this be true or not depends on one's philosophy of medical practice and public health, not on any good data at the present time. The significance of the disease in the life of the individual and the state of public knowledge about the disease in question must be considered. The public knows that diabetes is a controllable disease and a relatively large number of false positives does relatively little harm, whereas false positives in tuberculosis or cancer surveys may be of the very greatest importance in the personality function of the individual.

Finally, there are the programs of polyphasic screening, and particularly those that include a psychiatric test in the screen. Except for the psychiatric aspect, the problem is the same as discussed above, except that the administrative problems of error and time lag are increased in the polyphasic process. They are not less important in this case, however. As a generalization, it may be said that any person who fails to pass a screening test can no longer be treated as a member of a survey group; he must be considered as an individual and if the administrative structure fails to do this or is unable to do it, the survey itself should be abandoned.

Psychiatric screening with the present state of knowledge is impossible, and even if it were possible, there is every indication that the number of cases discovered would be so large that it would be impossible to adhere to the generalization at the end of the last paragraph. Polyphasic screens should not include psychiatric screening devices except under the most rigorously controlled experimental conditions and these should be used as a means of testing the screening devices and not as a means of "discovering" psychiatric illness or personality maladjustment. There are no tests now extant which are fully validated. This paragraph is not designed to cut down on very necessary, in fact, invaluable research, but this research must not arouse anxieties which psychiatry is not at all prepared to meet. As almost every administrator who is responsible for a psychiatric clinic service will testify, these services are almost invariably overloaded. Cases discovered by screening methods could not be crowded into the case load at once, but would only serve to make waiting lists longer. It should be repeated, however, that these considerations do not apply to frank research efforts set up to include the necessary care for the case found.

**Geriatrics.** Mental diseases of old age are usually secondary to organic degeneration of brain tissue, either primary degeneration or secondary to arteriosclerosis. This being the case, it might be assumed that the problem is a hopeless one prophylactically unless the basic brain pathology can be arrested or reversed. The situation is, however, not as hopeless as it appears, since there are contributing factors that may avoid and often cure the psychosis. The situation seems to be that degenerative changes lower the reserve of the brain and personality so that under stress, the personality becomes decompensated. Anything that relieves stress or tends to give support to the brain or the personality will probably be helpful in treatment and prevention. Two areas stand out as providing means for this support: nutrition, as discussed elsewhere in this volume, but it is perhaps appropriate to point out here that pellagrous psychoses frequently occur in old people and that they also frequently respond very promptly to treatment. The use of nicotinic acid as a vasodilator

tor of brain vessels is also reported to have improved brain function and thereby relieved psychotic symptoms.

The mental hygiene technics which appear to have been most effective in preventing psychoses of old age are those which offer stimulation and companionship to the elderly. Very often the aged do not fit well into the social situation \* and are lonely because they have too little opportunity to see others whose cultural background is that of their generation rather than that of their children's. Efforts to bring groups of older people together for work, intellectual stimulation and for recreation is a logical extension of health department services. This is done nowhere as an official function of the health department, but it is, nevertheless, the sort of effort that a health council might well wish to sponsor through a voluntary agency. Technics in this field are rapidly being worked out; the problem offers handholds of method and basis for further experimentation.

**Summary.** The attitude changing technics of mental hygiene are necessary for the success of most public health programs; most of the success of public health depends upon attitude changing or attitude development. The purpose of this section has been to give a few examples of using the technics and viewpoint of mental hygiene more widely in public health clinical, and, to some extent, nonclinical programs.

## THE EPIDEMIOLOGY OF MENTAL DISEASE

There seems to be a notion prevalent that nothing or very little is known about the epidemiology of the mental illnesses. This is true only in the sense that epidemiology has not solved the basic etiological problems of the most numerous and resistant types of mental disease, not that associative factors are unknown. It is also due to a tendency to remove from the concept of mental illness those diseases on which the epidemiological knowledge can lead directly to programs for prevention. Few people except the psychiatrist who has it to treat, consider paresis a mental disease; it is thought of rather as a late result of syphilis. The epidemiology of traumatic psychosis is as clear as the epidemiology of other types of accidents; it is precisely the same. The brain rather than the brawn is damaged. The mental deviations subsequent to meningococcus meningitis have the epidemiology of that disease. The list can, of course, be extended to include birth injuries, the sequelae of the encephalitides, some of the blood dyscrasias, and many others. Perhaps precisely because etiology and epidemiology of these diseases are relatively clearly understood, they tend to be looked upon as something apart from the larger groups of mental diseases.

But even for the most difficult psychiatric problem, that presented by the schizophrenic reactions, a great deal is known. Incidence of these diseases is known to be about the same in all populations thus far carefully studied, that is, in the neighborhood of 1 per cent all life incidence. All life prevalence is higher since the reactions appear early and are frequently chronic. The reactions occur more frequently in the rooming house areas where individuals tend to live alone and show a high mobility (Faris and Dunham, 1939). These reactions occur more frequently in the lower

\* See "Old Man Minnick," Ferber, Edna, in J. Strode (ed.), *Social Insight Through Short Stories*, Harper and Brothers, New York, 1946.

than in the higher economic groups, but it is not clear whether these latter two findings are due to the type of person in these groups, or whether the low economic status is the result of the symptoms of the disease. It appears that manic-depressive psychoses are somewhat more prevalent in the more responsible personality types, at least in relation to the amount of schizophrenia if not in actual incidence (Tietze and others, 1941). A great deal is known concerning the incidence of psychoses in various immigrant groups; these studies tend to indicate that the strains of acculturation increase the incidence of some types of psychoses, though there may be a relation also to the factor of the personality that leads to major migrations such as those across an ocean (Ødegaard, 1936). Alcoholic psychoses vary extremely widely in incidence in national groups, usually corresponding to the cultural pattern in those groups (Malzberg, 1940; Dayton, 1940). It is very interesting to observe the very marked difference in this regard between the figures for alcoholic psychoses in Italy, which are quite low, and those of Switzerland contiguous to the north, which are very high. This is probably related directly to the fact that little hard liquor is drunk in Italy but much wine, while in Switzerland, both wine and liquor are included in the drinking habits of the people.

The demography of the neuroses is much less well known since for these diseases hospitalization is rarely required. All of the careful studies now extant, tend to indicate that neuroses are less prevalent than psychoses, though common observation shows this to be completely false. The problem involved in accurate estimation of the prevalence of neuroses is the difficulty of definition of the illness; it is extremely difficult if not frequently impossible clinically to differentiate clearly between the "normal" and the "neurotic." No tests are available that are well enough standardized to use for surveys of population, and to get clinical judgments on any large segment of the population is a very expensive undertaking. There is some evidence that the complaint of "nervousness," as used by the public, is probably synonymous with "neurosis"; if this be granted, then the occurrence of neuroses in the population, so far as actual studies of prevalence are concerned, is between 1 and 2 per cent during any one year (Lemkau and others, 1941, 1942, 1943). Clinical estimates based on data from practicing psychiatrists and general practice case loads vary extremely widely and furnish little basis for confidence. Perhaps the most generally accepted figure is that 0.8 per cent of the population is neurotic to such an extent that treatment is indicated (Cobb, 1943).

Mental deficiency, largely because the modern intelligence test makes it possible to measure this faculty with relative ease and accuracy, has been studied extensively. It is known that rural populations show a relatively larger prevalence of mental deficiency than the urban areas, a fact not yet fully explained but possibly related to educational stimulation, to selective migration, and possibly also to inbreeding due to the relative isolation of some rural communities. Mental deficiency, defined as including those with I.Q. less than 70 "or the existence from birth, or from an early age, of mental defectiveness so pronounced that the person requires care, supervision, and control for his own protection or for the protection of others, or, in the case of children, that he, by reason of such defectiveness, appears to be permanently incapable of receiving proper benefit from the instruction in ordinary schools."

\* Definition from Report of the Mental Deficiency Committee, Part IV, His Majesty's Stationery Office, London, 1929.

occurs in the general population in from 1 to 2 per cent. It is reported as very much more common in children than adults, the reason probably being that the demands of the social order are less severe than those imposed by the requirements of success in school and to some minor extent because life expectancy is reduced in severe mental deficiency.

From these data and from experience in the practice of the care of the mentally deficient and mentally ill, it may be said with some degree of certainty that the community will require a minimum of one bed in psychiatric hospitals for each 200 of the general population and one bed for each 1,000 for the care of mental deficient.

This discussion of the demography of mental illnesses is by no means complete nor does it exhaust the literature in the field. What is attempted is simply to furnish some basic observations necessary for community planning in those areas where data are clear cut and positive.

There are particular problems in which it is clear that action based on epidemiological facts will in all probability decrease mental illness and distress; there are many others where mental hygiene efforts are justifiable on the basis of relieving distress for the particular patient and his family but the relationship to actual mental illness requiring hospitalization is not demonstrable.

The psychoses of old age represent about a third of all admissions to public psychiatric hospitals. Changing economic and social conditions in many areas, as well as because the population itself is aging, urbanization, changes in design and in the economics of housing, the changes in cultural attitudes toward the solidarity of the family, earlier retirement and the failure of the elderly to be able to find remunerative and satisfaction-affording employment and inadequate medical and nutritional care; all of these appear to be contributing factors accounting for the rise in the psychiatric hospitalization of the aged.

The demography of the psychoneurotic and other disorders not requiring hospitalization has already been discussed. Absenteeism and labor turnover in industry are known to be due in many instances to neurotic illness as well as to character disorders of other sorts (Frazer, 1947). Industrial mental hygiene can reduce these factors and can increase production, though no studies have as yet clearly demonstrated the financial advantage of such efforts to industry. There is no doubt that the programs are of advantage to the worker, however, and contribute to his morale. The fact that departments of industries in which the leadership is poor produce more "cases" for the psychiatrist than those with "good" leadership has been adequately demonstrated. Clinical observation indicates that the health service of industry, like that offered by the general practitioner, is to a large extent used by employees as a treatment center for emotional distress, even though they, and, unfortunately, frequently the medical staff as well, are unaware of the fact.

It is quite probable that there is an epidemiology of mental illness and emotional distress associated with most cultural environments and social conditions—poverty, housing, the concept of continuous advancement, the idea of universal education, etc. It is an unfortunate fact that difficulties of measurement both of these conditions and of the incidence and prevalence of mental disease, as well as the fact of multiple causation discussed earlier, have not yet yielded sufficiently to make many of the current statements in these fields reliable except in terms of clinical opinion. These

considerations do not, however, relieve organized public health from responsibility for conducting research in the area; they should rather point to the need for critical but also for creative thinking about the methods needed to do the necessary researches.

Even more remote from the area of mensuration by methods now known, is the epidemiology of fads, general anxieties, panic reactions, styles, political concepts, etc. The history of the world of the last five decades indicates how urgently knowledge in such fields is necessary. To be sure, the matter approaches philosophy and implies a definition of the goal of all humankind, but it is improbable that any citizen can escape responsibility in this area now. Perhaps the most pressing need at the moment is for an epidemiology of reaction to disaster. Studies are under way on this point and already appear to be furnishing some new understanding in the area (Cameron, 1950; Tyhurst, 1950).

### PUBLIC HEALTH ADMINISTRATION IN MENTAL HYGIENE

Administration in mental hygiene is somewhat different than in other public health programs because it inescapably involves general administrative practices within the department as well as a service to the public. The concept of working *with* a patient or client rather than *on* or *for* him demands that this same attitude be present in the administration of the department itself. Unless the department is prepared to practice good industrial mental hygiene, it cannot expect to find good mental hygiene carried out by the staff with clients and patients. The attitude of the administration will inevitably find expression in the staff-patient relationship.

Mental hygiene programs generally consist of three parts, staff education, the incorporation of mental hygiene in clinical and other services of the department not specifically called mental hygiene, and, finally, psychiatric diagnostic and treatment service to patients.

Staff education in mental hygiene is of two general types. The first has to do with the problems of human interrelationships. This is the material suggested in the section on basic technics (page 761) and it applies to everyone in the department, sanitarians, telephone receptionists, secretaries, nurses and the health officer himself. Its aim is to keep relationships within the department as well adjusted as possible so that there may be a minimum of emotional frustrations and irritations to be "taken out" on the public. It is no great secret that health departments have their fair share of difficult personalities, of jealousies, of competition that lowers morale and interferes with the productivity of the department. Mental health programs, whether by that or some other name, are designed to reduce the stresses arising from such conditions.

Efforts in this field may be specially set up for the purpose, or may be a part of general staff conferences, sometimes enlarged for the purpose. They may be led by a well informed health officer, or by an "expert" brought in from the outside a more common procedure at present. The selection of the leader is, of course, extremely important. It is not safe to assume that this sort of work can be done by any psychiatrist, social worker, specially trained nurse or psychologist, the particular person will usually have a background of training in one of these specialties but this does not mean that all so trained are either interested or capable of leading

a productive discussion. The recent advances in group psychotherapy and the study of the processes of group productivity will probably in the next few years clarify the issues involved in the selection of leaders for discussions.

Such discussions may deal directly with the subject matter of interviewing technic (Garrett, 1942) and interpersonal relationships, or they may deal with the material as exhibited in case situations reported by some staff member. For example, a very great broadening of concepts and increased understanding of society and individuals can come out of a staff discussion of a case of pediculosis, or of the refusal of a grocer to obtain his license to sell milk. The choice of method will usually be determined by the particular person to lead the discussions together with the group.

The second type of educational program for a staff is more specific and directed at a particular clinical area. The sort of material to be learned in such inservice training has been indicated but by no means exhausted in the section on mental hygiene in public health programs (page 1417). It is out of this sort of education that clinical work increases in breadth and depth so that it reaches the person rather than only the condition presenting. Suggestions for this part of the program in the health department are also contained in the section just mentioned.

The third area of mental health work in the health department is that of furnishing psychiatric treatment to the public. Ideally, such service will be carried out by the psychiatric team of psychiatrist, psychologist and psychiatric social worker. While the public health nurse with mental hygiene training may be included in this team for some purposes and will use it constantly as a source of consultation, this new specialty probably serves best in the staff education functions already mentioned; in this capacity she may also deal directly with the public in individual or group undertakings in mental hygiene, such as mothers' and fathers' groups, groups of parents of preschool children, etc. She will also act as consultant to the staff nurse and her supervisors regarding problems of interpersonal relations. The mental health nurse consultant is a relatively new specialist in the field of nursing; her function in the health department remains a matter for experimentation and the suggestions above are to be regarded as suggestions only and not as rules (Henderson, 1950; Lemkau, 1948; National Organization for Public Health Nursing, 1949).

The mental hygiene clinic presents some unusual administrative problems to the health officer. In the first place, its cost is high in terms of number of patients carried and it is difficult to fit into a tight budget structure. At the moment, it is relatively easy to arouse public interest and support for psychiatric clinic services, especially for children, and it seems likely that this will continue, because the clinic does deal with some of the most disturbing situations the community encounters and it can relieve a great deal of distress not otherwise treatable by medical science at the present time. A part of the high cost is due to the larger space necessary for psychiatric work. There must be offices which are relatively soundproof and are completely private for each of the staff persons. These offices have to be large enough to include space for play therapy materials and the latter must be provided. It is difficult to incorporate a mental hygiene clinic into the total program of the department, partly because the situation is likely to be a new one for the clinic staff itself—training in these clinical fields does not yet include very much consideration of public health practice and philosophy—and because the nature of the treatment procedures is geared so strongly to the individual rather than the group. Frustrations

arising because long waiting lists delay the acceptance of cases by the clinic tend to alienate it from the rest of the department that serves as its case finding and case referring agent. Finally, there is the problem that the personnel of the clinic establishes the close relationship with the patient necessary for treating emotional disorder and this may be resented by the referring nurse or physician. This latter problem is probably most severe for the nurse who tends to resent the intrusion of any one but the physician who enters her relationship with the patient, and for the psychiatric social worker who may well feel that the nurse has no professional right to the close relationship she had with the patient. While such problems are not unfamiliar to the health officer, and while it is probably true that they characterize the present exploratory period and will not persist when more experience has been gained, it seems well to indicate that they exist at the present time and will need attention in some situations.

The high cost of psychiatric service will probably mean that services will be shared by several communities, the aim being to have a full-time clinic team for each 100,000 of the population. Experience is already showing that this ratio will not supply the service demanded in most communities, but it is still very far in advance of services available in most areas of the country. When populations are not densely settled in cities, the clinic team will have to travel to smaller centers in order to make its services available. In general, it is believed to be almost impossible for treatment services to be effectively rendered unless cases are seen at least once a week. Therefore, planning should be done so that the team reaches each patient on its circuit at least that often if at all possible.

The modern movement to include social service consultants in the local health department offers an opportunity to combine mental hygiene with the other duties of this person, especially in small departments. Social service education generally includes enough training in psychiatric case work to allow the use of this consultant, though the ideal would be to have a fully trained resident psychiatric social worker in each community in which a clinic visits. In this situation, the effectiveness of the clinic as well as its case load may be greatly increased at relatively little increase in cost. If the specially trained social worker or mental health nurse is not available for this function, a staff nurse should be given responsibility for making appointments and seeing to it that as complete a history of the case is available for consideration of the visiting team when it arrives. Staff conferences on clinic days should include the nurse referring the case, and the persons in such other agency or agencies as the teacher, welfare department, social worker, minister, probation worker, who may be interested in the case and are available to help in making therapeutic plans and in carrying them out.

It is generally assumed that it is of advantage for all the personnel of a clinic team to be full-time employees. However this may be, it is a fact that under circumstances as they exist today it is impossible to obtain anything like the requisite number of skilled personnel necessary to meet the need if full-time personnel is the goal. Salaries in public agencies are not high enough to attract or hold the quality of trained personnel needed and it seems unlikely that the education of officials controlling salaries can be completed rapidly enough to have them raise salaries to attractive levels in the near future. A possible alternative that has positive advantages as well, is the use of part-time personnel. Many psychiatrists in private practice

are able to afford to give a day to public health clinic practice at a reduced income, both as a service to the community and as a means of extending their clinical experience. The latter consideration applies particularly to psychiatrists whose principal place of employment is in public or private psychiatric hospitals. These physicians often are extremely anxious to get outpatient, community clinic experience. Frequently, plans can be worked out with hospitals having residency programs to have residents obtain their outpatient experience in public health clinics. All of these measures are much more successful if supervision of the resident or practitioner by a qualified child psychiatrist can be offered by the clinic in question.

Clinical psychologists are also frequently available on a part-time basis. In Maryland as well as in other states, there are found to be well trained psychologists who have married and are no longer working, but who can take regular responsibility for a day or two a week in a clinic. The recruiting of such personnel is of particular advantage at this time when trained psychologists are all too few. The same situation obtains with psychiatric social work personnel.

While the part-time employee, particularly the psychiatrist, is not likely to be as well trained for his assignments as one selected for full time work, nevertheless, excellent results can be obtained in clinics organized on the principles outlined here. The team usually has but a single area to serve and it quickly identifies itself with that area, learns the organization of the community and cooperates with it to do as good a job as the situation will allow. A psychiatrist who might not be able to function in the highly organized clinic and social situation of a large city, may be able to meet many of the needs of a rural area quite satisfactorily and refer his highly complex problems to the more highly organized urban clinics. This is not to be interpreted as a plea to lower standards for personnel on the psychiatric team. It is a plea to use all available services to the fullest extent possible, realizing that it will be of different grades of excellence but that the safeguards of referral for consultation to the next medical echelon are not less operative in psychiatry than they are in general practice or hospital organization on a regional basis. It follows, to be sure, that there must be the administrative facilitation of consultation and the clinical facilities capable of furnishing it.

Administration at the state level has this as a major responsibility. The local health officer, although he should carry the responsibility for the clinic in his community if it is a health department clinic, does not yet have the training to select nor the opportunity to find personnel either on a part or full time basis except in the case of large urban centers. This is the responsibility of the state health department in most instances, or of the mental health authority if this is not the health department. Obviously, problems of distribution of clinic service to the various geographic areas and budgeting are also responsibilities which usually lie at the state level.

The state bureau or division is responsible for the inservice education of the clinic staffs and for the evaluation of their work. It is responsible for consultation services to the local health officer as regards administrative problems concerning the clinic staff, and as regards personnel problems in his department. This division will consult with the local health officer on community programs in mental hygiene and on mental health education in his community, including relations with community organizations such as the mental hygiene society, the health council, etc. In general, it will be the state bureau which plans mental health education programs

for the public, and, in collaboration with the local health officer, for inservice training in local departments.

The state division or bureau is responsible for the integration of mental hygiene principles in the work of the other bureaus at the state level. The contacts in this area will be primarily with the fields of child and maternal health, tuberculosis, and venereal disease. Personnel problems at the state level will find their way to the bureau chief's office very frequently, though these contacts are largely informal, as may be many of the other functions mentioned.

Finally, the state division will be responsible for such intensive educational programs as institutes and workshops for particular groups in the state (Ginsberg, 1950; Witmer, 1947; Maryland State Health Department, 1949). It will be responsible for cooperation with citizens groups, particularly mental hygiene societies, to help focus their efforts and to consult with them on programs.

It is not intended that the suggestions on administration in this section should be interpreted as a sort of standard operating procedure. While the principles are based on experience and study of various state programs, it must be recognized that each geographic and population unit will require planning designed to meet the problems of that unit.

The whole mental hygiene movement is barely 50 years old, the first state division of mental hygiene in a health department was set up only in 1920, and extremely few states had any organized programs before 1946, the year of the passage of the National Mental Health Act. The conclusions to be drawn from these remarks is that, while, in general, the principles set down above are of importance, there is ample room for further experimentation and for planning widely divergent from that outlined above.

In some states, the most important of which are New York and Massachusetts, the mental health authority resides in the department of the state government which is also responsible for the hospitalization of the mentally ill. There are some advantages to this arrangement; the responsibility for planning lies with the agency that usually controls the largest pool of psychiatric, psychological and psychiatric social work personnel available in the state. The mental hygiene clinic services do not form as large a proportion of the total budget for these systems as they do in the health department budget and they may for this reason be treated more generously by the financial authority of the state. On the other hand, hospital systems are generally heavily overloaded with the problem of inpatient psychiatry and are not free to give intensive study to the planning of well-integrated preventive and outpatient services. The principal difficulty in the way of the hospital system in building a competent clinic system in a state is that it has no local official organization such as the local health department with which to work. In no state in which the authority is in the hands of the hospital department has a collaborative relationship been highly developed though there is no reason why it should not be. The essence of the problem appears to be that, wherever the authority, collaboration of the health department in putting local programs into effect and of the hospital system in furnishing personnel, is essential for the success of any program (Lemkau, 1950).

**Health Education in Mental Hygiene and Selected References.** The public demand for mental hygiene material in almost every conceivable form from the pulp scientific digests of the newsstands to the slick paper magazines, from the joke

book to the sophisticated *New Yorker* cartoons, from the illicit publications on sexual technic to carefully compiled research reports by highly qualified scientists, has produced an enormous amount of printed material, beyond the reading and certainly beyond the judging capacity of any one person. Movies, both commercial and intentionally educational in purpose, are in great demand and are being produced in profusion. Very little of such material has ever been evaluated as to effect; indeed, evaluation of mental health educational materials presents extremely difficult problems, both practically and theoretically.

Health education in this field is still very largely in the hands of the psychiatric professionals. There are an increasing number of experiments attempting to use conventionally trained health educators in this field, but for the most part this type of activity is still in the hands of the psychiatrist, psychologist, psychiatric social worker, and specially trained nurse. The reasons for this are not difficult to understand. More knowledge about mental hygiene principles is, as we have seen, not the only issue in mental hygiene education; perhaps even more important is the question of attitudes. In mental hygiene these attitudes are intensely subjective and carry an extremely heavy emotional load. The question and answer period following a talk on some subject related to mental health is likely to reveal a great deal of tension in the questioner, taxing the skill of the best trained specialist to devise an answer satisfying to the questioner and the audience and at the same time not raising anxieties and straying too far from scientific truth as we know it today. These periods are likely very quickly to pass from a lecture followed by a discussion into a group therapy situation and thus test the art of the leader to a very marked degree.

Nevertheless, a great deal has been and can be successfully done by personnel below the academic and experience level of the psychiatrist. Usually, the success of these experiments lies in the restriction of the subject matter to that within the competence of the leader by announcement of topic and by selection of audience as well as by design of the leader. A trained layman might well announce the topic of feeding difficulties in children, selected with the knowledge that most of the audience would be mothers of preschool children with personal experience to share in the area of child behavior. In leading the discussion he would stick to the simpler possible factors of etiology of feeding difficulties such as the decrease in rate of growth, the difficulty of handling utensils because of the incomplete maturity of the nervous system, the common rejection of new or strange foods, etc., avoiding the more threatening possible factors such as maternal or paternal rejection, perhaps even of the competition for power in the household he may suspect in the cases. Anxieties would be relieved through the dissipation of the feeling many have that theirs is the only child with problems, through the sharing process. Indeed it is a brave—or perhaps rash—psychiatrist who will tackle the latter types of factor with any but the most highly sophisticated audience. There is a great deal of knowledge of child development and mental hygiene that is not threatening to the basic adjustment of any but the most sensitive people. It is not to be assumed that the “superficial” is not helpful to the population which is relatively healthy, and it is not to be forgotten that however frightening the statistics on the frequency of the mental illness may be, by far the largest part of the population is healthy mentally as well as physically.

Books on mental hygiene are too often actually books on mental disease. Some

of them are simply books on psychopathology diluted sufficiently for the educational level to which they are addressed. Inasmuch as most of these present a theory of etiology, they indicate a possible prevention; too often, however, the only etiology presented lies in the far past history of the sick individual so that nothing can be done about it. These books serve as case finding devices since the sick person tends to identify his own with the symptoms set forth. It is doubtful if they offer any help in a preventive sense at all. It is probable that they do inform the public of the field of psychiatry and they may help remove the feeling of stigma so frequently attached to mental illness. K. Menninger's *The Human Mind* (Knopf, 1930) is an example of the more sophisticated type of book of this kind. A pamphlet by Bingham (1949) is a more popular presentation of the same type.

Another type of book is that written by recovered patients. The paradigm of this group is Clifford Beers' *The Mind That Found Itself* (Doubleday & Co., 1948) which was an important factor in the growth of the mental hygiene movement in this country. It was a crusading book to better hospital conditions. More recent books of the same type are Maine's *If a Man be Mad* (Doubleday & Co., 1947) and Mary Jane Ward's *The Snake Pit* (Random House, N. Y., 1946). While these books allow some identification with the author and furnish some education in the mechanics and feelings of healthy and unhealthy living, they are primarily pleas for reform and not preventive in intent or, so far as can be seen, in effect. In this group fall also the book on how to be 100 per cent mentally healthy. We suspect that many of these are written by ill-informed faddists or by patients far from fully recovered. The psychiatrists see only people distressed by such works, not those helped by them; nevertheless, it is my impression that they frequently distress people by holding up an impossible ideal for which to strive which can lead only to frustration and intensification of distress.

Then there are books which attempt to define the whole field of medical practice with special emphasis on the treatment of the whole man, rather than simply of his organs. These are all too few; a good example is Binger's *The Doctor's Job* (Norton & Co., 1945) and W. Menninger's *Psychiatry* (Cornell Univ. Press, 1948) and the more ambitious *Psychiatry in a Troubled World* (The Macmillan Co., 1948).

Somewhat in a transition to types more common in the pamphlet field are those books which attempt to teach the patterns of emotional growth and development in order that the parent may anticipate and be prepared for what is coming as the child matures. An early example of this type is the Aldrich *Feeding our Old Fashioned Children* (The Macmillan Co., 1941) and the more recent and extremely popular *Infant and Child Care* by Spock (Duell, Sloane & Pearce, N. Y., 1945). Another example is Lerrigo's *Children Can Help Themselves; The Normal Child's Health Behavior* (The Macmillan Co., 1944), Jenkin's *These are Your Children* (Scott, Chicago, 1949), and the old but helpful *Parents Questions and Answers* by Gruenberg (Harper and Bros., N. Y., 1936).

Pamphlet literature can mainly be divided into three types. The first is that devoted to propaganda for hospital reforms and for the changing of attitudes toward mental illness. Many of the publications of the National Mental Hygiene Foundation\* in recent years have been devoted to these ends. A second type is devoted to

\*Now the National Association for Mental Health, 1790 Broadway, New York 19, New York.

giving general information about behavior disorders and mental illness but also to the psychological exploration of the importance of some features of living in the production of stresses and strains which may result in behavior disorder or illness. An example is *Mental Health is a Family Affair* (Pratt and Neher, Pub. Affairs Comm., N. Y., 1949). The third type deals with childhood behavior and the trials of parent and family that normal child behavior induces. There are many excellent examples of this, such as the series prepared by the New York Committee on Mental Hygiene, *Some Special Problems of Children Age Two to Five Years* (Ridenour and Johnson, National Mental Health Foundation, N. Y., 1947), and a short but similar series called *Babies Grow in Eating Habits* and *Babies Grow in Toilet Habits* (National Institute of Mental Health, U. S. Public Health Service, 1949). In general these pamphlets are cheap and are suitable for distribution through the usual literature racks in the health department.

A special note is deserved by the series of pamphlets of the latter type called *Pierre the Pelican* (Rowland, 1947). This was devised by the Louisiana State Health Department and is sent at monthly intervals to the parents of each child born in that state—as well as other states which buy the material from its publishers. One of the few attempts to evaluate such material has been made on this series by Rowland in the *A First Evaluation of the Pierre the Pelican Mental Health Pamphlets* in 1948. The research by no means meets the requirements of vigorous scientific method, but it does point the way for further studies. A series of pamphlets for prenatal distribution is now available also.

Larger displays, such as posters and exhibits are relatively new and may again be divided into those concerning hospital reform and those designed to give information about child growth and development. An interesting series of the latter type is that being published by the North Carolina Hospitals Board of Control. It deals very briefly with various behavioral problems advising one to *Find the Cause* (Raleigh, N. C., 1949). Again, there is real question as to how much effect such material actually has in teaching or reassuring; the problem invites serious research.

Newspaper material on mental hygiene presents such a kaleidoscopic variety that it is difficult to deal with in a brief space. The oldest and possibly the most widely read of such material are the “advice” columns. These have been recognized as having a good deal of influence but generally have been looked upon as somewhat below the dignity of scientific study and evaluation, though recently they are receiving some study, particularly as applied to marital problems (Mace, 1950). Along with these are the “psychology” columns which may be informative but too frequently, after they have run a few months or years, abandon their policy of teaching experimentally demonstrated facts to indulge in quotations of opinion no better than the “advice” columns. Feature stories about new treatments or treatment in institutions, clinic systems, etc., undoubtedly help inform the public about available services. Series of articles or columns on child care frequently are helpful and reach more people than do pamphlets on the same subject.

One type of newspaper material, also used in magazines, about which there is some difference of opinion concerns the “exposé.” Typically, this is an explosive burst lasting a few weeks, telling about conditions which exist in the public hospitals. The series aim is arousing the public to demand reform and this is usually frankly admitted by the writers to be done best by presenting only the shocking and not the

satisfactory or the good in the hospital or the system under study. Frequently, such series are a very powerfully effective impulse to momentary reform and genuine improvement. The danger in them lies in the possibility that the continuous vigilance and public sense of responsibility necessary for the maintenance of good hospitals will be neglected, it being assumed that the immediate reform will be enough to last; it never can be. The second danger is comparable to that discussed under screening procedures in public health: does the negative publicity arouse so much fear in the population that patients who can profit by hospitalization fail to reach the hospital? Dr. Kenneth Jones, for years a psychiatric hospital superintendent, once said that if he could only get the name of his hospital before the public he would not care at all what was said about it. He believed public apathy to be the greatest evil and anything that decreased it and improved public awareness was an asset. There is much to be said in favor of this view, for certainly public apathy is any institution's greatest enemy.

Movies have, in the last few years, received a tremendous amount of attention as means of public education. One great problem in this field is that it appears almost impossible to make movies in the field for a special audience if they have any dramatic appeal—they always get to the public, whether made for it or not. It is now generally agreed that no film on mental hygiene can stand alone. Whenever one is shown it should be followed by a discussion period, the leader of which can answer questions and, if necessary, dissipate the anxiety the film will almost certainly arouse. The National Institute of Mental Health of the U. S. Public Health Service has prepared an extremely useful catalogue (1949) of films about mental health and mental illness, as has the National Film Board of Canada.

The radio has furnished admirable examples of public education in mental health. The major broadcasting companies in the U. S. have occasionally sponsored special programs in the areas which are known to have had considerable audiences though their effect is unknown except that they were well received.

A set of "platters" for local sponsorship and broadcast has been prepared for each of the last three years by the National Mental Health Foundation.\* These series have shown steady improvement from the first to the third series. They have the advantage of local sponsorship which means a local drive for listeners, but the disadvantage is that local public service time is usually not at optimal radio time to reach a wide audience. Nevertheless, these series offer real opportunities to local groups interested in the education of the public.

Discussions of mental health material of nondramatic type on the air generally fall into the categories of speeches and group or panel discussions. Unless the speaker is famous, the former are generally agreed to be quite ineffective in holding listeners. The latter, partaking as they do of some dramatic technic and emotional force, are more likely to hold listeners. Programs of this sort are often arranged locally but also occasionally appear on the established national forum programs.

In summary, it may be said that the public appetite for educative material in the field of mental hygiene is very great and that there is a great deal of material ready to try to satisfy that need. Little of the material can stand alone; most of it needs to be accompanied by someone equipped to interpret it and to deal with the

\* See footnote on page 796.

anxieties it arouses. Almost none of the material has been tested for effectiveness in changing attitudes or in giving information, and it must, at present, be judged according to local needs and opportunities. Evaluation of such materials is very greatly needed; research is necessary in the field of method of testing as well as in the effect of any particular material used.

## SUMMARY

The preservation of mental health and the prevention of mental disease is an inescapable responsibility of public health inasmuch as mental illness and behavior disorder are the cause of tremendous morbidity and costly hospitalization. Prevention of many mental illnesses is clearly understood in terms of direct etiology, and programs in these areas have been notably successful. Those illnesses of multiple, psychogenic etiology present difficult practical problems. These are now best attacked through efforts to improve the mental health of the family through improved parental and parent-child relationships through health department, school and other programs, through efforts in industrial mental hygiene and by improving the social opportunities of the elderly. Many of the health department clinics are directly related to family health and have great opportunities to influence family relationships helpfully.

Specific mental hygiene programs will deal in the administrative health within the department itself, since the attitudes established here will influence for good or ill the ultimately effective relationships in clinic or home. There is also a mass of information in the field of mental hygiene that needs to be known by the various categories of personnel in the department, and which can be taught in inservice training programs which allow for the necessary setting in which attitudes may be changed or can change.

Difficult still to bring to a pointed, clear-cut program for attacking a very great area of health preservation, mental hygiene is rapidly becoming more defined and definable. While a very great deal of research is still necessary in all its ramifications, patterns for constructive action are not lacking.

## Section Four

# FOOD SANITATION

## 21

### FOOD INJURIES AND THEIR PREVENTION

In addition to the nutritional disturbances which are due to improper dietary habits, consumption of food may cause injury to health in a number of other ways. Probably the most frequent cause is allergy to specific protein substances. It is not uncommon to find individuals sensitive to seafood, strawberries, eggs, tomatoes, milk, and a variety of other dietary substances. The degree of sensitiveness varies widely, as does the severity of manifestations following consumption of an article to which an individual is sensitive. The allergic manifestations vary from scarcely noticeable urticarial wheals, or hives, furring of the tongue, ulceration of the mucous membranes of the mouth to such distressing symptoms as generalized urticaria and angioneurotic edema, eczema, asthma, hay fever, migraine, anaphylactoid purpura, etc. The reaction or illness is not due to any fault in the food but to personal idiosyncrasy. One man's meat may be another man's poison. The prevention and treatment of conditions such as these are the concern of individual patients and their physicians.

Eliminating nutritional disturbances and allergies from consideration, foods may serve as a vehicle for the transfer of pathogenic microparasites from one host to another. The biologic agents are present simply as contaminants, undergoing little if any multiplication in the foodstuff. Numerous examples have been cited in chapters on the control of communicable diseases in connection with the discussions of typhoid fever, salmonellosis, bacillary and amebic dysentery, cholera, diphtheria, streptococcal infections, Q fever, etc.

In similar manner, food may serve as the means of transfer of animal parasites. *Trichina* and tapeworms occur as antemortem infections in the flesh of the food animal. Plant foods may be contaminated with the eggs or larvae of parasitic helminths, some of which are capable of developing in the human body. The measures required to prevent the transmission of pathogenic micro-organisms and parasitic helminths through food as a vehicle are discussed in connection with each specific disease and parasitic cycle.

### FOOD POISONING

Food poisoning is a general term used to designate illness (commonly acute gastro-enteritis) due to the consumption of food containing deleterious chemical substances. There is a wide range of such substances. They may be naturally present in plants or fish which are eaten through mistake or in ignorance of their dangerous characteristics. Chemical poisons may be introduced into foods accidentally or with malice aforethought. But by far the most common form of food poisoning, however

is that due to toxic substances which are produced by the growth of certain bacteria in foods.

Insofar as certain varieties of foods may at times contain natural poisons or be accidentally contaminated with poisonous chemicals or the toxic products of bacterial growth, and groups of individuals may be actually or potentially exposed to the injurious effects, it becomes the concern of public health to exert every effort to protect the consumer. This is accomplished in part by the administrative enforcement of laws and regulations with regard to the conditions under which such foods are produced, processed and distributed, and in part by education of the general public as to the possible dangers and necessary precautions in the preparation and handling of food for human consumption. The laws and regulations are intended to protect the public not only against injury to health but against fraud and deceit. They restrain the sale of foods which are decomposed, adulterated, improperly preserved or misbranded. They provide specifically for the safe handling of such perishable and potentially dangerous foods as milk, milk products and meats. Finally, methods and procedures have been developed to reduce to a minimum the danger of contamination of foods with poisonous substances or with pathogenic micro-organisms.

#### FOOD DECOMPOSITION

Decomposition of food is usually the result of bacterial activity, but it may take place also as a result of physical, chemical or electrical agencies. The law condemns food that is "filthy, putrid or decomposed." The word "decomposition" is not used in a technical sense in the National Pure Food and Drugs Act of 1906. There it has the meaning used in ordinary everyday parlance. It is difficult to determine just where to draw the line between technical decomposition and objectionable decomposition. We purposely permit many foods to decompose. Meats are hung three days or longer in order to render them more tender and improve their flavor. Some prefer meat when highly decomposed or gamey. The gourmand hangs his pheasant by the tail and waits until it drops off. Bread, cheese, buttermilk, sauerkraut, vinegar, cider and many other foods are products of decomposition. Our principal concern is decomposition that may be harmful to health.

**Fermentation and Putrefaction.** There are very many kinds of decomposition. Two main groups are recognized: (1) fermentative decomposition and (2) putrefactive decomposition.

Fermentation refers to the breaking down of carbohydrates with the formation of acids (lactic, acetic, butyric), alcohol, carbon dioxide, etc.

Putrefaction, from *putrere*, to be rotten, is literally a process of offensive decay. It is generally restricted to include only those processes of protein disintegration which give rise to foul-smelling products. For practical purposes, it consists of the decomposition of organic matter, usually protein in character, due to bacterial action.

Pasteur pointed out that putrefaction is essentially an anaerobic process. This has since been abundantly confirmed. Rettger insisted that putrefaction is the work of certain obligate anaerobes, which are able to initiate and carry on the decomposition of native protein. They include particularly several species of large, Gram-positive spore-formulating rod-like bacteria classified as clostridia and found widely distributed in nature as soil organisms—*C. perfringens*, *C. histolyticum*, *C. sporo-*

*genes*, and others. Certain aerobes, such as the proteus family, the colon group, and the subtilis group, also play a part, although they cannot initiate changes in protein

The end products of putrefaction are ammonia, nitrates, carbon dioxide, hydrogen sulphide, methane, etc., all simple, stable compounds which in the concentration ordinarily found in decomposed food are not injurious. The intermediate cleavage products of putrefaction have been suspected. Each particular micro-organism breaks down organic matter in a specific and limited way. Ordinarily these processes result from a combination of bacterial actions in which aerobic and anaerobic organisms each play a part in turn.

**"PTOMAINÉ" POISONING.** Ptomaines are secondary cleavage products of protein putrefaction. Vaughan defined a ptomaine as an organic chemical compound, basic in character, and formed by the action of bacteria on nitrogenous matter. On account of their basic properties, ptomaines give some of the reactions of the vegetable alkaloids and have, therefore, been miscalled putrefactive alkaloids. They are sometimes called "animal" alkaloids, but this too is a misnomer, for they also are formed by the putrefaction of vegetable protein.

The term "leukomaine" is used to cover the same or similar basic substances which result from tissue metabolism within the body; that is, leukomaines are produced in the living body, ptomaines in dead organic matter.

The word "ptomaine" was coined by the Italian toxicologist, Selmi, in 1870, from *ptoma*, a corpse. He used the word to describe basic poisonous products analogous to the familiar alkaloids of plant origin. The further exploitation of the expressive word "ptomaine" was largely the outcome of studies by Gautier in 1872, who also introduced the term "leukomaines."

Ptomaines, in sharp contradistinction to toxins, are nonspecific, that is, they are not the products of intracellular metabolism characteristic of the micro-organisms which produce them. They are merely decomposition products of the protein molecule and are elaborated by all bacteria that are capable of producing this degree of protein cleavage when grown on suitable nutrient media and under favorable conditions of growth. They may be produced by bacteria which possess no pathogenic power, while on the other hand highly pathogenic bacteria which are not active in attacking protein may produce few or no ptomaines.

The term "ptomaine poisoning" is a misnomer. Savage stated that the term ptomaine poisoning is clearly incorrect, and Jordan stated that ptomaine poisoning is a refuge from etiologic uncertainty. Vaughan agreed with Jordan and Savage that the term ptomaine poisoning is incorrect and should not be applied to food poisoning. Novy stated that "the rather popular expression 'ptomaine poisoning' is a survival of the period when it was believed that bacteria produced their injurious effect by means of basic or alkaloid-like products. Long ago the importance of ptomaine disappeared, due in the first place to the discovery of toxins, and in the second place to the fact that these substances are not secondary products of protein cleavage. Chapin stated that ptomaine poisoning is a good term to forget.

Ptomaines include substances which are chemically very different. The classification is unscientific and abandoned by chemists. A few of them are physiologically active, even poisonous when injected parenterally. None of them is actively poisonous when taken by the mouth, and even the active ones do not produce nausea, vomiting, colic and diarrhea.

It is not *decomposed* food that may be dangerous, but foods prepared under conditions that favor the growth of certain kinds of bacteria.

**Bacterial Food Poisoning.** The growth of certain kinds of bacteria in foods may be injurious in two ways. First, if the conditions are favorable, small numbers of a potentially pathogenic species introduced through contamination may undergo multiplication so that when consumed by man he becomes infected with a dose which is temporarily overwhelming. This form of food poisoning has been discussed under Salmonellosis (see page 216). Second, if conditions are favorable, species of bacteria which are ordinarily noninvasive and relatively nonpathogenic for man may grow in certain foods and elaborate toxic substances which when ingested give rise to serious, even to fatal disease. These bacterial food intoxications are of two types: that caused by the enterotoxin of staphylococci, acting as a violent gastro-intestinal irritant, and that caused by the exotoxin *C. botulinum* which has an affinity for the central nervous system and gives rise to progressive muscular weakness and paralyzes in the symptom complex known as botulism.

#### STAPHYLOCOCCUS FOOD POISONING

Up to about 20 years ago attention was largely concentrated upon the Salmonella and Clostridia as causes of food poisoning, although other bacteria were suspected. Barber (1914) reported that he had found that milk drawn from one quarter of the udder of a cow which had been the seat of an attack of mastitis a few years previously contained a white staphylococcus which was responsible for sporadic cases of acute gastro-intestinal upsets on a certain farm in the Philippine Islands, during the years 1909 and 1913. This organism developed in sufficient numbers to be serious only in unrefrigerated milk and cream. A toxic substance was liberated which could be demonstrated only by feeding experiments in human volunteers. These findings, however, remained unappreciated for 15 years. The role of the staphylococcus in food poisoning was reopened by the investigation of an outbreak in Chicago affecting four different families which was traced to the consumption of three layer sponge cake with a thick cream filling (Dack and others, 1930). A bacteriological examination of this food revealed 19 different types of colonies. Three of these were further studied, as they were predominant. A filtrate from a veal-infusion broth of only one of these, incubated 40 hours, produced typical symptoms in a human being, beginning three hours after drinking a 25 ml. portion. The organism from which the toxic filtrate was prepared was a yellow hemolytic staphylococcus. This was the beginning of a long series of observations made by a number of investigators which established beyond question the role of staphylococci in food poisoning. It became apparent that they were the commonest cause of outbreaks of acute gastro-enteritis following consumption of contaminated foodstuffs. For example, in a recent analysis of outbreaks reported to the U. S. Public Health Service (Feig, 1950), out of a total of 476, in which effort was made to ascertain bacterial cause, 368 were attributed to staphylococci. Almost 80 per cent of all reported outbreaks of gastro-enteritis belong to this group.

**Incubation Period.** Symptoms usually appear in two to four hours after ingestion of the incriminated food; although the time interval varies from 1 to 11 hours. About 90 per cent will have symptoms within eight hours.

**Symptoms.** The onset is abrupt and sometimes violent with salivation, nausea, vomiting, prostration, abdominal cramps, and diarrhea of varying severity. In mild cases there may be nausea and vomiting without diarrhea, or there may be cramping and diarrhea without vomiting. There is usually little or no elevation of temperature; in fact, the temperature is more likely to be subnormal. Even with the same dosage, individuals may vary widely in the severity of their reactions. Ordinarily, the symptoms persist for several hours. The patient usually feels quite well in 24 hours after the beginning of the attack, although weakness and nausea may persist for a day or two. In normal children or adults, fatalities are extremely rare. Nearly every one is susceptible to this form of food poisoning. In outbreaks, attack rates are very likely to be high. It is doubtful whether an attack confers immunity; the same individual may have repeated attacks.

**Diagnosis.** A characteristic feature of staphylococcus food poisoning is the shortness of the time interval between eating the contaminated food and the onset of symptoms. In an individual it cannot be differentiated from acute gastro-enteritis due to other causes by any laboratory test now available. When several cases occur in a group of persons who have eaten together on some occasion, the diagnosis may be established by epidemiological evidence. When such an outbreak occurs, inquiry should be immediately instituted to obtain the list of foods served at the meal in question and information obtained regarding which article of food each individual consumed and whether or not he was subsequently ill. By such an inquiry it is frequently possible to ascertain the food which was responsible. With good fortune, in some instances, a portion of the suspected food is still available and the sample can be submitted for laboratory examination (Am. Pub. Health Ass'n, 1950). In the event that the food is responsible for the poisoning it will usually be found to contain hundreds of millions of staphylococci per gram. This by itself, however, does not afford conclusive proof. Staphylococci are ubiquitous; millions are contained in many foods without causing illness, since many strains do not produce enterotoxin. A conclusive test must demonstrate that the strain of staphylococcus recovered is capable of producing enterotoxin.

**Enterotoxin.** Methods for the identification of enterotoxin-producing staphylococcus have been extensively explored. Various cultural characteristics have been studied. Oral administration and parenteral injection of various species of animals have been tried. The use of monkeys and kittens for this purpose has been found to be highly suggestive, but interpretation of the results of tests on these experimental animals are fraught with difficulty and uncertainty. No test has yet received the sanction of common acceptance for routine laboratory use. The presence of small amounts of enterotoxin can be detected only by administering the suspected material to human volunteers; but this procedure is not to be lightly undertaken. Serious illness has occasionally resulted from such tests.

Nevertheless, by the use of human experiments, some of the qualities of the enterotoxin have been established (Dack, 1949). Empirically, certain foods may support the growth of staphylococci without the production of enterotoxin as, for example, canned salmon. Others, such as cured meat products and custard filled bakery goods, allow food poisoning staphylococci to grow well and produce enterotoxin. Aside from such empirical knowledge, however, little is known of the cultural requirements for the production of the enterotoxin. Enterotoxin, which was pro-

duced by growing a strain of staphylococcus in beef-infusion broth incubated aerobically, was boiled for 30 minutes. When 2 and 10 ml. were fed, respectively, to two human volunteers, typical symptoms occurred in both. Limited though this experiment be, it suggests that the enterotoxin is extremely resistant to heat.

**Source of Contamination and Kinds of Food.** Staphylococci are found widely distributed in nature. They are frequently found in the secretions of the nose and throat of human beings and may be present in large numbers as a result of chronic infections of the nasal sinuses. They are the cause of localized skin infections, boils and carbuncles. They are often in the dust and air of rooms. It is, therefore, practically impossible to trace the source of contamination of a food.

Foods implicated in staphylococcal food poisoning are chiefly pastries, milk and milk products; meats (particularly cured hams) and pastries containing custard or cream filling are frequent offenders. A number of outbreaks have been traced to meat or meat sandwiches. Most of the outbreaks due to milk have been from the consumption of raw milk.

**Prevention.** For the production of food poisoning there are three principal requirements. First, there must be sufficient contamination of the food with enterotoxin-producing staphylococci; second, the food must be a good medium for the growth of organisms and production of enterotoxin; third, the food must remain at about room temperature or above for several hours.

Prevention depends upon reducing so far as is possible the risk of the realization of these three conditions by appropriate methods of preparation. Due to the ubiquitous distribution of staphylococci very little can be done to prevent their introduction into the kitchen. Food handlers with infectious nasal discharges or purulent local infections of the skin should be excluded from this kind of work until healing has taken place. Cleanly methods and the use of various kinds of covers to exclude dust will reduce the risk of contamination with enterotoxin-producing staphylococci. Foods should not be permitted to stand at room temperature or above any longer than is necessary. Refrigeration at a temperature below 10° C will prevent the growth of these micro-organisms. Where refrigeration is undesirable, as is the case with certain bakery products, cream fillings, custard puffs and éclairs, special precautions are necessary. Methods have been developed for reheating puffs and éclairs for a period of time and at temperatures sufficient to kill staphylococci without impairing the flavor and appearance (Stritar and others, 1936; Gilcreas and Coleman, 1941).

When cured hams leave the packer they are safe. When they have been partially sliced they may easily become contaminated with staphylococci. At room temperature these organisms grow very well in ham without producing signs of spoilage as evidenced by odor or taste. The necessity of protection by refrigeration is obvious.

### BOTULISM

Botulism is a specific toxemia caused by the toxin of *Clostridium botulinum* (formerly *Bacillus botulinus*). The bacillus grows in a great variety of foodstuffs, both of plant and animal origin, and produces its poison in the food before it is eaten. The name botulism (from *botulus*, a sausage) has lost its original significance.

Botulism stands out as a distinct type of food poisoning. The bacillus itself is essentially a harmless saprophyte. Botulism further differs from other forms of

bacterial food poisoning in that the attack is chiefly upon the central nervous system. Acute gastro-intestinal disturbances usually do not occur. There is no fever.

A history and review of the literature from early times up to 1918 is found in Dickson's (1918) monograph, and for the decade following in an article by Meyer (1928).

**Etiology.** The cause of botulism was demonstrated by van Ermengem who studied a series of cases which occurred at Ellezelles, in Belgium, in 1895. In the first of these outbreaks, 23 persons became ill and three died after eating ham which had been preserved in brine. From portions of the ham and from the spleen and intestinal contents of one of the victims, van Ermengem succeeded in isolating a Gram-positive, spore-bearing anaerobic bacillus, to which he gave the name *Bacillus botulinus*. He found that infusions of the macerated ham and bouillon cultures of the bacillus produced the typical symptoms of botulism in guinea pigs, rabbits, cats, pigeons and monkeys. The bacillus itself he believed to be a saprophyte, and the poisoning to be due to a toxin which is formed when it grows in food under anaerobic conditions.

**Prevalence.** Botulism has been recognized by German clinicians since 1735, when the first authenticated case was recorded. The outbreak which first attracted the attention of the medical profession occurred in 1793 in Wildbad in Württemberg, where 13 persons became ill and six died after eating sausage packed in the stomach of a hog, and which contained a great deal of blood. The number of cases reported in Germany is as follows:

YEARS	CASES	DEATHS
From 1793 to 1820 .....	76	37
From 1820 to 1822 .....	98	34
From 1822 to 1886 .....	238	94
From 1886 to 1913 .....	about 800	about 200

It became apparent that botulism occurred throughout the civilized world. Meyer has collected data on 483 outbreaks occurring in the United States and Canada between 1899 and 1949. The distribution is shown in Table 21-1. During the past decade there have been about 12 to 15 outbreaks each year.

Botulism is one of the causes of forage poisoning in horses, and of limberneck in chickens and turkeys, and may also be responsible for various types of paralysis in domestic animals, including dogs.

**Period of Incubation.** The symptoms usually appear from 18 to 36 hours after ingestion of the poisonous food. However, cases are on record in which the incubation period has been as short as four hours or as long as six days. There is a direct correlation between the severity of the poisoning and the period of incubation—short period indicates a severe and often fatal intoxication. In a series of 246 cases collected by Geiger, of which 173 resulted fatally, 147, or 85 per cent, of the fatal cases were persons in whom the period of incubation was less than 48 hours.

**Symptoms.** The earliest symptom is usually a peculiar indefinite indisposition associated with a feeling of fatigue, sometimes headache and dizziness, and definite muscular weakness. When the period of incubation is short, the first symptoms may be gastric distress, nausea, vomiting and occasionally diarrhea, which, however, a

From Meyer, K. F., and Eddie, B., University of California Medical Center, July, 1950.

transient. Botulism differs from the common type of food poisoning, in that there are usually no indications of acute gastro-intestinal irritation. Constipation is almost constant.

Disturbances of vision occur early, and are scintillation and dimness of vision, sometimes progressing to blindness, due to impairment of both the extrinsic and intrinsic muscles of the eye. The third cranial nerve is early involved, causing blepharoptosis, dilatation of the pupils, loss of reflex to light, and diplopia. Loss of accommodation soon becomes complete. Nystagmus, strabismus, vertigo and, sometimes, photophobia occur. The ophthalmoplegia is merely a phase of the more general paralysis, but is a conspicuous symptom, owing to the striking character of its manifestations.

Coincident with, or closely following the onset of disturbances of vision, the patients complain of difficulty of swallowing and talking, and frequently there is a peculiar sensation of contraction of the throat. The mouth is dry and attacks of strangling occur. Thick, glairy mucus, with dryness of the throat leads to an ineffectual cough. The breath is offensive and fetid. Complete paralysis of peristalsis causes the stubborn constipation.

A striking feature is the progressive muscular weakness, which in severe cases closely simulates paralysis. Incoördination of muscular movement is common. The paralysis is usually of the ascending type, manifesting itself first in the intestines, perhaps due to involvement of the mesenteric plexus, then gradually passing upward, progressively involving higher centers, until the medulla is reached. The motor areas

seem almost never to be involved, although in the Montana outbreak paralysis of the right arm and leg was observed.

The *loss of nervous tone* manifests itself in vague, indefinite indisposition, marked fatigue, dizziness, headache, restlessness, indefinite sensations of chilliness, incoördination and unsteadiness in walking with a tendency to a "steppage" gait, great muscular weakness and sometimes urinary incontinence. The ophthalmoplegia may be partly responsible for some of the above symptoms.

Botulism is characterized by an almost complete absence of sensory disturbances. It is unusual to suffer pain, and the mind remains clear.

Inhibition of many of the secretions, especially saliva, sweat and tears, is an almost constant manifestation of botulism. Oliguria has been noted.

The pulse is usually rapid, and the temperature subnormal. Fever developing late in the poisoning indicates bronchopneumonia. Respiration at first is not impaired but later in the course of the illness disturbances of respiration become severe. Difficult articulation and perhaps complete aphonia, accompanied by an inability to swallow, soon appear, due to paralysis of the laryngeal and pharyngeal muscles. Increasing difficulty in breathing, leading eventually to death due to paralysis of the respiratory center, brings the scene to a close.

The general appearance of the patient is distressing; the muscular weakness, the anxiety and utter helplessness, the difficulty in swallowing, the attacks of strangling, the struggle for breath, with its resulting cyanosis, and the unsuccessful attempts to articulate constitute a clinical picture which once seen can never be forgotten. It is essentially that of a bulbar paralysis, with the earliest symptoms indicating injury high up in the brain stem. The disease must be differentiated from other causes of bulbar paralysis and ophthalmoplegias, such as encephalitis lethargica, poliomyelitis, cerebrospinal syphilis; also poisoning from belladonna, gelsemium, hyoscyamus and methyl alcohol. There is no constant pathologic lesion.

The duration varies greatly. Death may occur in 48 hours after eating the poisonous food; as a rule, it occurs in from four to eight days, and few die after 10 days. Dickson reports one death on the twenty-sixth day. Death usually is due primarily to respiratory failure. Convalescence is extremely slow and tedious, and the disturbances of vision and weakness may last for months.

The *case fatality rate* in botulism has varied in different outbreaks, depending upon the amount and virulence of the toxin. In the United States it is approximately 65 per cent, and surprisingly uniform.

The *Bacillus. Clostridium botulinum*, discovered by van Ermengem in 1895, is a large, slightly motile rod with rounded ends; four to eight flagellae, generally single, rarely occurs in filaments; stains readily, and is Gram-positive. It is anaerobic. The spore is large, polar and a true endospore.

The bacillus grows well at room temperature, between 20° and 30° C, but also thrives at 37° C. Contrary to previous opinion, it may grow in the body. It is a strict anaerobe. It grows under special conditions in symbiosis with certain aerobic bacteria, such as a white sarcina (van Ermengem) or with *B. subtilis* (Romer); and freshly prepared bouillon under aerobic conditions if a piece of sterile flesh or potato is placed on the bottom of the culture tube. The addition of glucose to the culture medium greatly increases its activity in growth and in toxin formation. In a medium consisting of one part sheep's brain and two parts water it grows well at

produces an abundance of spores. The strains studied by van Ermengem produced practically no change in the appearance of milk, but von Hibler and others find that milk casein is precipitated and peptonized. It is strongly proteolytic, and a putrefactive odor is given off. Gas which is usually formed is due to the fermentation of sugars in the medium. The 21 cultures studied in Rosenau's laboratory showed minor differences in cultural characteristics; only 10 of these strains produced toxin. Atoxic strains must be differentiated from *B. sporogenes*.

**TYPES.** Five types have been differentiated on the basis of specificity of their toxins. They are classified as *Clostridium botulinum* or *parabotulinum* types A, B, C, D and E. Animals immunized with a toxin of a specific type produce antitoxin in their serum which will neutralize only that type of toxin. Human botulism has been found to be due to types A, B and more recently E. No human outbreaks of botulism have been traced to types C and D.

Fig. 21-1. Curve 1, showing thermal death point of *Clostridium botulinum*.

**HABITAT AND DISTRIBUTION.** The spores of *C. botulinum* are widely distributed in nature. They are found in soil, on fruit and vegetables, in the larvae of worms, in dust and on food. They have been found in many parts of the world, even in the virgin soil of mountains. The habitat and distribution resemble those of other intestinal spore-bearing anaerobes, such as tetanus and the gas bacillus. Meyer and Dubovsky (1922) made an analysis of 1,538 samples of soil, vegetables, feed and manure collected from every state of the United States except Virginia. Briefly summarized, their conclusion from this survey was that the soil of the western states inclusive of the Great Plains, yield mainly *C. botulinus* type A, while in the Mississippi Valley and Great Lakes regions it is characterized by striking predominance of type B. Similarly prevalent is the latter type in the Atlantic States, Maryland, Delaware, New Jersey, North and South Carolina, while scattered findings of type A in Maine, New York and Pennsylvania indicate the existence of breeding places in

virgin forests of the mountains. Soil which is subjected to intensive cultivation and fertilization contains as a rule *C. botulinus*, type B.

**Thermal Death Point of the Spore.** To safeguard against botulism in canned foods, a series of thermal death points of the spore were determined by Weiss (1921). The various factors, such as age of the spore, number of spores, strain differences, hydrogen ion concentration, effect of desiccation, etc., which influenced the thermal death point were also determined.

Weiss found that, suspended in water, the most resistant types require five hours at boiling temperature, 40 minutes at 105° C, 15 minutes at 110° C, and 6 minutes at 120° C. These represent bath temperatures and include the time necessary to heat the spore itself to the temperature stated. Weiss further found that young spores are more resistant than old spores; that dry spores are much harder to kill than moist spores; and that acids, alkalis and various chemicals greatly diminish the thermal resistance.

Fig. 21-2. Curve 2, showing rate of destruction of botulinus toxin.

The time and temperature necessary to kill the spores varies with each food product, its pH, bulk, physical and other characteristics (Meyer, 1931). Es (1923) suggested time temperature relationships for completely destroying spores of *C. botulinum* as follows: 100° C, 360 minutes; 105° C, 120 minutes; 110° C, 36 minutes; 115° C, 12 minutes; 120° C, 4 minutes.

**Toxin.** The bacillus produces a soluble, true exotoxin comparable in all respects to the poisons produced in cultures of diphtheria or tetanus. The botulinus toxin is the only one of the true toxins that is poisonous when taken by the mouth. It is also pathogenic for guinea pigs, mice and monkeys, as well as for man. One or two drops of a culture placed upon a piece of bread causes death in a few days. Toxins of diphtheria and tetanus are not poisonous when taken by the mouth.

The toxin is secreted by the bacillus when it grows upon a suitable medium, under anaerobic conditions. Some strains do not produce toxin, and the property may be lost after prolonged artificial cultivation. Toxin production takes place between  $20^{\circ}$  and  $30^{\circ}$  C, but best at  $37^{\circ}$  C, contrary to our previous conception. It was stated that the toxin is always preformed in foodstuffs, but the work of Orr (1919) showed that guinea pigs and mice may develop botulism when fed enormous quantities of toxin-free spores. The significance of this observation to human botulism must await further study.

Botulinus toxin is not absorbed through the unbroken skin, but Geiger (1924) has shown that the possibility of absorption through fresh wounds or from mucous surfaces must be taken into account.

Botulinus toxin is exceedingly poisonous. It has been possible to obtain a toxin of which 0.000001 ml. would kill a 250-gm. guinea pig in from three to four days. In the Ellezelles outbreak in 1897, about 200 gm. of the poisonous ham were sufficient to cause the death of one of the patients; in the Darmstadt outbreak in 1897, a piece of preserved duck the size of a walnut was sufficient to cause an illness which lasted for eight weeks. In Dickson's series of cases, one patient died after "nibbling" a portion of a pod of the spoiled string beans, one died after tasting a small spoonful of the spoiled corn, and a third was ill after tasting a pod of beans which she did not swallow.

Strong toxin was produced by Dickson in pork and beef infusion, and also in media prepared from string beans and green corn; much less virulent toxins were obtained in media prepared from asparagus, artichokes, apricots, and crushed apricot stones. The most powerful poisons are produced in glucose broth. The toxin is not formed in brine containing over 8 per cent of sodium chloride or in syrup containing over 50 per cent of sugar. This is of practical importance in pickling and preserving foods.

In 1897 van Ermengem showed that the toxin was destroyed by heating at  $80^{\circ}$  C for one-half hour, and many later workers have verified this, showing in fact that there is a margin of safety in such a procedure. Thom and others (1919) showed that the toxin of the Boisé strain is destroyed at some point between  $70^{\circ}$  C and  $73^{\circ}$  C by heating for 10 minutes. Orr (1920-2) showed that the most resistant of the 10 strains of toxin studied by him is destroyed when exposed to  $80^{\circ}$  C for two minutes,  $72^{\circ}$  C for 10 minutes, and  $65^{\circ}$  C for 85 minutes. The toxins of most strains are killed at  $65^{\circ}$  C in 30 minutes. Cooking, therefore, is a safeguard. The toxin in solution is very resistant to exposure to light and air. It is not affected by drying or putrefaction. The toxin of *C. botulinum*, type A has been obtained in crystalline form by different groups of workers (Abrams and others, 1946; Lamanna and others, 1946). It has, therefore, been possible to study the physical and chemical characteristics and toxic properties with great precision.

The toxin has a special affinity for the central nervous system; it is almost a pure neurotoxin. It may also cause dilatation of the blood vessels, thrombi and hemorrhages in various portions of the body.

van Ermengem found that white mice, guinea pigs, rabbits, cats, pigeons and monkeys are susceptible to subcutaneous, intraperitoneal and intravenous injection, and that white rats, dogs, chickens, frogs and fish are highly resistant. In his feeding experiments, he found that mice, guinea pigs and monkeys are especially susceptible,

rabbits are less susceptible, and cats must be given enormous quantities of the toxin before they show symptoms. He found that dogs, rats and chickens are practically unaffected, the only result of feeding large doses being vomiting, diarrhea and emaciation. It is surprising that van Ermengem failed to obtain positive results in his experiments with dogs and chickens, for chickens may be used as test animals to determine the presence of the toxin in food. Horses, goats and other animals are susceptible.

**Antitoxin.** A true antitoxin may be obtained by injecting increasing amounts of the toxin into susceptible animals. Kempner first obtained the antitoxin in goats. It is now made by injecting horses. The botulinus antitoxin has both protective and curative virtues in experimental animals, even when given 24 hours after the ingestion of the poison, but before the onset of symptoms. For practical purposes at least two antitoxins must be on hand, one made by strain A, and the other by strain B. The presence and type of toxin in food can be determined in a few hours by injecting mice intraperitoneally. Some of the mice should be immunized with antitoxin type A and some with type B.

**Toxoid.** Nigg and others (1947) have prepared toxoids from botulinus toxins type A and B. Tested in guinea pigs and mice they have been found to produce a high level of antitoxic immunity. Both the fluid and alum-precipitated botulinum toxoids types A and B have been used to immunize man (Reames and others, 1947). It apparently affords protection to laboratory personnel working with these toxins who may be exposed to risk through accidents.

**Food Involved in Botulism.** It was originally thought that *C. botulinum* would grow only in meat, but it is now known that the presence of animal protein is not necessary for its growth. In Europe, the foods involved in outbreaks have been mainly meats, such as sausage and ham, but in this country other foods have been involved, such as string beans, cottage cheese, corn, asparagus salad, peas, spinach and ripe olives. Botulism has also been attributed to turkey, beef, chicken and fish.

Most cases of botulism are caused by food that has received some preliminary treatment, as smoking, canning or pickling, and not by fresh food. Home processed foods have been especially responsible, for the reason that they are often a day or more old when put up, and the temperature of processing is frequently not sufficient to kill the botulinus spores. All the olive cases were due to ripe olives, improperly processed, put up in glass, and insufficiently heated.

van Ermengem found that the outbreak in Ellezelles was caused by eating ham which had been preserved in brine. Smoked as well as pickled ham has been responsible. In Russia fish has conveyed the poison. Madsen also isolated *C. botulinum* from poisonous fish. A most interesting outbreak occurred in Darmstadt in 1904, caused by a salad prepared from home-canned white beans.

Sausages are a frequent source of botulism in Germany. The sausages readily become infected and present ideal anaerobic conditions for the growth of the organism, especially as they are rarely refrigerated and frequently contain old and contaminated scraps. Certain sausages, as, for example, the blood sausage and the liver sausage prepared in Württemberg and Baden, are likely to be toxic. Venison and old roasts have also produced the intoxication. Of 483 outbreaks in the United States and Canada (1899-1949), 361 were due to canned fruits and vegetables.

to meats, 30 to fish and other sea foods, 7 to milk and milk products, and in 48 the causative food was unknown (Meyer and Eddie, 1950).

**Prevention.** The prevention of botulism consists in greater care and cleanliness in the preservation of nitrogenous foodstuffs. The bacillus will grow and produce toxin only in foods containing protein. There is no danger of botulism in fresh food. In all instances, the trouble comes from food that has been canned, preserved, pickled or processed in some way. Home-canned foods are often at fault. It is, therefore, important to teach safe methods of home canning, especially the importance of putting up only fresh and clean food, heated sufficiently to kill the spores— $120^{\circ}\text{C}$  for 10 minutes. This is the minimum temperature and time to kill the naked spores under laboratory conditions. In actual practice a larger factor of safety is necessary in order to provide for penetration of the heat throughout the cans. Canned foods should be processed at a temperature sufficiently high and held there sufficiently long to render the contents of the can sterile, which will include the killing of botulinus spores. Food commercially preserved in the United States has not been connected with any recognized case of botulism since 1925. The canning industry has taken measures to safeguard against the intoxication. Sterile food is safe food. The cans should be tight.

The heat of cooking is sufficient to detoxicate the poison, but does not kill the spore. Food, therefore, that is allowed to stand around after cooking permits bacterial growth. The importance of proper refrigeration to prevent botulism, as well as other bacterial contamination, is evident.

Cooking is a safeguard, but it must be thorough and recent: thorough in order that the heat may penetrate throughout the mass and kill the toxin; and recent in order to prevent the re-formation of the poison. If the food is kept at ordinary temperatures after cooking, botulinus and other organisms may grow and may cause trouble. Toxin may re-form in cooked food allowed to stand 24 hours at room temperature. Home-canned goods or any other processed goods, if doubtful, should be again cooked just before serving. Food preserved in a brine of 8 per cent or greater is safe, for the toxin does not form in salt solution of this concentration. A syrup of at least 50 per cent sucrose has been found necessary to inhibit growth. A hydrogen ion concentration of 4.5 prevents the formation of this poison; therefore, botulism is unknown in acid fruits.

Reliance cannot be placed upon odor, taste or appearance to detect the toxin of botulism in food. It is true that in many instances a history is obtained that the responsible food looked spoiled, tasted wrong or smelled tainted. Experts can detect the peculiar butyric acid smell of cultures of botulinus, but some strains produce little or no odor. A safe rule is not to eat food that is soft, mushy, and shows gas with a spoiled or putrefactive odor. Canned food that shows gas formation or other evidence of spoilage should not be eaten, especially if home processed. A very small amount of the toxin-containing food is sufficient to cause symptoms and death. Merely tasting the contents, or just "nibbling" the food has been fatal.

The occurrence of limberneck in domestic fowl, if it has developed after they have eaten refuse from the kitchen, may be an indication for the prophylactic administration of the botulinus antitoxin to all persons who have eaten the suspected food.

Effective measures have been taken by the State of California (Meyer, 1931) to protect foods against botulism.

When a case of botulism occurs, persons who have eaten the suspected food should receive a prophylactic dose of botulinus antitoxin; both strains A and B should be used. The serum is of little avail after symptoms have begun.

**Chemical Food Poisoning.** The term chemical food poisoning usually refers to inorganic compounds introduced into foods as adulteratives or by carelessness or, occasionally, by maliciousness in sufficient quantities to cause illness. If the dosage is sufficiently large some of these chemicals may give rise to symptoms of acute gastro-enteritis causing confusion with bacterial food poisoning. Such symptoms may occur after ingestion of foods containing adequate amounts of antimony, arsenic, barium carbonate, cadmium, sodium fluoride, lead and mercury. However, the symptoms make their appearance from a few minutes to one to two hours after ingestion of the contaminated food. It is possible, therefore, in most instances where prompt investigation is instituted to obtain some of the suspected food and ascertain the nature of the poison by chemical analysis.

Typical of this type of food poisoning is an outbreak involving a total of 85 British soldiers as reported by Morten (1945). Thirteen men were admitted to a military hospital with acute gastro-enteritis. They had become ill one hour after eating their evening meal, which consisted of meat, vegetables and a marmalade tart. Three sergeants who had not eaten were not affected; five soldiers who had eaten some of the tart but no other part of the meal were affected. Before the results of a chemical analysis of the suspected food were available, 71 men in the same unit were taken ill two hours after a subsequent meal. It consisted of meat, vegetables, and a treacle tart. Only the men who ate the tart were made ill. The chemical analysis of the pastry of the tarts revealed a large quantity of barium carbonate. At the supply depot a sack containing four pounds of barium carbonate for use as a rat poison had been placed in error in the flour store, filled with ordinary flour and issued to the unit.

Much can be done to control accidental food poisoning by eliminating the presence in food handling establishments of poisonous chemicals which may be mistaken for such foods as flour and powdered milk. White sodium fluoride is commonly used to kill roaches in kitchens and food handling rooms; white powdered insecticides containing arsenic are also used. In some states regulations have been passed prohibiting the use in food handling establishments of compounds containing arsenic or fluorine in any form unless such compounds are distinctly marked with blue, green or red to a stated intensity. New York State requires an intensity of not less than value 8 chroma 4 in accordance with Munsell system of color notation. Prevention may be furthered by regulations forbidding the use of silver polish containing cyanide and prohibiting the use of lead, solder containing lead, cadmium, copper or other metals in food contact surfaces of containers or equipment. By the proper enforcement of effective pure food and drug laws and regulations the danger from adulteration and preservation can be greatly reduced.

### ADULTERATION OF FOOD

Adulteration of food consists of a large number of practices, some of which are fraudulent, others technical in nature. Some forms of adulteration are injurious to health, but for the most part they have an economic rather than a sanitary significance. Foods may be adulterated in a variety of ways, by the removal of nutritive

substances; by the addition of injurious substances; by the fraudulent substitution of cheaper articles; by misbranding; or by the sale of food that is filthy, decomposed or putrid.

Prior to the passage of the Pure Food and Drugs Act in 1906 a large percentage of the food sold in the United States was found to be "adulterated" in one way or another. In Massachusetts, the State Board of Health began to examine foods for adulteration in 1883. It was then found that between 60 and 70 per cent of all foods examined were adulterated. As a result of official surveillance the percentages fell in a few years to approximately 15 per cent and have remained between 10 and 20 per cent since. This does not mean that from 10 to 20 per cent of all foods found on the market are adulterated, for samples are collected from suspicious sources, so that the ratio of adulteration of food analyzed in the laboratory is higher than that of the same foods sold on the market. At the agricultural experiment station in Kentucky it was found that 40 per cent of 727 samples were adulterated; in 1899, at the Connecticut Agricultural Experiment Station, 41.5 per cent of 574 samples of spices and over 25 per cent of coffee samples were found to be adulterated. The situation has greatly improved as a result of the pure food laws.

**Kinds of Adulteration.** A food is considered adulterated in accordance with the Food and Drugs Act of June 30, 1906:

1. **MIXING.** "If any substance has been mixed and packed with it so as to reduce or lower or injuriously effect its quality or strength." This is the simplest form of adulteration, and a good example is the addition of water to milk. Cocoa shells are sometimes mixed with cocoa or chocolate. Glucose and caramel are added to maple syrup; talc to flour.

2. **SUBSTITUTION.** "If any substance has been substituted wholly or in part for the article." As illustrations we have the substitution of cottonseed oil or corn oil for olive oil; glucose or saccharin for sugar; cereals, which cost much less than meat, in sausage. Apple cores and parings are frequently used as a substitute for currants and other fruits in jellies.

Saccharin, or orthobenzosulphamid ( $C_6H_4.CO.SO_2.C_6H_4$ ), is made from toluene. It is several hundred times sweeter than sugar and comparatively cheap. It has, therefore, been used as a substitute for sugar as a sweetening agent in the inferior qualities of ginger ale and other soft drinks, and to some extent in canned corn, peas, etc., as well as in candies and other articles. Saccharin is a chemical obtained from coal tar and is without food value; it is not entirely harmless. The Referee Board reports that "the continued use of saccharin for a long time in quantities over 0.3 of a gram per day is liable to impair digestion; and the addition of saccharin as a substitute for cane sugar reduces the food value of the sweetened product and hence lowers its quality." Saccharin-containing foods are therefore regarded as adulterated within the meaning of the Food and Drugs Act. The substitution of cheap chemicals for high-priced natural flavoring extracts, the substitution of acetic acid or even mineral acids for genuine vinegar, the paraffin polishing of rice, and similar devices are nothing but common frauds, which may in some cases also be injurious to health.

3. **ABSTRACTION OF VALUABLE CONSTITUENTS.** "If any valuable constituent of the article has been wholly or in part abstracted." Skimming milk is a good illustration of this part of the law, or the abstraction of cocoa butter from chocolate. There is, however, no objection to abstracting valuable or nutritive substances provided

the label properly announces the facts; thus, skimmed milk or cocoa are legitimate foods. So also the caffeine may be taken out of coffee and the product sold as caffeine-free coffee. The essential oils are sometimes extracted from cloves or other spices, which are subsequently ground and used as an adulterant with unextracted spice. Abstraction without honest labeling is a fraudulent practice.

4. CONCEALING INFERIORITY. "If it is mixed, colored, powdered, coated, or stained in any manner whereby damage or inferiority is concealed." This is a frequent form of adulteration, and, as a rule, is undesirable and sometimes injurious. The artificial coloration and decoloration of foods has reached the point of being a fine art. Substances used to color foods are usually considered in four classes: (1) mineral dyes, (2) vegetable dyes, (3) aniline or coal-tar dyes, (4) ethylene for ripening and coloring. The principal *mineral dyes* are: copper sulphate, oxide of iron and potassium nitrate. Copper sulphate is used to give a green color to peas, pickles and similar foods. The copper probably unites with the albuminous matter to form new compounds which have a bright green, sickly color. The oxide of iron and also sulphites are used to redden meats; potassium nitrate will also give a bright red color to pickled or corned meat. Many *vegetable dyes* are used, such as annatto (the juice of the *Bixa orellana*, a South American tree), which is used to color butter. Carrot juice is also used; turmeric in mustard; and logwood in wines. The *coal-tar dyes* have largely replaced the vegetable and mineral pigments in foods, on account of their brilliant color and cheapness. They are used in sausages, confectionery, jellies and jams, meats, flavoring extracts, etc. The permitted dyes are harmless to health. Citrus and other fruits, tomatoes, etc., are artificially ripened and colored with ethylene. This practice has grown tremendously.

The artificial coloring of food is a false standard and serves no useful purpose. When the coloring is done to conceal damage or inferiority the practice is indefensible, as when spoiled meats are made to look bright red and fresh, or when oleomargarine is colored in order to imitate butter and sold as such. Flour may be bleached with nitrogen peroxide. The flour absorbs this poisonous gas as a sponge absorbs water and instantly becomes white. Processes of this kind should be regarded as a common fraud, for the flour is not improved in any way except in appearance, which is, after all, a deception. The City of New York requires flour that has been bleached with oxide of nitrogen, or nitrous oxide or nitrates, or chlorine to be legibly and conspicuously labeled "Bleached with ————." Dried fruits are bleached by exposure to sulphur fumes, which leaves objectionable sulphur compounds. Candies and chocolate are coated with gum benzoin or shellac. Concealing inferiority may be both an economic fraud and a health menace.

5. ADDITION OF POISONS. "If it contains any poisonous or other added deleterious ingredient which may render such article injurious to health." This section of the law is intended to include adulterants, such as formaldehyde, sulphites, arsenic, hydrofluoric acid, lead, salicylic acid, borax and boric acid, as well as any other injurious substance. Most of the storm center of the opposition to the Pure Food Law centered around this paragraph, owing to the difficulty of deciding in certain instances whether small amounts of benzoic acid or benzoates, boric acid or borates are injurious to health or not.

6. DECOMPOSITION. "If it consists in whole or in part of a filthy, decomposed or putrid animal or vegetable substance or any portion of an animal unfit for food."

whether manufactured or not, or if it is the product of a diseased animal or one that has died otherwise than by slaughter." Examples: oysters, contaminated with sewage; eggs known as "rots and spots"; animals which have died from disease or by accident; figs containing an excessive quantity of worms and worm excrement. This paragraph of the law has caused much discussion, especially the meaning of the word "decomposed."

7. MISBRANDING. The term "misbranding" is specifically defined in the Pure Food and Drugs Act and provides for all possible conditions of fraud, mislabeling, imitation, substitution and other forms of deception. Misbranding is regarded as a form of adulteration under the provisions of the Pure Food and Drugs Act.

Misbranding practices under any circumstances are so evidently fraudulent or dishonest that they cannot be justified on any score and are wholly condemned. It is true that many instances of misbranding do not directly affect health, except in so far as they deceive the consumer; that is, he is purchasing at a high price an article which contains less nutritive value than claimed for it. An honest label which correctly states the character, origin, amount, and the constituent parts of an article is as much a desideratum in food products as it is in commercial articles of all kinds. Honest labeling is the heart and soul of the pure food movement.

## PRESERVATION OF FOODS

The preservation of meat, vegetables and other perishable foods is one of the important questions we have to deal with in hygiene. The proper preservation of foodstuffs involves not only the art of keeping them "fresh" and wholesome, but also keeping them so that they will not lose their nutritive value. Finally, foodstuffs must be preserved so that they will not acquire injurious properties. The preservatives ordinarily in use are: cold, drying, salting, smoking, canning, preserving, chemical treatment, fermentation and physical processes. The preservation of food by cold, or sterilization by heat have the advantage over other processes in that they cause comparatively little alteration in the food.

Practically all these methods have long been in use. The only modern innovations in the preservation of foods are the perfection of the old processes, and the use of mechanical means, such as vacuum, filtration, pressure, radiation, etc. Heat and cold represent old family methods which have been extended and improved in the modern canning and cold storage industries. The drying of fruits, fish and meats is a practice of very ancient origin. The use of salt doubtless antedates all historical records. Sugar either alone or with acetic acid in the form of vinegar and with various spices is an old contrivance and well known everywhere. The application of creosote obtained crudely from the smoke of incompletely burned wood is the ancient forerunner of some of the modern packing processes. Fermentation to preserve food is one of the oldest of the arts.

Concerning the value and legitimacy of these old family methods there is comparatively little difference of opinion; salt meat is not as good as the fresh article; dried apples do not make the best apple pie; chipped beef is not an adequate substitute for a fresh steak. However, it is absolutely necessary to preserve food in some way in order to tide over the winter or the dry seasons, to furnish food to people living and working in desert and arid regions, and to feed the hordes of people

massed together in great cities. It would be impossible to maintain the large population of a modern metropolis if it were dependent upon a daily supply of fresh food materials.

The art of preserving foods successfully is largely a problem in applied bacteriology. It is now possible to keep most foods for long periods without materially injuring their nutritive value or seriously interfering with their appearance and taste.

The chief mischief was the threat of a blind use of chemical germicides without regard for their effect upon health. The simplest and cheapest way to preserve food is by adding one of these chemicals, and the method was, therefore, seized upon by alert men whose chief interest was of the pecuniary kind. The question was to find the smallest percentage of a chemical which would prevent the decay of some particular food product, trusting to luck that the preservative used might prove harmless to the consumer. Often these chemicals were added with a liberal hand and the abuse grew; further, it was soon found that chemicals could be used to preserve food products for the market from material already so decayed as to be unsalable in their original condition, and the unscrupulous profited thereby.

The National Pure Food and Drugs Act \* of 1906 was passed largely to meet this situation. This law considers any food which contains "any added poisonous or other deleterious ingredient which may render such article injurious to health" as adulterated. To Harvey W. Wiley belongs the credit of inducing Congress to pass this legislation against opposition and for an aggressive administration that proved useful in bringing the whole question prominently before the public.

**Refrigeration.** Cold prevents or hinders bacterial activity. Low temperatures in themselves do not kill bacteria, but prevent the growth and multiplication of most of them. In other words, cold is bacteriostatic rather than germicidal. The effect varies with the temperature. Many plants and even frogs may survive freezing; in fact, some molds will grow at the freezing point. Furthermore, cold delays or checks the action of enzymes, which cause ripening. Little change occurs in chemical, enzymic or nutritive properties in freezing. The rate of chemical and biological activity is a function of temperature. Changes are largely physical. Frozen food should be consumed as such or within a few hours after defrosting.

Burdon-Sanderson, in 1871, was the first to show that freezing does not kill bacteria. Von Frisch demonstrated that subjecting a putrefying solution to a temperature of  $-87^{\circ}\text{C}$  for some hours did not effect sterilization. Leidy, in 1848, showed that water derived from melted ice contained not only living infusoria, but also rotifers and worms. Pictet and Young found that anthrax and symptomatic anthrax cultures were not killed after an exposure of 108 hours to  $-70^{\circ}\text{C}$ . Later Macfayder proved that the temperature of liquid air does not kill bacteria; he subjected culture to a temperature of  $-315^{\circ}\text{F}$ . Ehrlich has shown that cancer cells kept cold will live and remain virulent for at least two years.

While no micro-organism pathogenic for man will grow and multiply at the low temperatures of the refrigerator, there are a number of saprophytic bacteria and molds that develop abundantly at temperatures as low as  $0^{\circ}\text{C}$ . Milk, meat, egg and other products kept in cold storage, but below the freezing point, may show a notable increase in the number of bacteria. In the case of milk these low temperature micro-organisms belong mainly to the putrefying and proteolytic group. The

\* Now known as Federal Food, Drug and Cosmetic Act, 1938.

produce an alkaline reaction in the milk and a bitter taste. There is no evidence that poisonous products are formed under these conditions.

For the most part pathogenic bacteria withstand freezing temperatures. They, however, suffer a quantitative reduction when frozen. The element of time here plays an important role, as most of the frailer pathogenic bacteria eventually die. In the ripening of cheese where bacteria cultures are used, pathogens such as *Salmonella typhosa* (*E. typhosus*) gradually die off, possibly as the result of end products of the culturing organisms. When cheese is made from raw milk naturally infected with *S. typhosa*, experience has shown that the cheese after storage for 60 days or more does not cause typhoid fever in persons who eat it, although it would cause disease if eaten a week or two after manufacture. From a sanitary standpoint the protection afforded by refrigeration is partial; it cannot be depended upon to disinfect. In fact, it acts as a good preservative for some viruses.

Some *animal parasites* die in cold storage; some, however, survive. Thus, *Trichinae* die at or below 5° F in less than 20 days (see trichinosis, page 891). If the temperature is maintained at 15° F or below, the larvae of *Taenia saginata* (the beef tapeworm) are killed within six days, but this cannot be depended upon for *T. solium* (the pork tapeworm). Rabbits refrigerated may not be safe so far as tularemia is concerned.

**TEMPERATURE OF REFRIGERATION.** The best temperature at which foodstuffs may be kept must be determined in each case. Some substances, such as meat and poultry, are better preserved when actually frozen; others, such as shellfish, eggs, milk, potatoes, oranges, etc., are materially injured by freezing. For temporary preservation fish are kept at refrigerator temperatures. If preserved in cold storage, they may be frozen, then dipped in water and refrozen in order completely to encase them in ice. They are then stored at a temperature of -16° C. The coating of ice, which is renewed as occasion requires, prevents loss of water due to surface evaporation. Under these circumstances fish may be preserved two years without appreciable change in appearance, flavor or nutritive value.

**HOUSEHOLD ICEBOX.** In any event, the temperature of the icebox should not rise above 7° C. At this temperature bacterial growth does not entirely cease, although very markedly hindered. The temperature of modern mechanical refrigeration can be set and controlled. Few household refrigerators depending on ice maintain a satisfactory low temperature. A study of such iceboxes disclosed the fact that the temperature is often 15° C and higher. Such conditions make good incubators, favoring bacterial growth. *S. enteriditis* will grow at 10° C. The necessity for scrupulous cleanliness, aeration and dryness in all refrigerating devices needs only be mentioned.

**COLD STORAGE.** There has been a phenomenal growth in the frozen food industry in the past few years. For example, there was a production in the United States in 1930 of 320,000,000 gallons of ice cream, 77,000,000 pounds of poultry, 30,000,000 pounds of strawberries, 100,000,000 pounds of fish, and correspondingly huge quantities of meats, fruits, vegetables and other frozen products.

In ordinary refrigerating plants moisture condenses on the surface of the objects exposed. In the case of meat this moisture dissolves some of the proteins, extractives and salts, and makes a perfect culture medium for bacteria and molds. It is, therefore, better to hang meats in a current of dry, clean air, in order to desiccate the

surface, before they are placed in the refrigerator. The dried surface delays the inward growth of the inevitable bacterial contamination upon the surface.

Articles of food may be kept in a satisfactory condition in cold storage for a long time. The time varies with the article and its condition when placed in storage, also with the temperature and other factors. A striking illustration of the great preserving power of low temperatures occurred some time ago in northern Siberia. In consequence of a great landslide on the banks of the Kolyma, the head of a mammoth became exposed and was so well preserved that even the fleshy trunk remained. It is said that famished wolves and half-starved natives began to eat of the flesh. The Russian government sent Hertz to rescue what remained. The mammoth had remained in cold storage perhaps thousands of years. Some of the soft parts were sent to the Museum at Leningrad. This must not be taken as justification of prolonged storage or the "cornering" of foods for economic gain in mammoth cold storage warehouses. While meat, poultry, eggs and vegetables may be kept in a satisfactory condition for months and transported over seas, cold storage should not be unduly prolonged. In any case, the consumer is entitled to know whether the article is fresh or stored, and the time it has been in cold storage. These facts should be stated upon the label or stamp.

The question of cold storage poultry was investigated by the Massachusetts State Board of Health, and the conclusion was reached that it made practically no difference whether the fowl were drawn or not, but that they must be perfectly fresh when placed in cold storage. Poultry kept below 0° C shows little or very slow change. It was found that cold storage fowl are even less contaminated with bacteria than freshly killed birds that have hung for a few days. However, the cold storage foods, when removed from the refrigerator, decompose more quickly than the fresh.

Contrary to what might be expected, drawn poultry decomposes more rapidly after removal from cold storage than undrawn. This is because in the process of drawing, the intestines are broken and the carcass is exposed to intestinal and other bacteria. If the entire alimentary canal, esophagus, crop, gizzard and intestines are removed intact, and with bacteriologic care to prevent contamination, the bird is practically safe from putrefaction.

The deterioration of foods held in cold storage is slow but nevertheless real when measured in terms of months or years. Storage temperatures may vary from 31° to 40° F for such products as meats, fruits, vegetables, milk, cheese and eggs, and 0° F for frozen foods. In general, lower temperatures permit longer storage without bad effects. Some foods cannot be frozen without damage. The principal deleterious effects of long storage are desiccation, discoloration and loss of texture and flavor. There is no definite evidence of any deterioration that may affect health directly. It has been demonstrated that at fixed temperature some foods may be held much longer than others without serious effect on quality. Cold storage for short periods may even improve quality, as in storing freshly slaughtered meat for tenderizing. It is believed that the action of enzymes at low temperatures is responsible for much of the change in foods in storage.

Many states have enacted laws and regulations governing the operation of cold storage warehouses. Enforcement generally rests with the state health department, the state department of agriculture, or a dairy and food, or food and drug commission. Regulations are designed to require the maintenance of low temperatures, to

permit inspection and access to records, to prevent holding foods for unreasonable periods of time, and to require labeling as cold storage products.

**FROZEN FOODS.** With the development of the quick freezing method resulting in little structural damage to foods so processed, this method of preservation is becoming popular both with respect to foods commercially packaged and frozen to those packaged and frozen at home in so-called "deep freeze" units. A few studies have been made of the total bacterial counts of commercially frozen foods. The counts on some of the prepared creamed foods are rather high. However, there is no present indication that the bacteria present have caused illnesses (see salmonellosis, page 208). Studies show that methods of handling frozen foods in transit are not ideal and that at times the temperature within the package instead of being at  $0^{\circ}\text{F}$  may be above the freezing point, as indicated by the melting of incorporated ice cubes. Inadequately refrigerated freight cars, long hauls on poorly insulated trucks, and exposure on platforms while loading or unloading are all factors. Mechanically refrigerated freight cars that will hold packaged goods at well below  $0^{\circ}\text{F}$  while in transit are in experimental use. The general substitution of such cars for the present refrigerator cars with ice bunkers should be helpful in improving the quality of frozen foods subject to long hauls.

The development of locker plants for frozen foods has created problems. Any failure to maintain foods continuously in a frozen state may cause spoilage with possible danger to health. Because of the money value of foods in storage it is likely that the operator will try to conceal temporary lapses by refreezing the foods in which toxins may have developed while the foods were warm. It has been recommended by the Committee on Sanitary Engineering and Environment of the National Research Council that official regulations covering locker plants include the approval by the state health authority of plans for new plants to insure the maintenance of adequately low temperatures and prevent nuisances; that special attention be given to securing sufficient and reliable insulation of floors, walls and ceilings of storage rooms; that duplicate compressors be provided; that wherever possible standby electric service be provided, and that to avoid nuisances or health hazards efforts be made to anticipate future requirements for services such as slaughtering animals, meat and food processing and baking.

**SUMMARY.** From a sanitary standpoint, then, refrigeration is one of the best methods of preserving foodstuffs. The advantages of cold as a preservative are that it neither adds any constituent to the food nor takes away any constituent from the food. Cold imparts no new taste, nor does it seriously alter the natural flavor. It does not diminish its digestibility nor cause a loss of nutritive value. It has slight if any effect on most of the vitamins. The material is left in approximately its original condition. Many bacteria will live but not multiply. Cold may, therefore, be regarded as one of the simplest and best antiseptics we have for the preservation of foods. It is now almost universally applied to prevent decomposition and decay. The farmer uses it to keep food in cold cellars, deep wells and the like. Its value and usefulness have been enhanced by the introduction of quick freezing methods with storage at  $0^{\circ}\text{F}$ . The use of mechanical refrigeration in many ways in the preservation and marketing of food is on the increase. Fresh and wholesome food may now be transported to and from the tropics, and the sustenance of large communities in

insular and arid regions is made possible and pleasurable through the preserving use of cold.

**Drying.** Drying, desiccation or evaporation is a favorite and primitive method of preserving meats, and in recent years it has been extended to include vegetables, milk, eggs, and almost every kind of watery food. Dryness furnishes ideal antiseptic conditions. Micro-organisms must have moisture to grow and multiply. Most pathogenic bacteria soon die when dried, hence the process has a decided sanitary advantage. Furthermore, dried fruits, vegetables or meats are rarely eaten raw, and the cooking is a further sanitary safeguard.

Drying has two principal advantages which simplify the problem of handling and distribution: it improves the keeping qualities of the food and it reduces the weight and bulk.

The effectiveness of drying as a food preservative depends upon the thoroughness with which the process is carried out. It is not so well adapted to meats as to vegetables and fruits. Dried meats lose their natural flavor, which may be replaced with others less real. The keeping qualities of dried food depend upon the degree of dehydration.

**EFFECT ON VITAMINS.** Drying has little or no influence upon some of the vitamins. It certainly does not diminish the activity of vitamin B which protects against beriberi. Dried leaves, such as celery tops and alfalfa, are still good sources of vitamin A, even when dried in the sun, or by artificial heat in a current of air after preliminary treatment with steam. Dried milk is also an efficient source of vitamin A. Drying affects chiefly vitamin C. A diet of dried foods has long been associated with scurvy. Even Captain Cook knew that this deficiency disease could be prevented by the use of fresh food. Milk may be dried so that it contains about one-half its original antiscorbutic property.

**CHANGES IN DRIED FOODS.** The changes which take place in dried foods are more than simple loss of water. There may be physical changes which are not reversible. Some of the constituents become insoluble. Enzymes and oxidation continue their activity, although slowly. Milk and eggs under ordinary conditions of desiccation in time turn rancid.

**METHODS.** The methods of drying have been greatly improved and widely extended. The old-fashioned sun drying has been replaced by vacuum drying. In the tunnel method, the food is placed on racks in tunnels or chambers through which the current of heated air is passed. In the kiln method, the food is placed on the perforated floor and heated from below by means of a furnace. Each food must be processed by a method best suited to its peculiarities. Birdseye describes a process he called dehydration. The basic principle is the very rapid removal of moisture from the food, as a result of which he claims that the food upon reconstitution with water much more nearly resembles the original food than if it were dried by the slower methods in common use.

**DRIED MEAT.** The successful drying of meat requires a suitable temperature and the absence of air. The temperature must be kept below the point where the proteins coagulate and the fats melt. If the drying is too slow, the meat will spoil in the process; if too rapid, a hard protecting layer forms on the surface. Meat is therefore best dried in a vacuum in cut pieces at a suitable temperature. Dehydration by the vacuum method is, in fact, generally applicable to many different foods.

In the dry climates of South America and on our western plains, meat is cut into thin strips, suspended in the air, and exposed to direct sunlight. In a short time the moisture disappears and the hard, dry pieces keep indefinitely, or as long as they are kept dry. The meat retains a fair degree of palatability and practically all of its nutrient properties. This is known as jerked beef.

Dried beef is also prepared by first treating the meat with condiments and then drying it artificially. Chipped beef or dried beef is prepared in this manner, except that the meats are often smoked as well as salted and desiccated, so that in their preparation more than one method of preservation is employed.

Powdered meats are prepared by complete desiccation, and such products are found upon the market as a finely ground powder. Meat powders are made not alone from fresh meats in their natural state, but are also prepared after more or less artificial digestion.

**DRIED FRUITS.** Dried apples are taken as a type of dried fruits and vegetables. The apples may be dried naturally by cutting them into convenient sizes and exposing them to the action of the sun. This is more a domestic than a commercial industry. When apples are dried by this simple process they darken and become unattractive in appearance, which is due to the oxidizing action of the enzymes when exposed to the air. When properly prepared the dried apple has its moisture content reduced to 24 per cent. Dried apples containing 26 to 27 per cent are apt to ferment.

In order to prevent the darkening of the surface, apples are usually subjected to the fumes of burning sulphur. The sulphur dioxide acts as a bleaching agent and the sulphurous and sulphuric acids retained in the apple act as preservatives. Apples treated with sulphur fumes are less likely to decay or become infected with molds than a similar product not exposed to sulphur fumes. The process is objected to from the standpoint of health, for the reason that the sulphurous acids and sulphites are admittedly injurious. The United States Department of Agriculture found that approximately half of the evaporated fruits purchased on the open market had been treated with sulphur fumes. In order to obtain a satisfactory dried product it is of some importance that the fruits be selected so as to reject all imperfect, rotten or infected specimens.

*Evaporated apples* is a term applied to apples dried artificially instead of being exposed to the sun's heat. The process is rapid and satisfactory, and has no sanitary objections.

**DRIED MILK.** Milk must be dried quickly in order that it will not spoil during the process, and the temperature must not be high enough to coagulate the lactalbumin, otherwise the addition of water would not restore the milk to its former homogeneous state. Milk may be dried in a thin film on heated and revolving metal drums or on belts in a current of dry, warm air; or *in vacuo*. In this way the milk can be reduced to a dry state in a short time and without reaching a temperature sufficiently high to materially alter its quality. A favorite method of drying milk consists in atomizing it under pressure and projecting it into a warm chamber, the temperature of which is so regulated that the fine particles are completely deprived of their water before they reach the bottom of the cabinet. The milk is thus reduced almost at once to a fine powder.

Milk that has been dried and is then mixed with water is practically restored to its original condition, except that the solubility of some of the constituents is inter-

ferred with. It is difficult to preserve milk powder against rancidity. It keeps well if it contains less than 2.5 per cent water, but even then the results may be disappointing in handling whole milk.

North reports upon a process for packaging butter oil in tins under nitrogen which he claims will keep without refrigeration for two years or more. A special carefully prepared skimmed milk powder when canned also may be similarly kept. By combining butter oil and skimmed milk powder with water without special equipment but following directions, he claims that a reconstituted milk can be easily prepared that has an acceptable flavor and good food properties.

Dried milk should, of course, be made from milk derived from healthy cows handled under sanitary conditions and free from infection. The milk should be pasteurized before it is reduced to a powder. Powdered milk is finding an increasing and legitimate field of usefulness for cooking, household purposes, as a beverage for adults and even for infant feeding.

Dried milk seems to retain all the essential qualities of the fresh product, except that it has lost some of its antiscorbutic property, and is less attractive. Since practically 88 per cent of milk is water, there is a decided gain so far as handling, transportation and keeping are concerned. For partially dried milk, such as condensed and evaporated products, see section on Milk.

**DRIED EGGS.** Eggs are broken out, mixed and dried by spreading the mass in a thin film on a revolving drum, or by the spray method, similar to that of drying milk. Egg powder keeps well and retains practically all the nutritive value of the original egg. The presence of bacteria in dried eggs is to be expected in view of the frequency with which bacteria are found in the yolks of fresh eggs and the good possibilities for bacteria on the shells to find their way into the egg mass during the cracking process. With the limit set on total bacteria count on dried eggs for the use of the armed forces in World War II, processors experimented with some success with washing eggs prior to cracking and with mild heat treatment.

**Salting and Pickling.** The preservation of meat with brine or common salt is one of the oldest processes known. The brine should contain from 18 to 25 per cent of salt. For red meats a little potassium nitrate is often added; this salt has slight antiseptic properties, but brings out the red color. Haldane has shown that nitrite is formed from the nitrate, and that some nitrous oxide hemoglobin is formed, which gives a bright red color to the meat. In the process of salting, some of the meat protein, bases, and extractives are dissolved out and the fibers become hardened; the nutritive value and digestibility, therefore, are somewhat diminished. The brine should never be less than 8 per cent, for *C. botulinum* will not grow and produce its toxin in this concentration.

The preserving action of salt depends largely upon dehydration, but also upon the direct effect of the chlorine ion, removal of oxygen, and on interference with rapid action of proteolytic enzymes.

Pickling includes preservation of food in brine, vinegar, weak acids and the like. These substances have bacteriostatic and also feeble germicidal properties, depending upon their concentration.

*Pickled meats* are prepared by soaking meat, especially pork, in a brine made of common salt, though other substances, such as sugar, vinegar and spices, are often added. Sulphite of soda, boric acid, borax and benzoic acid, and other chemical

preservatives formerly used are no longer permitted by the United States Bureau of Animal Industry (see page 887). With proper methods chemical antiseptics are not necessary. The vinegar which is employed, or acetic acid, may be injected into the carcass before it is cut up. When the arteries are filled with vinegar in this way it rapidly permeates to all parts of the meat and acts as an excellent and unobjectionable preservative in cases where an acid taste is desired. It is stated that carcasses which have been injected with vinegar are easily preserved and require far less salt and other condimental substances than when not so treated. The process has no sanitary objections.

*Trichinae* die after prolonged periods of pickling. *Cysticerci* die a natural death in 21 days following the death of the host. They are killed promptly in brine, provided the salt comes in direct contact. Owing to the difficulties of penetration, this cannot be depended upon and, therefore, pickled beef from infected cattle is considered free from viable *cysticerci* only after the expiration of three weeks following slaughter. The life of many pathogenic bacteria is shortened in brine, depending upon the concentration and temperature, but the salt must be looked upon as an antiseptic rather than a germicide; that is, it prevents growth rather than kills the bacteria that are present. From a sanitary standpoint there is some, though slight, danger of conveying infection in foods that have been improperly salted or pickled. Attention is called to the fact that the first cases of botulism studied by van Ermengem were caused by ham kept in brine under conditions favoring anaerobic growth. Ripe olives which were responsible for botulism were also treated in brine. In the first instance, the ham stuck partly out of the water, and in the second instance the brine was very weak and dirty, and the heat of preserving insufficient.

**Preserving.** JELLIES AND PRESERVES. By preserving is commonly understood the addition of a large amount of sugar. The principal preserves are jellies, marmalades, jams and fruit butters. These substances are entirely free from the danger of conveying infection, mainly because they are always cooked in preparation. A strong solution of sugar will prevent growth, but cannot be depended upon to kill parasites. However, most pathogens die under such conditions in the course of time. A strong syrup (50 per cent sugar) is necessary to prevent the growth and development of *botulinus* toxin. Jellies and preserves have a comparatively clean bill of health.

Jellies are frequently adulterated by the substitution of apple stock. Apples contain a large number of pectose bodies which favor jellification. Pectose is a carbohydrate similar in composition to cellulose. When boiled with an acid, pectose bodies are hydrolyzed to pectin which takes the jell form on cooling. Pectose bodies which will insure jellification may be purchased on the market.

A common method of manufacturing jelly for the trade has been to use a stock of apple juice or cider, or a preparation made from the cores, skins and rejected portions of the apple at evaporating factories, or from whole rejected apples. This stock is used as a common base for the manufacture of jellies of different kinds. Apple juice used as a substitute for other fruit juices in the making of preserves is a common fraud and an adulteration, according to the Pure Food and Drugs Act, unless plainly stated upon the label. Jellies are also colored artificially, particularly with the coal-tar dyes. Artificial flavors are sometimes employed. The chemical preservatives most frequently added to jellies and preserved fruits are benzoic acid and benzoate of soda. Salicylic acid and others are prohibited.

**Smoking.** The smoking of fish, beef, hams and other food products consists mainly in rapid drying plus the germicidal action of certain substances in the smoke. The meat or fish is exposed to the smoke of a smoldering wood fire of oak, maple or hickory, usually after a preliminary salting. The articles so exposed become dry and impregnated with pyroligneous products—acetic acid and creosote, formaldehyde and other germicidal substances. An artificial or quick method of smoking meat formerly used, but now contrary to law, consisted in brushing the pieces or dipping them in pyrolignic acid at definite intervals, and finally drying them in the air.

The effects of smoking do not go deep—the penetration is only partial; therefore, in sausages of generous diameter putrefaction often occurs in the interior. Smoked sausage may, therefore, be dangerous, as far as various parasites and bacterial injury are concerned, and the same is true of smoked ham and other meats exposed in large pieces. As smoked meats are often eaten raw, the occasional survival of parasites in such products has some sanitary significance.

**Chemical Preservatives.** Chemical preservatives are nothing more nor less than bacteriostatic substances and in the proportions commonly used may have little or no germicidal action. Such substances as sugar, salt, vinegar, vinegar extract of spices, and the pyroligneous products in wood smoke are not regarded as “chemical” preservatives, but as “natural” preservatives or condimental substances, although their mode of action is precisely the same as the chemical preservatives.

There was a great increase in the use of chemical preservatives in foods during the several decades prior to 1906, when the Pure Food and Drug Act went into effect. Chemical preservatives were grasped upon, owing to the fact that this method was cheap, easy and sure. Fortunately, we possess two efficient and wholly unobjectionable processes for the preservation of food, *viz.*, refrigeration and sterilization by heat, which for the most part make it unnecessary to resort to the use of chemical preservatives. One of the most objectionable uses that can be made of chemical preservatives or any other method of food preservation is to conserve foods which are so decayed as to be unfit or possibly injurious to health if used fresh. The law cannot be too strictly enforced in order to prohibit the use of chemical preservatives and condiments used to disguise such foods, which may then be sold at high prices as first quality.

Upon general principles it is undesirable to add a chemical substance of whatever nature to food for the purpose of preserving, coloring, or improving its appearance, and in most countries this practice is prohibited by law. There are, however, a few instances in which the addition of some chemical preservative in minimal amount seems harmless, and occasionally even desirable, as, for example, small quantities of benzoate of soda in catsup; a thin film of gum benzoin as a protective coating for chocolate, etc.

Countries differ widely concerning the use of chemical preservatives in food. No sweeping generalization can be made concerning all chemical preservatives. Each substance must be considered for itself, and each substance must further be considered in relation to the particular foodstuffs for which it is proposed. It may, however, be stated as a general rule that any chemical which is poisonous in large amounts should be considered as poisonous in small amounts until the contrary is proved. In other words, the consumer is entitled to the benefit of the doubt. The

toxicology of various food preservatives is in its infancy and frequently presents a very difficult and complex problem. Thus, lead in one large dose is not particularly harmful. The older practitioners frequently gave 20, 30, and more grains of sugar of lead (acetate of lead) for diarrheal affections. Only a minute portion of the lead taken in one large dose is absorbed; the rest is quickly eliminated. However, if the same amount of lead should be taken in small subdivided daily doses, enough would be absorbed and retained by the tissues so that serious chronic lead intoxication would develop, resulting from the cumulative action. On the other hand, hydrocyanic acid, one of the most poisonous chemicals known, is harmless in small amounts, for the reason that when introduced into the body it meets the available sulphur ( $H_2S$ ), with which it unites to form a sulphocyanide, as  $KSCN$ . The potassium sulphocyanide is not poisonous, and it has been shown experimentally that animals are able to withstand larger quantities of hydrocyanic acid by first giving them substances which increase the available amount of sulphur to form this chemical combination. Benzoic acid in large amounts is irritating and produces well-defined symptoms of poisoning; small amounts of benzoic acid are paired in the liver and eliminated by the kidneys as hippuric acid, a harmless constituent of the urine. Hydrochloric acid and possibly acetic acid and alcohol are all poisonous in large amounts, but they may be regarded as harmless if the amounts taken are sufficiently small. There can be no defense for the use of formaldehyde, salicylic acid, sulphites, and a host of other chemicals. So far as we know, the human organism possesses no natural mechanism for rendering them harmless. There can be no defense for the use of chemical preservatives to hide inferiority.

**BENZOIC ACID AND BENZOATE OF SODA.** These are weak germicides at best, and benzoate of soda in dilutions of 1:1,000 commonly used in food has feeble bacteriostatic power. Benzoic acid is an organic acid contained largely (12 to 20 per cent) in gum benzoin, and also in balsam of Peru and balsam of Tolu. It is obtained from gum benzoin, from the urine of herbivorous animals, and artificially from toluene, by treating it with chlorine and heating with water to  $150^{\circ}C$ .

The reason why benzoic acid in moderate amounts is believed to be harmless is that the body possesses a special mechanism for taking care of this substance. Many of our ordinary foods contain substances which are transformed in the body into benzoic acid. Some foods, such as cranberries, contain this acid in notable amounts. Benzoic acid meets glycocholic acid (one of the decomposition products of protein) in the liver to form hippuric acid. We know, therefore, that the human organism is prepared to take care of and render harmless a certain amount of benzoic acid; we know that this mechanism is efficient and is capable of taking care of relatively large amounts of benzoic acid.

The United States permits the use of benzoate of soda in quantities not exceeding 0.1 per cent in certain foods, but the addition must be plainly stated on the label. There can be no serious objection from the standpoint of health to the addition of these amounts of sodium benzoate to catsup, on account of the small quantity of this article consumed at any one time. Further, on account of the long time a bottle of catsup is usually kept after it is opened in the household, there is, thus, the added economic gain of preserving the catsup until it is all consumed. The same object may be obtained by the use of a sufficiently strong vinegar extract of spices, but the ques-

tion may be asked whether the aromatic and preserving substances in the vinegar extract of spices may not be more irritating than the sodium benzoate.

**BORAX AND BORIC ACID.** Both boric acid and borax are only mild antiseptics. They are generally used together, for the reason that the combination of the two is more efficient than either one alone. Locally boric acid is not very irritating, and for this reason it has been extensively used in surgical practice. To some skins, however, it is irritating, and cases are reported of its absorption from wounds and cavities when used too freely, causing depression and eruptions, such as erythema and urticaria. Fatal results have been reported in a few cases from injecting the solution into abscess sacs, or from washing out the stomach with it; or from taking a large amount by mouth.

Borax and boric acid are not allowed as preservatives in food in the United States and most countries. Canada and France allow them in butter, condensed milk and cream under restriction as to the amount. Formerly, they were extensively used for preserving meats, milk, butter, oysters, clams, fish, sausage and other foods.

The effect of small amounts of boric acid and borax upon healthy human beings has been extensively studied and has resulted in conflicting testimony. These substances are not normal constituents of the body, nor are they normal constituents of foods. Furthermore, there are better methods of conserving food. Therefore the use of borax and boric acid for food preservation should be prohibited.

**FORMALDEHYDE.** Formaldehyde was used extensively as a preservative for milk and occasionally for other articles of food. Concentrated solutions of formaldehyde in large quantities are irritating, and death in isolated instances has been reported from the swallowing of amounts of from 1 to 3 ounces. There has been much discussion as to the effect of the small quantities ordinarily used as a food preservative. Bliss and Novy in 1899 and Halliburton in 1900 have shown conclusively that small quantities of formaldehyde greatly delay the digestion of proteins by the gastric and pancreatic juices, the digestion of starch by the pancreatic juice, and the curdling of milk by rennet. It is also known that some individuals are especially susceptible to the effect of formaldehyde, small quantities in the food causing dyspepsia and other disturbances of digestion. Formaldehyde unites directly with protein matter to form new compounds of an undetermined nature. It hardens tissues, so that it will render fish and meat tough and brittle, even in proportions as dilute as 1:5,000, hence it is not generally applicable as a food preservative. In small amounts it delays decomposition; in large amounts it is an active germicide. Its use in milk was advocated by no less an authority than von Behring, but this view met with almost unanimous protest.

There can be only one opinion concerning the use of formaldehyde in foods, and that is absolute condemnation of the practice. It is prohibited by the statutes of practically all nations having pure food laws.

**SALICYLIC ACID.** Individuals differ greatly in their susceptibility to salicylic acid. In mild cases of poisoning with this substance there is a feeling of fullness in the head with roaring sounds in the ears, dimness of vision, profuse perspiration, confusion and dullness. Large doses of the acid cause intense irritation of the throat and stomach, leading to vomiting and difficulty in swallowing. Later there may be diarrhea. Eczema and other skin eruptions may appear, and dimness of vision and deafness may continue for some time. The long-continued use

salicylic acid and its salts has led to a form of chronic poisoning in which the chief symptoms have been loss of appetite, diarrhea alternating with constipation, irritation of the kidneys, skin eruptions, and mental depression. Such results are said to have followed the use of articles of diet preserved with salicylic acid. The use of such foods may be objectionable in the case of aged, feeble and susceptible persons. Salicylic acid and the salicylates are more efficient antiseptics than boric acid or borax, but they are not used extensively on account of the taste, or rather the tendency to cause unpleasant flavors. They were for the most part used in jams, fruit juices, soda water syrups, cider, wines and other sweet preparations. The objection to the use of salicylic acid in food is practically unanimous and well founded. It is prohibited by the regulations under the pure food act of the United States, and by England, Bulgaria and France, while some countries allow its use in minimal amounts.

**SODIUM NITRATE AND NITRITE.** Sodium nitrate or potassium nitrate (saltpeter) is not used as a preservative, but as an indirect coloring matter. It is reduced to nitrite and thus retains and accentuates the red color of meat. It is not known to be harmful in the small quantities in which it is commonly employed to give a good color to corned and pickled meat products (Grindley & Mitchell, 1917). The Bureau of Animal Industry of the U. S. Department of Agriculture allows nitrates to be used in meat in curing provided the finished product contains not more than 200 p.p.m. Heat used in cooking destroys nitrites but it cannot be depended upon, since the amounts destroyed vary with the degree of heat and the length of cooking. When nitrites are ingested in sufficient quantities they cause a chocolate brown discoloration of the blood by the reduction of hemoglobin to methemoglobin. This condition, known as methemoglobinemia, unless promptly treated may result fatally. Occasional instances of nitrite poisoning are reported. Greenberg and others (1945) report an outbreak in which 11 men were poisoned eating oatmeal in which sodium nitrite was used instead of table salt.

**POTASSIUM PERMANGANATE.** Potassium permanganate is used in the surface of meat to destroy the surface evidence of decomposition. This may be detected by heating a knife in hot water, plunging it into the meat, and withdrawing it quickly, which brings out the hidden odors if putrefactive changes have taken place.

**SODIUM FLUORIDE.** Sodium fluoride has been extensively used as a preservative, antiseptic and insecticide. It has considerable antiseptic power, putrefaction being delayed by the addition of 1 part to 500; and 1 in 200 arrests completely the growth of bacteria. It is highly poisonous to nearly all the lower forms of life, especially to micro-organisms, including algae. It does not coagulate protoplasm but acts as a general protoplasmic poison. For mammals, sodium fluoride is a toxic substance, the fatal dose by the mouth being 0.5 gm. per kilogram of body weight, and subcutaneously 0.15 gm. per kilogram of body weight. The fluorides in administration are deposited in the bones, which usually become white and brittle, and contain crystals of calcium fluoride. It is well to call attention to the fact that fluorine, in small traces, is a normal constituent of bone, teeth, milk, eggs, etc. In large amounts and concentrated, it is directly irritating to the mucous membrane and produces vomiting, diarrhea and abdominal pains. Death of a 10-year-old girl has been caused by the ingestion of one teaspoonful in a little water, given in mistake for Rochelle salts. Baldwin in 1899 reported a number of cases

of sickness and death resulting from the accidental ingestion of sodium fluoride, usually taken in mistake for baking powder. In a classic incident in 1942, in which all 467 of the exposed individuals became sick and 47 died, it is reported that white sodium fluoride, mistaken for powdered milk, was added to eggs in the preparation of scrambled eggs at a state hospital for the insane at Salem, Oregon. Recovery from nonfatal doses is usually rapid and complete. Small quantities ingested daily for a long period of time do not appear to be harmful, but should not be allowed.

Sodium fluoride forms the basis of most roach powders which contain from 16 to 47 per cent of the fluoride finely ground up and intimately mixed with the bait. It is fatal to roaches when so ingested.

**HYDROFLUORIC ACID.** Schultz in 1889 exposed cats for four days to concentrated fumes of hydrofluoric acid without serious effects. The air was so impregnated that glass held at some distance from the source was etched. Hydrofluoric acid is much used for disinfecting vats and tanks in making fermented drinks. It is a powerful germicide.

**SULPHUROUS ACID AND SULPHITES.** Sulphites act as antiseptics and also preserve the red color of meats. Sodium sulphite and bisulphite and sulphurous acid are used principally upon fresh meats, where they act as a preservative and as a retainer of color. Sulphites, even in minute amounts, interfere with the action of ferments, and thus influence digestion. Free sulphurous acid is very irritating. Sodium sulphite is very poisonous when injected subcutaneously or intravenously. Death occurs by paralysis of respiration. Much larger quantities are tolerated by the mouth, the sulphite being slowly absorbed. The greater part is converted to the harmless sulphate during and after absorption. The quantities ordinarily used in preserved food cause no immediate symptoms, even when continued for several months. In 1908, the Imperial Board of Health in Germany forbade the use of sodium sulphite in food on account of its dangerous properties, and it is also forbidden by our Federal Pure Food Act of 1906. On the other hand, sulphurous acid is allowed by more countries than any other preservative.

Sulphur dioxide is much employed for the bleaching of fruits. No objection is made to foods which contain the ordinary quantities of sulphur dioxide, if the fact that such foods have been so prepared is plainly stated upon the label of each package. An abnormal quantity of sulphur dioxide placed in food for the purpose of marketing an excessive moisture content is regarded as fraudulent adulteration under the Food and Drugs Act of June 30, 1906.

**SODIUM BICARBONATE.** Sodium bicarbonate is sometimes added to milk in order to neutralize the excess of acid, and this delays souring. It is too ineffective as a germicide for general use as food preservative.

**HYDROGEN PEROXIDE.** Hydrogen peroxide is perhaps one of the least dangerous of the chemical preservatives, and is considered by some to exert no deleterious effect whatever in the quantities commonly used. It was at one time advocated and used for the preservation of milk and also of wine, beer and fruit juices. It oxidizes and destroys vitamin C.

**ARSENIC.** Arsenic in food comes from a variety of sources. Glucose was found to contain it, especially if impure acid had been used to hydrolyze starch in its production. This was the source of the arsenic in the beer which caused the

demic of peripheral neuritis in 1900 in England. Samples of the glucose contained from 0.01 to 0.1 per cent of arsenic. The finished beer contained from 1 to 3 grains of arsenic per gallon. Arsenic may also contaminate certain aniline dyes as well as shellac which is now so much used as a coating for some kinds of cheap confectionery and baker's goods, and also as a varnish on receptacles and containers of various kinds. Another source of arsenic in food is from insecticide sprays.

In England liquid food is considered adulterated if it contains as much as 0.01 grain of arsenic per gallon, and solid foods are considered deleterious if they contain as much as 0.01 grain per pound.

The use of preservatives containing lead, arsenic or other substances known to be poisonous finds no advocate.

**SPICES.** Hoffman and Evans (1911) have shown that ginger, black pepper and cayenne pepper fail to prevent the growth of micro-organisms. Nutmeg and allspice have slight bacteriostatic properties, but only for a few days. Cinnamon, cloves and mustard, on the other hand, have marked antiseptic powers and are valuable preservatives. The active antiseptic constituents of mustard, cinnamon and cloves are the aromatic or essential oils which they contain.

Recent years have brought a tremendous increase in the use of chemicals in the broad field of food technology. Commercial competition with resultant widespread establishment of control and research laboratories has led to extensive use of chemicals in food by producers, manufacturers and processors.

**Canning.** The process of canning is practically synonymous with sterilization and is, therefore, one of the best sanitary safeguards we have against parasites and bacterial injury in foodstuffs. The process of canning was discovered by the confectioner, M. Appert, of Paris, in 1804 to 1809, long before the days of bacteriology.\* Appert found that meats and other foods in sealed vessels would usually keep indefinitely if, after being sealed, they were kept for an hour in boiling water. He improved the process, in 1810, by introducing a method of sealing the cans after the heating process had driven out the air and replaced it with steam, so that when cool a vacuum is formed. For all practical purposes this is the universal method of canning today.

The time and temperature vary for each food, for the size of the can and technologic technic. Bacteria are killed at definite temperatures in a given time, but the heat must penetrate to the center of the can. It takes longer to heat the contents of a large can than a small can, and penetration is much slower through corn (cream style) or sweet potato than it is through clear soup. The time and temperature for processing each article, therefore, depend on various factors which have been determined, depending on the size of the pressure cooker and the load. The time of processing should be counted from the time when the retort reaches the holding

\* Nicholas Appert, in France, first preserved food in glass jars by sealing them hermetically and heating, in 1804. He published *The Art of Preserving Animal and Vegetable Substances* in 1810. In 1810 Peter Durand obtained a patent in England for preserving fruits, vegetables and fish by hermetically sealing them in tin and glass containers. In 1820 William Underwood and Charles Mitchell, emigrant employees from a canning factory in England, opened a factory in Boston where they canned plums, quinces, cranberries and currants. Glass was used extensively until 1825, when Thomas Kensett secured a patent for use of tin cans and commenced use them in his factory.

temperature. Unless attention is given to these matters, spoilage is inevitable. These same principles apply to home canning. Only fresh and sound fruits and vegetables should be put up.

There is also a mistaken notion that once opened, the contents of the can should be emptied into some other vessel. It is generally believed that food kept in an opened tin can acquires injurious properties. This is a fable, like the souring of milk due to a thunderstorm. On the other hand, canned food may become contaminated or infected after opening, and the same care as to cleanliness and refrigeration is necessary with canned food that has been opened as with any other food in the kitchen.

The process of canning fortunately does not interfere seriously with most vitamins. Its effect varies with the food and the vitamins. It is now well known that most of these "unknown dietary factors" are not destroyed by heat in an acid medium and in the absence of oxygen; practically all our foodstuffs have an acid reaction. The antiscorbutic vitamin (vitamin C) is sensitive to heat and oxidation, especially in an alkaline medium. Vitamin B is also affected in some canned products. It has been shown that it is oxidation rather than heat which affects vitamins, and that when the "accessory factors" are injured it is usually when the food is heated in contact with the air, as in cooking. The pH of the medium is an important factor. The effect of heat on the vitamins is complicated, and the literature is large. It has been collected and tabulated by Kohman in 1919. Hess has shown that canned tomatoes retain their antiscorbutic properties.

Before meats are canned they are first parboiled for 8 to 20 minutes, in order to secure the shrinkage before the meat is placed in the can. In the parboiling there is a certain loss of fat, soluble mineral matter, meat bases and water. However, the shrinkage of the meat concentrates it, as far as nutritive value is concerned and, therefore, compensates for the loss. The parboiled meat is then placed in the tin, a small quantity of the soup liquor added, processed and sealed.

Canned foods are sterile foods; they are the safest foods that come to our table. Canning is synonymous with cooking, and when properly canned, the contents are thoroughly cooked. The process of canning has proved of inestimable benefit to mankind. It enables nourishing food of a perishable character to be kept and transported to great distances and to be used in localities where fresh food are unobtainable. Without this method of preserving foods the pioneer and the explorer would be seriously handicapped. Large army and navy maneuvers would be materially impeded, and great metropolitan cities would be impossible. Wik states that "the winning of the West has been marked by the debris of the rusty can

Canned foods are not only safe, but wholesome and nutritious. The process permits us to have a well-balanced ration throughout the year—irrespective of season. Canning has this further advantage, that the products used must be well ripened; whereas, many fruits and vegetables are picked green and allowed to ripen for the market. The canning industry has grown to enormous proportions and, on account of the great importance of the process, the character and quality of foods thus preserved should be wholly above suspicion, and no adulteration or sophistication of any kind permitted. In the interest of honest and informative labeling, every can should be plainly stamped with the quantity and true nature of its contents. The keeping qualities of canned foods vary with the product

many instances they may be kept two to three years without appreciable change. Some products, for instance loganberries, change in color and flavor. Heat hastens the change and promotes spoilage. All canned products keep better cold.

Spoilage may result from insufficient processing, defective cans or the use of unfit material. These losses are generally classed under the heads of *swells*, *flat sours*, and *leaks*. The ends of a swelled can bulge, and when opened there is evidence of gaseous fermentation and spoilage. "Flat sour" is a term applied to acid decomposition without the formation of gas. "Leaks" are usually due to defective cans, defects in sealing cans, or to corrosion.

If we analyze the different factors responsible for the unsatisfactory results with canned fruits and vegetables, we will find that the most important are: (1) use of unfit raw material; (2) use of unfit cans and glass jars; (3) carelessness in the matter of technic in cleanliness; (4) overfilling of the cans; (5) carelessness in sealing the cans; (6) imperfect degree of processing. *No can that shows evidence of spoilage should be used as food.*

Emphasis has always been placed upon the necessity of a vacuum for the proper preservation of canned foods. Bacteriologists, however, have shown that sterile foods may be kept indefinitely in the presence of air. *Sterility*, then, is the great desideratum, both from the sanitary and economic standpoints. The time and temperature of processing varies with the food and its condition as to freshness and cleanliness. Allowing foods to stand before processing causes deterioration of the product and may render sterilization more difficult.

Practically all foods canned in the ordinary way contain some tin. The amount varies with the acidity, and also the age and temperature of the package and other factors. Canned lobster and shrimp are relatively active as solvents of tin on account of the amino acids they contain and are therefore packed in lacquered or enameled cans.

Fortunately, tin is not very toxic. Cushny stated that chronic poisoning from tin is unknown, and that animals present no symptoms when subjected to prolonged treatment with larger quantities of tin than are contained in any preserved foods. Schryver found no indications of cumulative action when as much as two grains per day is taken. So far as we know, tin plays no part of importance in toxicology.

The tin used to coat sheet iron is practically free of lead. The tin coating is not always perfect and may be injured in manipulation. The exposed iron is attacked by some foods and may spoil the contents by discoloration or metallic taste. For certain foods the tin is coated with lacquer, which is not acted upon by the contents of the package. However, the kind of product to be canned determines the selection of the lacquer coating. A special lacquer was developed for beer cans. Glass containers have some advantages, which are counterbalanced by expense, weight, bulk and breakage, both in handling and in processing.

## PREPARATION

**Cooking.** Cooking protects us against infection. Fortunately, most microorganisms pathogenic for man are comparatively thermolabile. Therefore, thorough cooking renders food reasonably safe so far as these dangers are concerned. Cook-

ing has other advantages. It softens the connective tissue and renders meat more tender. The bundles of fibrillae are loosened from each other, the albumin is coagulated, the flavors are improved, and new flavors are developed, which enhance digestibility. Cooking breaks open and softens the cellulose envelops and fibers of vegetables; the starch grains swell and burst, and the insoluble starch is converted into soluble starch or dextrin.

Metchnikoff in his "new" hygiene dwelt upon the great sanitary value of cooking. Perhaps no other single factor in preventive medicine protects us to an equal degree against infection. Metchnikoff believed that we should eat nothing in its raw state. This is as extreme as the cult which proclaims the contrary. The newer knowledge of nutrition confirms the experience that it is advantageous to eat a certain amount of raw food, particularly fruits and vegetables.

One of the important functions in the preparation of food is to render it savory, tender and appetizing. Foods that appear inviting aid digestion by stimulating the secretion and flow of the digestive juices. Foods that are rendered soft and tender are more readily digested, but it should not be forgotten that the teeth need exercise to keep them in good condition, and the digestive tract needs roughage.

Cooking has a few minor disadvantages (McCance and Shipp, 1933)—there is a loss of mineral salts, and some of the other nutritive constituents, also a diminution in the antiscorbutic property of food generally.

**POISONS AND PARASITES.** Heat also kills the true toxins,\* which are destroyed in a few minutes between 70° and 80° C. Foods may sometimes contain heat resisting poisons. Thus, boiling has no effect upon muscarine, a poison in certain toadstools. Heat also does not destroy a principle sometimes found in poisonous mussels. Furthermore, some toxins of bacterial origin are known to be heat stable.

Trichinae, according to some authorities, die at 65° C, but the United States Bureau of Animal Industry after repeated experiments places the thermal death point at a temperature of 55° C. Some writers state that cysticerci, or the larva stage of tapeworms, die at 52° C. The nonsporulating bacteria are for the most part destroyed at 60° C. Food thoroughly cooked throughout will always reach these temperatures, but much meat and many vegetable food substances are preferred rare or underdone, and, while the outside of a large piece of meat may be thoroughly cooked or even charred, the interior may be practically raw or at least not have reached the temperature necessary to destroy parasites. A dish of spaghetti, charred on the outside, may not kill typhoid bacilli in the center of the mass.

**TEMPERATURES.** Meat that is well cooked throughout always reaches from 60° to 70° on the inside. It should be remembered that heat penetrates a large piece of meat slowly. Küchenmeister found that joints require boiling for several hours for the interior to reach a temperature of 77° to 80° C. Perroncito placed a ham of about six kilos weight in cold water which was then raised to the boiling point. The water boiled when the interior of the ham was only 25° C. After 3 minutes, it was 35° to 40° C, and after two hours, the temperatures in different parts of the interior were 46°, 55°, 58°, 62°, 64°, and 67° C. Rupprecht found that boiling for 45 minutes, as practiced in Saxony, did not produce a higher tem-

\* The toxin of scarlet fever is heat resistant but not a danger in food.

perature than  $75^{\circ}\text{C}$  throughout, and this only in thin pieces of meat. He found that the interior temperature of a rapidly roasted sausage was only  $28.7^{\circ}\text{C}$ . Meat placed in a quick oven or boiled soon forms a hard, coagulated and insulated coating that retains the juices, but retards the penetration of the heat.

Delepine and Howarth carried out experiments upon the temperatures reached in baking meat pies. They noted that the temperature of the center of the pie, said to be underbaked, but having all the external appearances of being well baked, did not exceed  $47.2^{\circ}\text{C}$ . The center of a pie, obviously overbaked and acknowledged to be so, had not reached beyond  $86.6^{\circ}\text{C}$ . Delepine points out that pies might be so cooked that bacteria might continue to grow in their center during the greater part of their stay in the oven, and the bacteria would certainly not be killed.

**FIRELESS COOKERS.** The observations of Becker, Grove and others concerning the heat of cooking are practical and important in the preparation of food. Exposure to moist heat at  $60^{\circ}$  to  $70^{\circ}\text{C}$  for a long time has the advantage of cooking foods thoroughly throughout. This treatment prevents burning or the results of overheating; the juices are retained. The process requires little or no attention. Meat is thereby rendered tender and juicy, vegetables thoroughly soft, and the starch grains are all opened. Practical application of this method is found in the fireless cookers. These devices consist simply of a well-insulated box. The food is heated, placed in insulated compartments, and a temperature above  $70^{\circ}\text{C}$  maintained for many hours.

**COOKING UTENSILS.** Certain precautions are advisable in the choice of pots and pans used in cooking. Brass and copper are not advisable, and if used should be lined with tin and must be kept scrupulously clean. Copper acetate (verdigris) which sometimes forms in copper food containers, is greatly feared but is not very toxic. Acid foods should not be cooked in copper vessels, and milk and saccharine substances should not be kept in copper containers on account of the possibility of the organic acids dissolving the copper. Foods should not be fried in copper pans owing to the dissolving action of oleic, palmitic and stearic acids in lard and other fats. Mallory (1925) believes that chronic poisoning with copper is the cause of hemochromatosis. While the fully developed disease is relatively rare, he states that the early stages and lighter forms are fairly common but unrecognized. Iron, tin, nickel and aluminum ware are least objectionable. Enameled ware is satisfactory provided the glaze does not contain antimony or lead. If the glaze contains one of those metals it must be insoluble in acid of the concentration that may be found in food. Glassware, being insoluble, is least objectionable from this standpoint. Foods cooked in metal pots and pans always contain some of the metal, which is usually in solution in the form of salts, or may be in metallic form, or combined with chemical constituents of the food. The amount varies especially with the reaction, temperature, time of cooking and other factors. No harm is known to result from the small amounts of aluminum, tin and nickel which get into food from pots and pans.

**METHODS OF COOKING.** Much depends upon the method of cooking. The principal methods in ordinary use are: roasting, broiling, boiling, frying and stewing.

*Roasting* or *broiling* causes considerable shrinking, due mainly to loss of water. The heat coagulates the exterior of the meat and thus prevents the further loss of juices and drying up. In order to obtain adequate heating of the meat

throughout a large joint without burning and drying the exterior, it is necessary to baste it from time to time with hot melted fat. This also helps to form a protective coating.

In *boiling* the meat is placed either in hot or cold water, depending upon the object desired. If it is desired to maintain the flavors within the mass, the meat should be plunged into boiling water. This quickly coagulates the albumins at the surface. If a rich broth is desired, the meat should be placed in cold water and gradually heated. In this way the soluble proteins and extractives pass out into the surrounding water. The albumin of meat begins to coagulate at 134° F (56° C); the connective tissue is changed to gelatin and dissolved above 160° F (72° C). Long boiling makes meat fibers tough. Some of the mineral constituents are leached out, especially from vegetables.

*Frying* consists in placing meat or other substances into very hot fat, lard or vegetable oil. This causes a speedy coagulation of the surface similar in all respects to that brought about in the first mentioned process of boiling. The flavors and juices are thereby retained. If the fat is not very hot it will penetrate and cause the food to become greasy and unpalatable. Heating starches in fat favors greater thoroughness of cooking on account of higher temperature. Fried substances may be indigestible on account of the large amount of grease that adheres to and penetrates into them. It is, therefore, better to plunge food into deep fat, piping hot.

In *stewing* the meat is cut into small pieces and placed in cold water, which then is heated slowly to about 180° F (84° C), at which the whole is kept for several hours. If heated above 180° F the meat becomes tough, stringy, unpalatable and of diminished digestibility.

*Fermentation* is of great use in the preparation of foods. The best example is the leavening of bread. The yeast ferments the carbohydrates in the flour with the production of carbon dioxide and alcohol. The carbon dioxide renders the bread porous; the gas is held within the loaf on account of the glutinous property of the protein (gluten) in the flour. Fermentation is an adjunct in the preparation and preservation of many other foods and beverages, such as cheese, sauerkraut, vinegar, beer, wine, cider, etc.

# 22

## MILK AND MILK PRODUCTS

Milk is our most important food. It is the best single food. The exceptional value of milk is due to the fact that it contains the essentials of a balanced diet; it is rich in some vitamins; the quality of its protein is especially good, the fat favors growth, and it has a high calcium content in readily usable form. Milk, furthermore, is palatable, readily digestible, and is subject to a great variety of modifications. Even at present prices, it is one of the cheapest of the standard articles of diet, and the most economical source of protein. In times of economic stress, it is a mistake to cut down on milk. In a low cost diet, the U. S. Department of Agriculture stipulates one quart daily from early childhood to adolescence, and one pint or more daily for adults.

The pastoral peoples of the world, whose diet has consisted largely of the products of dairy animals, have always displayed fine physical development. The peoples who have made liberal use of milk as a food have attained greater size, greater longevity, have been much more successful in the rearing of their young than the non-milk-using peoples, and have achieved much greater advancement in literature, science and art. Such development has a physiologic basis, and there seems every reason to believe that it is fundamentally related to nutrition (McCullum and Simmonds, 1925).

In the United States in 1954, there were 22,406,000 milch cows, producing 123,502 million pounds of milk. About one half of the amount consumed is taken as milk and table cream, one quarter as butter, and one quarter as cheese, ice cream, condensed, evaporated and dried milks. The average per capita consumption of fluid milk in the United States has risen to about one pint daily. It was 0.5 pint in 1900; 0.90 in 1925; and 0.86 in 1954. More milk is used in the north than in the south; very little is used in the tropics, and practically none in China, Japan and some other countries. About 16 per cent of the average dietary in the United States consists of milk and milk products.

While good milk has done more than any other single food to obtain and maintain health, bad milk was formerly responsible for more sickness and death than perhaps all other foods combined. There are several reasons for this: (1) Milk conveys a greater variety of infections than any other food. Bacteria grow well in milk at temperatures above 50° F; therefore, a slight infection may produce wide spread and serious results; (2) of all foodstuffs milk is the most difficult to harvest, handle, transport and deliver in a clean, fresh and satisfactory condition; (3) it is the most readily decomposable of all our foods; (4) finally, milk is the only standard article of diet obtained from animal sources that is likely to be consumed without being cooked.

Fresh milk products may be quite as dangerous as the milk from which they are made. Milk laws which ignore milk products are incomplete from the sanitary side, and will fail to accomplish their purpose from the economic side.

Milk is the only single substance whose sole function in nature is to serve as a complete food. It is a perfect food for the suckling of the same species. The milk of one mammal does not fit all the needs of the nursling of another kind: cow's milk is best for the calf, bear's milk for the cub, lion's milk for the whelp, and mother's milk for the baby. After weaning, milk is the best single food to promote growth and nutrition in children. All students of dietetics favor the free use of milk for growing children, who may well take as much as a quart a day, depending upon the amount and character of the remainder of the diet, and also upon individual idiosyncrasies. Milk is quite as nutritious and beneficial whether drunk as milk or taken as part of various food preparations.

As a sole article of diet for adults, milk is low in iron and some vitamins; it has too much water and too little roughage. Adults should get no less than a pint of milk a day in the diet.

In view of the many advantages and few drawbacks, sanitarians unanimously encourage the production and use of pure milk, and discourage the distribution and use of poor milk. It is the only food for which there is no effective substitute.

Practically all large cities in the United States forbid the sale of loose milk. Milk is such a precious article of food and so susceptible to infection that it deserves to be handled with respect. It is entitled to an individual package. The bottle should be clean and sterile and effectively sealed, at least the cap should cover the lip.

**Composition.** Milk is the secretion of the mammary gland. In composition it is exceedingly complex, consisting chiefly of water; several proteins in colloidal suspension; fats in emulsion; sugar, and a number of inorganic salts in solution; also vitamins, phosphatides, enzymes, as well as antibodies, cells, gases, pigments and other substances. Milk from all species of animals shows a general agreement in physical properties and composition, containing essentially the same ingredients, which differ in relative amounts.

In its fresh state, the average figures for cow's milk are as follows: it has a specific gravity of 1.028 to 1.034; it freezes at a temperature somewhat lower than the freezing point of water ( $-0.550^{\circ}\text{C}$ ); the electrical conductivity is about  $5.0 \times 10^{-4}$  for cow's milk, and about  $22.6 \times 10^{-4}$  for human milk. The specific heat of whole milk containing 3.17 per cent of fat is 0.938 at  $15^{\circ}\text{C}$ . The coefficient of expansion is greater than that of water. Milk shows no maximum of density above  $1^{\circ}\text{C}$ . It contains about 20 calories per ounce.

Freshly drawn milk of carnivorous animals is, as a rule, acid in reaction. This is probably due to carbon dioxide and acid phosphates. Human milk and that of most of the herbivora is slightly alkaline; cow's milk has been described as amphoteric. Fresh cow's milk is slightly acid to phenolphthalein; but alkaline to methyl orange, indicating that the acidity is due in part to the acid phosphates. The pH values of fresh cow's milk range between 6.5 and 6.8; fresh mother's milk varies between 7.1 and 7.6.

Under the microscope milk is found to contain fat globules and cells, as well as bacteria, debris and other objects.

The gases dissolved in milk are oxygen, nitrogen and carbon dioxide (3 to 4

per cent by volume). These gases are carried into milk mechanically from the air in the process of milking. Other substances found in milk, but in small quantities, are lecithin, cholesterin, citric acid, lactosin, orotic acid and ammonia.

Van Slyke and Bosworth (1915) suggest the following as representing the principal constituents of milk more closely than previous statements. The amounts are based on milk of average composition:

<i>Constituents</i>	<i>Per Cent</i>
Fat . . . . .	3.90
Milk sugar . . . . .	4.90
Proteins combined with calcium . . . . .	3.20
Dicalcium phosphate ( $\text{CaHPO}_4$ ) . . . . .	0.175
Calcium chloride ( $\text{CaCl}_2$ ) . . . . .	0.119
Monomagnesium phosphate ( $\text{MgH}_4\text{P}_2\text{O}_8$ ) . . . . .	0.103
Sodium citrate ( $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7$ ) . . . . .	0.222
Potassium citrate ( $\text{K}_3\text{C}_6\text{H}_5\text{O}_7$ ) . . . . .	0.052
Dipotassium phosphate ( $\text{K}_2\text{HPO}_4$ ) . . . . .	0.230
Total solids . . . . .	12.901

The composition of cow's milk may be understood from the schemes prepared by Lucius L. Van Slyke and S. M. Babcock, given on page 843.

**MILK PROTEINS.** The proteins constantly found in milk are casein, an albumin, a globulin and an alcohol soluble protein. The four proteins are immunologically distinct. The casein and the lactalbumin are basic nitrogenous constituents of milk and occur also in colostrum. Together, the proteins are complete, containing all the amino-acids in proper proportions to build tissue. Traces of fibrin, mucin and other proteins sometimes occur.

The proteins in milk of a given breed are quite constant in composition, but vary in amount. There is even an individual variation in cows of the same breed. The amount of protein in mixed milk of cows of the same breed is quite constant. There is always more fat than protein in the complete milk of a healthy cow. In a sanitary analysis of milk it is not the rule to make a special test for proteins. They may be estimated by subtracting the fat, sugar and ash from the total solids.

*Casein* is a highly specialized protein found in the secretion of the milk gland of all mammals, but nowhere else in nature; it is a nucleo-albumin, and as such contains phosphorus. Casein is a complete protein. It is insoluble in water, but by virtue of its property as an acid it forms soluble salts with alkalis. There are two series of casein salts, basic and neutral; solutions of the latter have a milky appearance. In milk, casein is found dissolved in the form of a neutral calcium salt, which accounts in part for the white opalescent appearance of milk whey. Casein exists in milk in combination with calcium phosphate. It is not coagulated by heat in an alkaline medium, but is precipitated by acids, for the reason that acids take the calcium from the calcium phosphate, and thus throw the casein out of solution as a curd. This flaky or lumpy precipitate is again soluble in lime-water and dilute alkalis. Casein is also precipitated by pepsin. Cow's milk contains about 2.5 per cent of casein; woman's milk between 0.5 and 0.75 per cent.

*Lactalbumin* is similar to the serum albumin of the blood, but it appears to differ from this in some particulars. It coagulates by heating to  $70^\circ\text{C}$ , but not with dilute acids, and is precipitated by a saturated solution of ammonium sulphate, but, in

all other albumins, is not precipitated in a neutral solution of sodium chloride and magnesium sulphate. Lactalbumin contains sulphur but no phosphorus. It is present in amounts varying from 0.2 to 0.8 per cent, but is much more abundant in colostrum.

*Lactoglobulin* occurs in milk merely in traces, while colostrum is comparatively rich in this protein. It coagulates at 75° C, it is precipitated in the same way as serum globulin, and, like serum globulin, is insoluble in water, but is soluble to some extent in weak salt solution. Lactoglobulin and serum globulin are chemically indistinguishable.

**FAT.** The fat is suspended in the milk serum in the form of an emulsion. The droplets or globules vary in size. On the average they are smaller in milk from Holstein than from Jersey, Guernsey, or shorthorned breeds. Under the microscope some of the fat globules seem to have an albuminous membrane, but this interpretation is questioned. The fat droplets are lighter than the milk whey, therefore they rise on standing (gravity cream), or may readily be separated by centrifugal force (centrifugal cream). Cream, or top milk, does not consist of fat alone, but contains a portion of each of the constituents of the milk; it is simply milk rich in fat. Churning causes the fat globules gradually to coalesce into larger drops and lumps to form butter.

The first milk drawn from the udder is commonly poor in fat. This is known as "fore" milk. The middle portion contains about the average percentage, and the last, known as "strippings," is always the richest in fat. The strippings may contain as much as 9 or 10 per cent.

Milk fat consists of a mixture of different neutral fats, the principal of which are olein, palmitin and stearin. These are neutral triglycerides of the corresponding fatty acids. Besides these are found the triglycerides of myristic, butyric and caprylic acids. The last two are volatile and give to butter its characteristic odor and flavor. Crowther and Hynd (1917) state that the only acids present in more than minimal proportions are the unsaturated acid, oleic acid, and the eight saturated acids of the acetic series ( $C_4$  to  $C_{18}$ ), namely, butyric, caproic, caprylic, capric, lauric, myristic, palmitic and stearic acids. The composition of the fat is subject to variation, depending upon racial or individual peculiarities, and other conditions.

Milk fat is rich in vitamin A. This vitamin promotes growth; its absence induces xerophthalmia and serious disturbances of nutrition. Osborne and Mendel have shown that butter fat may have a blast of steam passed through it for two hours and still retain its peculiar growth-promoting properties. This observation is in harmony with those of McCollum and Davis, that heating butterfat to the temperature of boiling water does not affect its peculiar dietary value. It is apparent, therefore, that any conditions to which milk fats are liable to be subjected during the cooking of foods will not greatly alter its value as a source of vitamin A. Evaporated and dried milks also retain the virtues of this vitamin.

Milk fat contains ergosterol, and vitamin D appears to be a stereoisomer of ergosterol. The amount of vitamin D in milk fat varies from a trace to about 1 Steenbock units per quart, depending on the vitamin D in the food intake of the cow. Ordinarily in wintertime the milk of stall-fed cows contains only traces of vitamin D.

It is now clear that milk fat has no superior among hydrocarbons in dietetic or nutritional value. It is the chief source of vitamin A in our diet.

The percentage of butterfat in milk has long been one of the standards by which milk is tested. The richness of milk gauged by the amount of fat it contains is more of an economic than a sanitary question. Milk with a lower percentage of fat from Holstein cows is relatively as nutritious as richer milk from Jersey and Guernsey cows. Even skimmed milk containing little or no fat is a valuable food. The problem is one of honest labeling and the marketing of various grades at prices corresponding to their nutritive contents. When the standard for butterfat in milk is relatively low, say 3.25 per cent, it is a temptation for dairy men to standardize or adjust. A high fat standard encourages the breeding of better cows.

In normal milk the larger proportion of fat droplets agglutinate into tiny clusters or masses. At a temperature of  $65^{\circ}\text{C}$  or above, these clusters are broken up and the globules are more homogeneously distributed throughout the liquid. When milk is atomized under a pressure of about 1,500 pounds or over, at a temperature of about  $75^{\circ}\text{C}$  the individual fat globules are broken up into fine particles, which remain as a uniform and permanent emulsion known as "homogenized milk." This process applied to cream increases its volume and viscosity, so that cream containing 20 per cent butterfat appears to have the body and richness of a 30 per cent cream.

Heat hinders the rising of the fat drops; if heated above  $63^{\circ}\text{C}$  for 40 minutes or longer the formation of the cream line is retarded or prevented. For this and other reasons, therefore, the richness of milk cannot always be judged by the depth of the cream layer.

Researches of Huebner, Keller and Czerny show that the fats rather than the proteins are the cause of much of the digestive disturbances in infants. When the fat is excessive in amount the infant at first seems to thrive, but sooner or later loses weight and appetite, and shows other symptoms, associated with stools composed largely of fat soaps and of a pale gray, hard and dry constituency. The alkaline bases are so largely drawn upon from the body to saponify the excessive amount of fat in the intestines, that a condition resembling acidosis may appear; furthermore, fermentative changes take place in the intestines and the "catastrophe" ensues.

Fat is the most variable constituent in milk. The amount varies with different animals, and even in the same animal from time to time.

**MILK SUGAR, OR LACTOSE.** Milk sugar, or lactose ( $\text{C}_{12}\text{H}_{22}\text{O}_{11}$ ), is peculiar to milk; it is found nowhere else in nature. Commercially, milk sugar is obtained from whey as hard rhombic crystals, which have a slightly sweet taste and are soluble in six parts of cold water. Lactose is readily acted upon by micro-organisms and reduced to glucose and galactose; the glucose is further changed to lactic acid. This is the common cause of sour milk (page 856).

Lactose, like glucose, reduces Fehling's solution when heated; it is dextrorotatory. When heated above the boiling point of water it changes to a brownish color as a result of the formation of lactocaramel.

The amount of lactose in milk of any given species is remarkably constant. Goat milk contains (7 per cent) much more than cow's milk (4.9 per cent).

Lactose is not digested and absorbed as quickly as other sugars and therefore favors the fermentative flora in the intestines (see page 856).

**VITAMINS.** The early impression that milk must be rich in all the vitamins has met with some disappointments. Milk may be rated as an excellent source of vitamin A, a fair to good source of vitamin B<sub>1</sub>, a variable source of vitamin C, a poor source of vitamin D and an excellent source of vitamin B<sub>2</sub>; and contains vitamins E, K, biotin, choline, folic acid, inositol, niacin, and pantothenic acid. The diet plays an important part in determining the amount of each vitamin, except B and G, in milk. (See vitamins, page 591.)

The fat of milk is a rich source of *vitamin A*. Therefore, butter, cream, ice cream and all kinds of cheese which are made from whole milk or mixtures of milk and cream are outstanding sources of vitamin A. Milk itself, with its natural high water content, is not a concentrated source of vitamin A, but in the quantities in which it should enter the dietary it becomes an important source. Dairy products taken together constitute the chief source of vitamin A in the American and European food supply.

The amount of vitamin A in mixed market milk is reliable and fairly uniform. It is stable and heat resistant.

Compared on the basis of solid matter, milk is a good source of *vitamin B*. Milk, however, is not outstandingly rich in this vitamin, but is a constant and reliable source.

Vitamin B<sub>1</sub> as it exists in milk is comparatively stable to heating at 100° C. It has been found that there is no measurable diminution of it in milk powder when heated dry with free access of air at 100° C even when this heating was continued for 48 hours.

The *antiscorbutic* property of milk is variable, being readily oxidizable, and the baby, whether nursed or bottle fed, should have orange juice or tomato juice.

Since the animal body does not synthesize vitamin C nor carry any large store of it, the amount of this vitamin in milk must be more or less dependent upon the food of the nursing mother or of the lactating animal, as the case may be.

According to Hess, a pint per day of average milk supplies the antiscorbutic requirement of a child. If the antiscorbutic value is materially lessened by oxidation, heating or aging of the milk or by faulty feeding of the cow, more milk will be required.

Brief boiling of milk in open utensils, as in ordinary household practice, has been reported by different investigators to result in losses of one-fifth to one-half its vitamin C content. The diminution of antiscorbutic value involved in commercial pasteurization is probably of similar order. Milk in clear glass bottles standing on the doorstep in the sunlight will lose vitamin C rapidly.

That Hart and others report practically complete destruction of vitamin C in commercial "evaporated," while Hess and also Hume find it well conserved in commercial "condensed" milk, is in accordance with the different heat treatments involved.

Hess, working with dried milk prepared by a roller process, and Cavanah, Dutcher and Hall, working with spray-dried milk, both report good conservation of vitamin C in these products. The vitamin is more stable in the dry state than in the aqueous solution.

Ordinary market milk contains only about 5 to 12 Steenbock units of *vitamin D* per quart. This may readily be increased to 50 or more units by feeding irradiated yeast to the cow, irradiating the milk, or by adding cod liver oil concentrates or irradiated ergosterol to the milk (page 601). It may also be increased by irradiating the cow. Commercial practice is to add about 400 units of vitamin D per quart to milk sold as vitamin D milk.

Whole milk has important antirachitic value, due in part to the vitamin D which it contains when produced under favorable conditions, and in part to the fact that it contains liberal and well balanced proportions of calcium and phosphorus.

The nutritive condition of the mother influences the storage of vitamin D in the body of the baby before its birth, and her bodily store of this vitamin (or lack of it) affects the antirachitic potency of her milk.

The total amount of vitamin D obtained through milk fat is considerable because of the consumption of the latter not only in the form of milk itself but also of cheese, butter, cream and ice cream.

*Vitamin E* has been found in milk and butter.

There is evidence that milk as ordinarily produced is a rich and reliable source of *vitamin G* ( $B_2$ ) at all seasons of the year. When account is taken of the amounts ordinarily eaten in reasonably well balanced dietaries and food supplies, milk is doubtless the most important source of vitamin G for the American and European peoples.

**FERMENTS.** Milk contains a large number of active ferments or enzymes which have taken a back seat since the discovery of vitamins. Milk also possesses certain other properties common to blood and living tissues, but, while milk may properly be regarded as a vital fluid, it is not a living fluid as was formerly claimed. In fact, milk begins to decay the moment it is drawn; oftentimes before.

Some of the ferments in milk are normal constituents of that secretion, while others are produced by bacterial activity. Many tests have been devised to determine the kinds and activity of the ferments in milk. The tests which have been most frequently and most successfully used are those for catalase and reductase, and more recently phosphatase.

The enzymes in milk are the following:

**Phosphatase.** Phosphatase or phosphomonoesterase is a heat labile enzyme commonly present in raw milk which is known for its property of hydrolyzing mono-esters of phosphoric acid. By chance the heat treatment required to inactivate this enzyme in milk is almost exactly equivalent to that required to be applied to milk by the standard definition of pasteurization. Kay and Graham utilized these properties in their phosphatase test for pasteurization. Modifications of this test, particularly those of Gilcreas and Davis, Scharrer and Sager, are now extensively used in the official control of public milk supplies. The basic principle of the test is that the phosphatase enzyme if present in milk, upon incubation will break down an added standard buffered di-sodium-phenyl phosphate solution releasing free phenol which is readily detectable in cleared solution by a simple color test using Folin's or Gibb's reagent. Small quantities of phosphatase enzyme remaining as a result of incomplete pasteurization or the addition of as little as 0.1 of one per cent of raw milk to pasteurized will release a detectable quantity of phenol, making the test extremely useful.

*Galactase.* Galactase is a proteolytic ferment, similar to trypsin. It was found by Babcock and Russell to be abundant in separator slime. Ordinarily galactase by itself acts too slowly to cause any material change in the proteins in the short intervals which elapse between the withdrawal of the milk from the animal and its consumption as food. Snyder claims that this enzyme probably assists digestion, in that when milk is used in a mixed diet the proteins have been found to be from 4 to 5 per cent more digestible than when milk is omitted from the diet.

*Lactokinase.* Hougardy has shown that milk contains a ferment or a kinase similar to enterokinase. Lactokinase has been found to accelerate the digestion of proteins by pancreatic juice. This property is destroyed by heating the milk at 73° to 75° C.

*Lipase.* This fat-splitting ferment was found in milk by Marfan and Gillet. Human milk exhibits this property to a higher degree than cow's milk. The former has a lipolytic activity of from 20 to 30 on Harriot's scale, while cow's milk shows an activity of only six to eight. Lipase withstands cold, but is destroyed by heating to 65° C; it is nondialyzable and is held back by a porcelain filter. It probably hydrolyzes the higher fats of milk, at least to some extent, and accounts for the so-called "cappy" or slightly rancid flavor in milk.

*Catalase.* Milk contains no true oxidases or oxidizing ferments proper (Kastle). It decomposes hydrogen peroxide and has the power of effecting the oxidation of a considerable number of easily oxidizable substances in the presence of hydrogen peroxide or ozonized oil of turpentine. In other words, milk contains catalase and peroxidase. Catalase is widely distributed among animals and plants; in milk it is probably of bacterial origin. Jolles has pointed out that human milk decomposes five or six times as much hydrogen peroxide as cow's milk. Considerable importance has been attached to this difference, which has also been used to distinguish human milk from cow's milk. Little is known of the function of catalase. Hydrogen peroxide is probably formed in both animal and vegetable tissues during vital activities. The catalase would destroy it and thus prevent its accumulation in the cell, which otherwise would destroy its life.

*Peroxidase.* Milk contains substances capable of inducing the oxidation of guaiacum and other readily oxidizable substances by means of hydrogen peroxide or ozonized oil of turpentine. These substances are known as peroxidases. The peroxidases are destroyed when milk is heated to 80° C. The color reactions for these ferments are a convenient test to determine whether milk has been heated beyond a certain temperature. The interpretation of this reaction must, however, be guarded, as Gillet and Kastle found that even normal fresh milks vary in the amount of peroxidases which they contain.

*Reductase.* Raw milk possesses reducing properties; for example, it reduces Schardinger's reagent, which consists of a solution of methylene blue containing small amounts of formaldehyde. The reductases in milk are probably of bacterial origin. On account of the bacterial origin of both the catalases and reductases in milk, the detection of these enzymes has a sanitary significance.

*Diastase (Amylase).* Béchamp in 1882 isolated from milk a ferment which hydrolyzes starch and converts it into sugar as readily as diastase. These observations have been confirmed. The presence of diastase in milk is now used as the basis of an important method of distinguishing between raw and pasteurized milk.

**LEUKOCYTES.** A large number of cells are normally present in milk. These are not to be regarded as the result of inflammation, unless they have the characteristics of "pus" cells. Those found in normal milk are leukocytes and degenerated epithelial cells. The number of cells in milk is greatly increased in the presence of mastitis or "garget"; toward the end of lactation; on approaching calving time; during periods of excitement; and by various other factors. Hucker (1933) suggests that the presence of more than 500,000 cells per ml. indicates an abnormal or pathologic condition in the udder.

The Breed method, commonly used, consists in staining 0.01 ml. of the milk spread over an area of 1 square centimeter on a glass slide—dried and stained with methylene blue or other standardized stain. Both the cells and the bacteria may thus be counted. This method does not distinguish between live and dead bacteria, although it is evident that all dead bacteria do not take the stain.

An excess of pus cells, especially if associated with streptococci, indicates inflammation of the udder. When a mixed milk shows such an excess, say more than a million per milliliter, it may be run down to an individual cow with mastitis. When this cow is eliminated, the mixed milk clears up. This is the usual picture and practice.

**MINERAL CONSTITUENTS.** Mineral constituents of milk are of the highest importance to the growing animal. The inorganic salts of milk have already been stated.

Milk is the best source of calcium in the diet, both on account of the quantity and the usable form in which it exists. Sherman and Hawley (1922) have shown that growing children need one liter of milk a day for optimum calcium intake. Children up to the age of puberty, therefore, should get about a quart of milk a day, adults at least a pint. The vegetables are the only other class of foods where calcium content is high enough to be a source of the mineral in children's diets, but children do not utilize the calcium of vegetables as efficiently as they do that of milk.

Milk also contains useful amounts of other inorganic constituents, potassium, phosphorus, chlorides, sulphates, etc. The buffer value of milk protects the gastric glands against strain.

Milk is deficient in *iron*, averaging only 0.00024 per cent.\* An exclusive milk diet may, therefore, cause iron anemia. Milk is also deficient in copper and manganese. The iodine content depends upon the iodine intake of the cow.

The mineralization of milk is proposed. This would include the addition of iron, copper, iodine, manganese and other elements. The project does not meet with approval of health authorities except when accomplished through the feed of the cow. The content of some minerals, such as iodine, can be increased by adding the element to the cow's feed but the content of some other minerals, such as iron, cannot be so increased.

**Colostrum.** Colostrum is the fluid secreted by the mammary gland during the first few days after birth and before lactation becomes established. Colostrum and milk differ markedly in appearance, quality, composition and function. Colostrum

\* It has long been known that there is deposited in the liver of the newborn animal a reserve supply of iron, which ordinarily suffices to tide it over the suckling period. Ordinary drinking water almost always contains small amounts of iron, and this doubtless aid in some degree in preventing iron starvation in the infant.

contains on an average much less fat, but four times as much protein as the milk of the same cow. This increase is mainly due to the presence of a great quantity of globulin.

In women, colostrum does not appear for at least 12 hours after delivery. Not more than 5 ml. is secreted in the first 24 hours, and not more than 90 ml. after 48 hours. The cow's udder, on the other hand, is filled with colostrum at the time of parturition. The calf takes about two pounds at the first feeding shortly after birth.

Theobald Smith and his co-workers (1922, 1923, 1925) discovered that colostrum is the chief agent for transferring protective antibodies to the newborn calf. It is difficult to raise a calf if colostrum is withheld or even postponed 24 to 36 hours. Without colostrum, calves usually succumb during the first week to intestinal infections and interstitial focal nephritis caused by a particular type of colon bacillus, which is nonmotile, indol-producing, and fails to act on saccharose. Colostrum, then, is essentially protective against miscellaneous and ordinary bacteria which are harmless later on when the immunity functions of the calf have begun to operate.

The calves are protected whether the colostrum is fed to them or injected intravenously or subcutaneously. The specific agglutinin against this type of colon bacillus is present in the cow's blood and in colostrum, but is absent from the blood of the newborn calf; it appears within 15 minutes of a feeding of colostrum.

Human colostrum seems to be less important. No harm has been discovered in infants deprived of it altogether. The human placenta is much more permeable than that of ruminants, because there is only a single layer of cells separating the maternal blood from the fetal blood, whereas in ruminants the placenta has a barrier of a three-cell layer. Antibodies pass the human placenta readily; thus diphtheria, scarlet fever and tetanus antitoxins have been demonstrated in the cord blood. Measles and other antibodies have been extracted from the human placenta by McKhann. The difference in the amount and composition of colostrum in man and cow corresponds to the difference in the requirements and functions of the baby and the calf.

**The Mammary Gland as an Excretory Organ.** The mammary gland acts to some extent as an excretory organ, in the sense that waste nitrogenous substances filter through from the blood into the milk. Among these are the so-called non-protein nitrogenous extractives, amino acids, urea, creatine, creatinine and uric acid. Milk may therefore occasionally become a vehicle of substances that are undesirable as a dietary ingredient. Every efficient physiologic mechanism fails at times. Foreign proteins may occur in the milk, but in minute quantities, demonstrable only by anaphylactic reactions. More important is the excretion of drugs and foreign substances in milk.

**Excretion of Drugs in Milk.** The following drugs taken by the mouth have been found in the milk of nursing women: aspirin, iodine, mercury (calomel), arsenious acid, potassium bromide, and probably also hexamethylenamine, salicylic acid and salicylates, ether, antipyrine, bromides, caffeine and many others; the list is long. It is probable that opium, all volatile oils, purgative salts and rhubarb are excreted to a certain extent in the milk. It is well known how readily the flavor of cow's milk is affected by turnips, garlic, wild onions, moldy hay and grain, or damaged ensilage. Fermented distillery waste gives a bad flavor and may also cause

the secretion of small quantities of alcohol in the milk. The importance of these facts is self-evident. Cows in pastures sometimes feed on poisonous weeds, and these poisons may pass into the milk. Certain substances, as ensilage, when fed to cows, cause a laxative property to appear in the milk, and thus it is possible to affect the baby through the feed of the cow. The color of milk is also influenced somewhat by the feed, accounting for the richer color when cows are put out to pasture in the spring.

**Differences between Cow's Milk and Woman's Milk.** The following table modified from Rotch summarizes the principal points of differences between cow's milk and human milk.

WOMAN'S MILK DIRECTLY FROM THE BREAST	COW'S MILK, FRESHLY MILKED
Reaction, amphoteric (more alkaline than acid)	Amphoteric (more acid than alkaline)
pH values, 7.1 to 7.6	pH values, 6.5 to 6.8
Water, 87 to 88 per cent	86 to 87 per cent
Mineral matter, 0.20 per cent	0.70 per cent
Total solids, 13 to 12 per cent	14 to 13 per cent
Fats, 4.00 per cent (relatively poor in volatile glycerides)	4.00 per cent (relatively rich in volatile glycerides)
Milk sugar, 7.00 per cent	4.75 per cent
Proteins, 1.50 per cent	3.50 per cent
Caseinogen, $\frac{1}{3}$ to $\frac{1}{2}$ of the total proteins	2.66 per cent
Whey-products, $\frac{2}{3}$ to $\frac{1}{2}$ of the total proteins	0.84 per cent
Coagulable proteins, small proportionately	Large proportionately
Coagulation of proteins by acids and salts, with greater difficulty. Curds small and flocculent	With less difficulty, curds large and tenacious
Coagulation of proteins by rennet, does not coagulate readily	Coagulates readily
Action of gastric juice, proteins precipitated but easily dissolved in excess of the gastric juice	Proteins precipitated but dissolved less readily
Ash, 0.2 to 0.3 per cent	Ash, 0.6 to 0.7 per cent

The above are averages, for the quantity and quality of milk secreted depends upon the size and anatomical structure of the gland, the amount and kind of food ingested, heredity, environmental conditions, such as fresh air, sunshine and the amount and intensity of work, rest and exercise, and also the emotional psychic make-up of the person, etc. The constituents of milk change during the progression of the period of lactation. This change occurs not only from day to day but also varies at different times of the day, and also between the first and last halves of nursing. The fat, protein, nitrogen, total solids and phosphorus tend to increase with the progression of nursing.

The differences between these two milks are greater than the table indicates. While cow's milk may be modified to approximate woman's milk in composition, it can never be just the same or just as good for infants.

Cow's milk is more opaque than woman's milk, although the latter may contain a greater percentage of fat. This is due to the opacity of the calcium-casein, which is present in greater proportion in cow's milk. Cow's milk is faintly acid or amphoteric when freshly drawn, but ordinarily is distinctly acid in reaction when consumed. Woman's milk is amphoteric or alkaline.

There is more than twice as much protein in cow's milk as in woman's milk.

The reason for this is obvious, when we recall that the size and ratio of growth of the calf to that of the infant is about as two to one. Furthermore, the protein in cow's milk consists chiefly of casein (3.02 per cent) and little lactalbumin (0.53 per cent), while woman's milk contains 0.59 per cent of casein and 1.23 per cent lactalbumin. Furthermore, while casein is a complete protein, it is relatively deficient in the indispensable amino-acid cystine. The sugar in the two milks varies greatly in amount, but not in kind. Cow's milk contains almost four times the amount of inorganic salts compared to woman's milk. Of more importance, cow's milk contains more calcium and phosphorus than breast milk, and the ratio of calcium to phosphorus is lower in cow's milk. These differences have an important bearing upon infant metabolism. There is no great difference in the average amount of fat in the two milks; however, both in woman's milk and in cow's milk the fat is a variable constituent. Mother's milk is richer in diastase than cow's milk.

Table 22-1. The inorganic food substances in milk

	Woman's Milk gm. per 100 ml.	Cow's Milk gm. per 100 ml.
Na	.010	.051
K	.047	.143
Ca	.034	.120
Mg	.005	.012
Fe	.0001	.0002
Cl	.035	.106
P	.015	.093
S	.005	.034

The energy and structural components also show differences:

WOMAN'S MILK

Total solids, 12.5 gm. per 100 ml.

Salts	2		

COW'S MILK

Total solids, 13.0 gm. per 100 ml.  
Partition of solids:

	Per Cent		Per Cent
Fat	31	} Energy	67
Sugar	36		
Protein	27	} Structure	33
Salts	6		

*The importance of mother's milk for the baby cannot be emphasized too often. There is no adequate substitute. Breast nursing is best for the baby and best for the mother. Mother's milk contains specific and useful antibodies and other unknown qualities, inadequately represented in cow's milk. Cow's milk can be modified to*

resemble human milk, but there are essential differences that may have remote effects upon the soundness of the teeth, the resistance of the tissues, etc.\* Babies should be nursed at least three or four months unless there are contraindications.

The diet of the mother affects the quantity and quality of the milk. The lactating woman needs a generous diet, varied with vitamins, well balanced and with about one-third more calories. The nature of the diet even influences the quality of the proteins in the milk. The mother should lead a calm life, for emotional stress, fatigue and worry may affect the milk. She needs exercise, sunshine, plenty of rest and food for two.

**Milk Standards.** The word "standard" used in this connection is not intended to imply excellence, but simply to express the lowest limit that the law permits. There are at least four standards by which milk should be judged: (1) *physical standards*, specific gravity, temperature, taste, odor, etc.; (2) *chemical standards*, especially the percentage of fat and total solids; (3) *bacteriological standards*, the number of bacteria per ml. and absence of pathogens; (4) *sanitary standards* determined by veterinary and medical inspection. Standards have also been established for pasteurization, production, transportation and handling. All are necessary for the satisfactory control of a milk supply.

It has been found an advantage to keep the butterfat standard relatively high and the total solids at a minimum of 12 per cent. This allows 8.5 per cent for solids not fat, such as the proteins, milk sugar and inorganic salts. A 3.25 per cent butterfat and a 12 per cent total solids is the minimum required by many sanitary codes. This should be 3.5 per cent fat for 12 per cent total solids, which is the relation in mixed milk at present.

If the law recognizes a low standard for total solids, it permits manipulation, especially watering. Low fat and high total solids permit skimming. It also permits the production of milk from inferior cows. High standards encourage good dairy methods, require good food, and place a premium upon the better breeding of milch cows.

The ratio of fats to total solids is used to detect skimming; however, it is possible to skim milk within limits, without detecting it by this method.

If dependence is placed upon the total solids, mistakes may also occur. The total solids represent the proteins, fats, sugar and inorganic salts. They may readily be tampered with. Skimming can readily be determined by a fat-protein ratio. Watering does not alter this ratio, but may be detected by a cryoscopic examination.

A milk ordinance and code has been drawn up by the U. S. Public Health Service (1953) and is being widely adopted.

**Grades of Milk.** Milk varies greatly in sanitary quality and in nutritive value. These differences are not obvious to our unaided senses. Milk should, therefore, be graded just as other commodities, such as wheat, beef, fruit, coal, etc., are graded.

From the standpoints of health and sanitation, the grading of milk was very useful during the period in which sanitary standards were being raised. Before the tuberculin testing of cows on an area basis was practiced extensively, work was stimulated in some areas by authorizing dealers in raw milk, who maintained tuber-

\* Oliver Wendell Holmes said, "Nature has provided a substantial pair of mammary glands, which have the advantage over the two hemispheres of the most learned professor's brain in compounding a food for babies."

culin-tested herds and met other high standards, to label their products "Grade A," while others, who otherwise met the standards but had to wait for testing, were required to use a "Grade B" label. Naturally, under such a system, it was impossible to defend the continued sale of relatively unsafe milk beyond the time necessary for milk dealers generally to meet the higher standards.

Every consumer, regardless of ability to pay, should have safe, clean milk. Furthermore, competition forces dealers in milk of lower grades to raise their standards. Thus, all of the milk in most markets reaches the sanitary standards set for "Grade A Pasteurized," whether under that designation or some similar one, and grading from the standpoints of health and sanitation loses its importance as a tool for improving safety and sanitary quality. The attempt to introduce factors of questionable health significance, as distinctions between grades, cannot be justified as a means of continuing grading when reasonable standards of sanitary quality have been reached. Consumers have come to recognize the label Grade A Pasteurized or its equivalent as a warranty of the safety of the product within the container on which the label appears.

Grading based on such general qualities as butterfat content will continue to have considerable economic significance, providing that the consuming public is protected against fraudulent labeling. Without official control such grading becomes a farce and a means of defrauding the public. An example of this is the labeling of ordinary milk as "natural vitamin D milk."

The grades commonly used today are:

**GRADE A. *Grade A Raw.*** Milk from cows tuberculin tested and free from brucellosis and other disease, produced and handled by persons free from infection, the bacterial count not to exceed 30,000 per ml. at the time of delivery to the consumer, coming from dairies meeting standards equivalent to those of the milk code recommended by the U. S. Public Health Service. This is a clean milk of questionable safety. It is rapidly being replaced by pasteurized milk.

***Grade A Pasteurized.*** Milk containing at no time more than 200,000 bacteria per ml. and coming from farms that meet all the essential requirements for those producing Grade A raw milk. All milk of this class shall be pasteurized under official supervision and the bacterial count shall not exceed 30,000 per ml. at the time of delivery to the consumer. The trend is toward also setting standards for adequate heat treatment as determined by the phosphatase test and the coliform test, serving the dual purpose of detecting recontamination of pasteurized milk and possible minor flaws in pasteurization.

**CERTIFIED MILK.** Certified milk is produced under the supervision and direction of a medical milk commission. It is fresh, clean and unaltered. It is raw milk of good quality and uniform composition, obtained by cleanly methods from healthy cows. The term "certified milk" was coined by Henry L. Coit of Newark, New Jersey, who in 1892, needing good milk for his own baby, formulated a plan for the production of clean, fresh, good milk under the auspices of a medical milk commission.

Certified milk is a fine ideal which has helped raise the quality of the entire supply. There were 30 farms producing certified milk in 1954, making about 10 million quarts per year, much of which is pasteurized. This represents only about

1/8 of one per cent of the total milk supply; many communities have no certified milk. The economic trend is toward fewer and larger certified dairies. It is not, therefore, a public health problem of any magnitude.

The medical milk commission is appointed by the county medical society; in some places the commission is either organized by or associated with the health department. The commission should include at least five members to look after (a) the sanitation of the dairy, (b) the veterinary supervision of the herd, (c) the medical supervision of the employees, and (d) the chemical and bacteriological supervision of the milk.

The use of the term "certified milk" should be limited to milk produced in accordance with the requirements of the American Association of Medical Milk Commissions.\* The first requisite in the production of certified milk is to enlist the cooperation of a trustworthy dairyman who is willing to enter into a contract with the medical milk commission. In accordance with the terms of this contract, the dairyman binds himself to comply with the specifications set forth and in return his milk is certified. The certificates are the caps for the bottles which are furnished by the commission.

The dairies are subjected to periodic inspections, and the milk to frequent analyses. The cows producing certified milk must be free from tuberculosis, as shown by the tuberculin test and physical examination by a qualified veterinarian, and from brucellosis and all other communicable disease, and from all diseases and conditions whatsoever likely to deteriorate the milk. They must be housed in clean, properly ventilated stables of sanitary construction, and must be kept clean and properly fed and cared for. All persons who come in contact with the milk must exercise scrupulous cleanliness, and must not harbor the germs of typhoid fever, tuberculosis, diphtheria, pathogenic streptococci, or other infections liable to be conveyed to the milk. Milk must be drawn under all precautions necessary to avoid contamination, and must be immediately cooled to 45° F, placed in sterilized bottles, and kept at a temperature between 35° and 45° F until delivered to the consumer. Pure water, as determined by chemical and bacteriological examination, is to be provided for use throughout the dairy farm and dairy. Certified milk should not contain more than 10,000 bacteria per ml., and should not be more than 36 hours old when delivered.

Certified milk is raw milk and, therefore, may convey the infectious agents of disease; in fact, this has happened. Such occasional danger may be guarded against by pasteurization.

**CERTIFIED-PASTEURIZED.** The pasteurization of certified milk is optional. It was established legally in Boston in 1929 and since recognized by the American Association of Medical Milk Commissions. Thus, the cleanest, freshest raw milk obtainable in large cities may be made safe. Standard plate counts of pasteurized certified milk often show no growth and average less than 500 colonies per ml.

**Decomposition of Milk.** Milk spoils in various ways as the result of bacterial growth, the kind of decomposition depending upon the kind of bacteria which predominate. Milk, as a rule, ferments, but sometimes it putrefies. In the former case

\* See annual reports of this Association; *Methods and Standards for the Production of Certified Milk*, adopted by the American Association of Medical Milk Commissions, 1954-55,

the main change takes place in the carbohydrates; in the latter the proteins are broken down. The fermentation, known as the souring of milk, is accompanied by an acid reaction and a precipitation of the casein. Putrid milk turns alkaline and bitter, owing to the formation of peptones. Sour milk is regarded as the "normal" form of decomposition, because it is the usual change and is not harmful. Putrid milk is believed at times to contain toxic substances; it is at least suspicious.

**SOUR MILK; LACTIC ACID FERMENTATION.** Milk curdles or sours when the soluble caseinogen is precipitated as casein. The caseinogen exists in milk as a complex molecule containing calcium phosphate loosely bound to it; it also contains calcium as part of the molecular complex. The formula may be expressed thus:

The casein is held in solution (colloidal suspension) by the calcium phosphate and other soluble salts of calcium. Any chemical reaction that removes the calcium phosphate from this combination causes a precipitation of the caseinogen as casein. The casein may be precipitated by various substances, such as rennin or acids. In the normal curdling or souring of milk the casein is precipitated by lactic acid produced through the action of bacteria upon lactose. The lactic acid results from hydrolysis of the lactose as follows:

The bacteria usually concerned in the souring of milk are: *Lactobacillus acidophilus*, *L. bifidus*, *L. casei*, *E. coli*, *Streptococcus lactis*, *L. bulgaricus* and a great number of other micro-organisms capable of fermenting sugar with the production of acid. Sour milk, obtained from clean milk, is a beneficial food.

**Sour Milk and Intestinal Flora.** Sour milk contains myriads of lactic acid bacteria. Metchnikoff called attention to the importance of a normal lactic acid flora in the large intestines, which inhibits putrefactive processes and thereby stands guard against "auto-intoxication." He recommended the use of certain bacteria in sour milk, especially *L. bulgaricus*. It is a fallacy, however, to suppose that the flora of the intestines may be influenced through ingestion of these bacteria by the mouth, even when taken in enormous numbers, as in sour milk. A sour milk diet is uncertain in its effects and often disappointing in its results.

Contrary to widespread belief, the bacterial flora of the alimentary tract is not a replica of bacteria ingested. Of the many varieties of micro-organisms gaining entrance into the alimentary tract, few succeed in establishing themselves. The diet of early infancy is rich in carbohydrates in the form of lactose. The *L. bifidus* then establishes itself in the intestines. As the diet changes with age, the colon group of bacteria begins to assert itself, not because these organisms dominate in the diet, but because they, above all others, thrive as well in a medium from which carbohydrates are absent, as in one containing them. *E. coli* and related bacilli constitute nearly 60 per cent of the viable fecal flora.

The number and kinds of bacteria vary in different parts of the digestive tube. The number becomes enormous in the large intestine. It is estimated that about

$3 \times 10^{12}$  are excreted daily by a normal adult. Bacteria supply 46 per cent of the total fecal nitrogen. It has even been questioned whether we could live without intestinal bacteria. Levin, however, found the intestines of a number of Arctic animals sterile. Loeb and Northrup have been able to raise large numbers of banana flies under sterile conditions. These experiments show that the duration of life of these flies varies inversely as the temperature of their environment.

When it was shown that the Bulgarian bacillus cannot be seeded in the intestines because it is not a normal inhabitant of man, in fact does not occur in the feces of Bulgarian peasants, attention was turned toward the closely allied *L. acidophilus* which is a normal inhabitant of the human alimentary tract, especially of children and some adults, where ordinarily it is found in small numbers. It is doubted if they can be "implanted" or increased in numbers by taking them by the mouth. Efforts to implant them are variable, often disappointing, and probably never permanent. Living cultures in milk, reinforced with lactose, as advocated by Cheplin and Rettger, are claimed to relieve constipation and otherwise be beneficial especially by restraining putrefactive processes. However, indican and phenol excretion in the urine continue and may even increase with milk lactose cultures of *L. acidophilus*. Lactose alone is laxative. It is so poorly absorbed from the bowel that it gets into the lower ileum and colon and there modifies the culture medium so that the fermentative bacteria outgrow the putrefactive ones. *The intestinal flora are controlled by diet rather than by bacteria ingested.* Furthermore, the bacteria passed in the feces are not so much those taken in by the mouth as those that grow in the bowel. In order to get the best results it is necessary to take daily about a quart of milk containing no less than 200 million viable acidophilus bacilli per ml., with the addition of lactose. The secret of acidophilic and other lactic acid therapy may not be to emphasize the administration of the microbe, but to regard the intestinal flora as an indication of a corrective and successful regimen.

**PUTRID MILK. Alkaline Putrefaction.** When boiled milk is allowed to stand at room temperature, it gradually acquires an alkaline reaction,\* a bitter taste, and finally turns putrid, yielding a soft, slimy curd. On further standing this curd is peptonized to form a somewhat clear fluid, and if these putrefactive changes are allowed to proceed for a sufficient length of time a semi-transparent liquid is obtained, having no resemblance to milk. In this form of decomposition the main change occurs in the protein constituent of the milk. These putrefactive changes seldom occur; they are undesirable and are believed sometimes to be dangerous, in that toxic substances may be produced. The principal cause of putrefaction in milk is the spore-bearing group of bacilli, belonging to and resembling the hay bacillus and also the anaerobes.

**SLIMY OR ROPY MILK.** Under some circumstances certain mucilaginous substances develop in milk through abnormal fermentation. This occurs mainly in the spring. Slimy milk has been obtained of such viscosity that it could be drawn out into threads 10 feet in length, and of such thinness as to be scarcely visible. In Norway such milk is esteemed a delicacy; in this country, however, it is objectionable. From a health standpoint ropy milk is not injurious unless it is slimy as a result of mucopurulent materials caused by diseased conditions in the mammary

\* Schorer found that such milk becomes less acid but seldom actually alkaline in reaction.

glands. The bacteria which produce ropy milk are widely distributed in nature. Of these *Alcaligenes viscosus* is the commonest organism found in Europe, and a similar organism occurs in this country. *Alcaligenes viscosus* is very hardy; it may find its way into the milk as by the cows wetting their udders and teats in pools of water just before milking, and then become widely diffused. It is sometimes very troublesome, but may be eradicated through cleanliness. It often requires a liberal and repeated use of hypochlorites and steam disinfection. Other organisms producing sliminess in milk are the *Micrococcus freudenreichii*, two forms of streptococci, and certain of the lactic acid bacteria.

**ALCOHOLIC FERMENTATION.** This is an unusual fermentation which sometimes occurs as a result of yeasts, aided in their action by certain species of bacteria. Alcoholic fermentation of milk seldom occurs spontaneously, but may be induced by direct inoculations with certain ferments, such as those employed in the production of kumyss and kefir.

**Kumyss** was originally made from mare's milk; it is now also made from cow's milk by the addition of cane sugar and yeast. **Kefir** is a similar beverage, originating in the Caucasus, where the fermentation is carried out in leather bottles and is started by means of "kefir grains" which contain yeast and various micro-organisms.

**Bitter Milk.** Freshly drawn milk sometimes has a bitter taste; in other instances milk acquires such a taste on standing a few hours. The former is due to improperly feeding the cow with such herbs as lupines, wormwood, raw Swedish turnips, cabbage, etc. The latter case is due to the growth of certain bacteria in the milk after it is drawn. Conn ascribes the power of ruining the taste of freshly drawn milk in a few hours to a micrococcus, while Weigmann thinks a bacillus is responsible. The condition is undesirable, and sometimes causes much trouble for the dairyman, but it has no particular sanitary significance.

**Off Flavors.** Milk sometimes has an off flavor as it comes from the cow. The causes are not always clear. One of the most annoying is called cardboard or metallic taste. The cardboard flavor is believed to be caused by an oxidation reaction which is accelerated in several ways, including exposure of the milk in clear glass bottles to direct sunlight. It develops gradually on standing. It is more common in wintertime and is likely to disappear in the summer season.

**Colored Milk.** Blue milk is usually due to the *Pseudomonas synecyanea*. Such milk is apparently harmless. Red milk may be due to the presence of blood coming from an injury, or acute infection of the udder. Sometimes it results from the feeding of the cow on plants containing red pigment, such as the madder root. A red color may also be produced by the *Bacterium erythrogenes*, *Serratia marcescens* and *sarcinae*. Red milk caused through the agency of bacteria is not known to be harmful.

**Soft Curd Milk.** The milk from some cows produces a much softer curd than that from others. The toughness of the curd is determined by the curd tension. Milk with a curd tension of less than 30 gm. is called soft curd, and that above 30 gm. is hard curd. It is assumed that a soft curd is more readily digested.

Natural soft curd milk is obtained from selected cows. Artificial soft curd milk is made by homogenizing milk between 100° and 104° F at 3,000 pounds pressure. Boiling also softens the curd. A small quantity of blood serum added to milk will do the same. Cows having a pathological condition of the udder secrete a soft curd

milk. It has been learned by experience that selecting cows for the production of soft curd milk generally results in picking out those with diseased udders, so this method is impractical.

*Homogenized milk*, also called viscolized milk, not only has a softer curd but the fat is in a stable emulsion and the cream does not rise on standing. It is palatable and digestible.

**Adulterations of Milk. SKIMMING.** The removal of part or all of the cream and selling the remaining fluid as whole milk is an economic fraud, and has no reference to health, except that the milk is correspondingly lowered in nutritive value. Adding skim milk or condensed milk is a form of tampering difficult to detect.

**WATERING.** The practice of watering is not nearly so frequent as formerly. If the water be pure it must be regarded more as a fraud than a health problem. The addition of water to milk may be detected because it lowers its specific gravity, raises its freezing point, and lowers its index of refraction, its viscosity and its conductivity.

*Alkalis*, such as sodium carbonate or bicarbonate, are occasionally added to milk to reduce its acidity or to improve its taste or to delay curdling. Condensed skim is added to raise the total solids.

**CHEMICAL PRESERVATIVES.** Chemical preservatives, such as borax and boric acid, salicylic acid, benzoic acid and benzoates, potassium bichromate, peroxide of hydrogen, fluorides, formaldehyde, and others, have from time to time been used in milk. The oxidizing preservatives injure the vitamins, and the alkalis camouflage acid fermentation. The practice of adding any chemical preservative to milk meets with the unqualified disapproval of the sanitarian. Almost all countries prohibit the use of such foreign substances. The only proper preservatives for milk are *cleanliness* and *cold*.

**Dirty Milk; The Dirt Test.** Practically all milk contains more or less dirt. For the most part, this dirt consists of cow feces and dust from feed. The presence of dirt may best be determined by filtering a pint of milk through a little disk of absorbent cotton. This produces a stain varying in intensity from a yellowish to a brownish or black spot. A Gooch crucible, a Lorenz apparatus, or simply an ordinary funnel may be used to filter the milk. Warm milk filters much more readily than cold milk. This simple test is one of the practical routine tests used for the administrative control of milk supplies. The intensity of the stain and the amount of deposit upon the cotton is a telltale which appeals strongly to farmers and dairymen, as well as to consumers. It is a good practice to send these disks of cotton, with a letter, to the farmer, showing him the amount of dirt contained in his milk. The disks may be dried and kept with the records of the health office. There is a trend toward the use of sediment testers designed to pump a pint of milk from the bottom of a can as delivered and force it through a standard cotton disk. This is rapid and easy to use.

It should be remembered that milk that has been "clarified" or strained will not show the dirt test. The use of the test may result simply in more effective straining of the milk at the dairy farm.

**Clarification.** Clarification consists of mechanical straining by the use of centrifugal force. Clarifiers of the de Laval type whirl the milk with sufficient force to throw the heavier substances to the circumference of the revolving bowl where they

become attached while the milk serum with its fat and normal solids escape through the central outlet. Milk so treated, therefore, will not deposit a sediment on standing and the value of the dirt test is destroyed. The material adhering to the circumference of the bowl is called *separator slime* and consists of dirt, foreign particles of all sorts, bacteria, pus, blood, mucus, leukocytes, epithelial cells and cell detritus, and a small amount of the substances normally present in milk. Cold clarification is the only acceptable type, for warm clarification tends to break up the dirt into particles more difficult to remove.

The advantages of clarification are that it is more efficient in removing visible dirt than filtration through a strainer. But, it is not a substitute for sanitation, since it does not remove soluble dirt, nor is it a substitute for pasteurization since it does not effectively remove pathogenic bacteria. The merits of the process have often been abused by dealers who have made exaggerated claims and mislead the public with a false sense of security.

Filtration and straining are commonly used in the milk room of the dairy barn, but are also much practiced by the city dairy. The use of single service filters and fabrics should be required and, in plants, filtration should precede pasteurization.

**Number of Bacteria in Milk.** Milk may contain more bacteria than any other known substance; in fact, many more than are found in sewage. Sour milk contains myriads. Mere numbers, however, need not alarm us, for it is the kind that most concerns us. By universal consent, however, milk containing an excessive number of miscellaneous bacteria is not suitable for infant feeding. If milk were a transparent fluid, the enormous overgrowth of micro-organisms which are sometimes present in market milk would be plainly visible to the naked eye.

The bacteria get into the milk from a number of different sources. Some of them are in the milk before it leaves the udder. They may migrate up the milk ducts into the milk cistern; hence, the foremilk contains more than the midmilk or strippings. It is practically impossible to obtain sterile milk directly from the teat in any large quantity. As soon as the milk leaves the teat it receives additional contamination from all objects with which it comes in contact, as the hands, the pail, the dust in the air, etc.

The most important factors to obtain milk with a low bacterial count are: clean and sterilized pails, cans and other utensils; clean dry hands and clean milking machines; healthy cows with clean udders and teats; and the use of the small top milk pail. Experiments have shown that the greatest number of bacteria come from the dirt and dung that fall into the pail during milking and from the pail itself, if not clean and scalded. Milking machines, which are being used in increasing numbers, may contribute many bacteria when carelessly washed, sterilized and stored. To keep the counts low, it is necessary to chill the milk at once and to hold it below 50° F.

It has been repeatedly demonstrated that the rank and file of dairy farmers in their ordinary cow stables can, by the practice of elementary sanitary methods, produce milk which regularly contains less than 10,000 bacteria per ml. This requires not only intelligence but also conscientiousness.

Judged by the number of colonies on Petri plates, the number of bacteria in milk increases every time it is handled or exposed in any way. Separator milk seems to contain more bacteria than the original milk. The same is true of filtered

milk. This is due to the fact that while some of the dirt is taken out, the particles, including clumps of bacteria, are broken up and the bacteria dispersed throughout the fluid, thereby giving more colonies on plate cultures.

Mastitis (garget), or inflammation of the udder, is a common affection of cows, and is associated with streptococci, staphylococci, and colon bacilli, etc. Milk from a gargety udder will contain enormous numbers of micro-organisms.

When milk contains bacteria harmful to man, they almost always get into the milk from human sources, either directly or indirectly. The chief exceptions to this rule are the bovine tubercle bacillus, *Brucella*, bovine hemolytic streptococci, and the virus of foot and mouth disease.

The bacteria in milk are not equally distributed throughout the fluid. There are more bacteria in cream than in the underlying skim milk, particularly in gravity cream. As the cream rises it mechanically carries many of the bacteria along with it, much as a snowstorm sweeps the atmosphere. Milk formulae for infant feeding are often made of top milk, which, however, may contain from five to one hundred times the number of bacteria per ml. found in the whole milk. In 26 samples of milk Anderson found the gravity cream contained about four times as many bacteria as the sediment layer, and about one-third as many as the whole milk. Schorer found that the cream from milk of high bacterial count contained several thousand times as many bacteria as the underlying skim milk.

Formerly, our milk supply contained millions of bacteria per ml. In Washington, in 1908, the average bacterial count of market milk was 22,000,000 per ml. The great reduction is due to sanitary supervision and pasteurization. It is seldom now that raw milk for pasteurization reaches the plant containing over 500,000 bacteria per ml. and most ordinances do not permit over 200,000.

Excessive numbers of bacteria in milk indicate that it is dirty, old or warm. One or any combination of these factors favors a rapid growth and multiplication of the bacteria in milk.

*The phosphatase and coliform tests collectively constitute the best index of safety and the number of bacteria in milk is the best single index we have of its general sanitary character.*

**PATHOGENIC BACTERIA IN MILK.** For the most part, bacteria do not pass a healthy udder. However, we can place no trust in the filtering ability of the mammary gland. It is known that the virus of foot and mouth disease, which is ultra-microscopic, and the organisms causing brucellosis (undulant fever) (*Brucella abortus suis* and *melitensis*), and *Mycrobacterium tuberculosis* (bovis) are frequently found in the milk of infected animals. *E. coli* in milk comes from manure. A milk free from *E. coli* is an especially clean and carefully produced milk; but when large numbers are present, the milk is very dirty or from a herd of cows infected with these organisms.

For the most part, when milk contains bacteria pathogenic for man, the milk is contaminated from human sources. This is almost invariably the case with diphtheria, scarlet fever, septic sore throat and typhoid fever. Occasionally, however, the udder may become infected with bacteria pathogenic for man. For example, *Streptococcus pyogenes* (Group A), the cause of septic sore throat, may get into the udder where it grows and multiplies and may thus infect the milk for a long period. Brooks, in 1939, stated that two outbreaks of scarlet fever in different localities,

eight months apart, were traced to raw milk from a single cow whose udder was shown to be infected with Lancefield Group A streptococci. These bacteria persisted in the udder during a breeding period and the second outbreak occurred soon after the cow freshened. In this case, however, the original infection is introduced from human sources (see page 869). Some hemolytic streptococci ordinarily found in milk are not known to be pathogenic for man. Many of them are of bovine origin or Lancefield Group B.

**Mastitis.** One of the commonest diseases of milch cows is mastitis, sometimes called garget, often caused by injury, and associated with the bacteria of inflammation, especially streptococci, often a hemolytic type and sometimes of human origin. The presence of mastitis may be determined by use of the strip cup or the squirt test, which consists in straining the first three squirts from the udder through black fabric (silk), when flakes of precipitated casein are clearly visible. Veterinarians use deep palpation of the udder to detect indurations of the tissue. Inflammation of the udder also causes a great increase in the number of leukocytes and an increased alkalinity in the milk which may be detected by simple tests, such as the brom thymol blue test.

**Bacteria in Human Milk.** Investigation of the breast milk of one hundred women disclosed streptococci in 49 per cent of the samples (Dudgon and Jewesbury, 1924). Only 2 per cent of these were regarded as an indication of a pathologic process in the breast, although the number of streptococci in milk with a high polymorphonuclear count was greater than in normal milk. *E. coli* and micrococci (staphylococci), especially *Micrococcus pyogenes* var., were found in normal milk from apparently healthy glands. The bacteriology of mother's milk has received scant attention, but it is now plain that it may be significant in the problem of infant feeding.

**The Bacteriostatic Property of Milk.** The bacteriostatic property of milk has been much misunderstood. It is specific and varies in different animals and even in the same animals at different seasons. In some instances it persists for six hours or more. It is destroyed at 75° C for 15 minutes, or between 80° and 90° C for two minutes. At most, the bacteriostatic action is transitory and cannot take the place of cleanliness and ice, but may be taken advantage of by prompt use of fresh milk and in the prompt delivery of uncooled milk to plants for processing and cooling. It is true that bacteria develop more quickly in heated milk than raw milk, provided the raw milk is fresh; it should be remembered, however, that stale milk, even milk that is a day old, no longer possesses this restraining action. The bacteriostatic property, therefore, is ordinarily absent in market milk. Milk contains agglutinins, lysins and other antibodies similar to those found in the blood.

Rosenau and McCoy have shown that, judged by the number of colonies that develop upon agar plates, the bacteria in milk first diminish, then increase in number. This occurs only in raw milk during the first 8 or 12 hours after it is drawn. Although the bacteria seemingly decrease in numbers, they never entirely disappear. After the initial decrease there is a continuous and rapid increase, until the milk contains almost infinite numbers in each milliliter. The power of milk to restrain the development of bacteria lasts from 6 to 24 hours, depending upon the temperature at which the milk is kept. When the milk is kept warm, 37° C, the decrease is pronounced within the first 8 or 10 hours; after this the milk has entirely lost its restraining action. When the milk is kept cool, 15° C, the decrease is less marked.

but more prolonged. They further showed that at least part of this decrease is due to agglutination.

## MILK PRODUCTS

**Adjusted or Standardized Milk.** The addition or subtraction of cream with the object of obtaining a uniform and definite percentage of fat is known as adjusting or standardizing milk. Holstein and Jersey milks are blended so as to adjust the fat content. Not infrequently cream is removed so as to reduce the fat to the minimum legal limit. A more commendable practice is to fortify the fat content by separating the cream from a portion of the milk and adding this to the general supply.

Adjusting and standardizing is a common practice among large milk dealers. Sanitarians have always looked askance upon the practice, for while the addition of cream can hardly be objected to, its subtraction cannot be approved. The process should be limited to mixing whole milks and controlled by the health authorities. In some areas adjustment other than by blending is illegal.

**Reconstructed Milk.** Reconstructed milk is also called remade milk; sometimes "synthetic" milk. A better name is recombined milk, or reconstituted milk, for it consists in combining powdered whole milk or skimmed milk powder, condensed or evaporated whole milk or skimmed milk, with butter, butter oil, or milk fat, and water. The fat is homogenized to form a fine emulsion in the reconstructed milk. If such products are made entirely from milk constituents, they may be labeled "recombined," or "reconstructed" milk, but if any other fat or oil is substituted in whole or in part for milk fat, then the product should be labeled "artificial milk," "milk substitute" or "filled milk." In some states the sale of such products is illegal.

There is a legitimate field for remade milk. Thus, during World War I it became necessary to find a milk supply for the new city of Nitro, West Virginia, with 25,000 and more inhabitants. The city was established in a section unsuited for dairying and no available supply of fresh milk could be found. The Government relieved the emergency by reconstructing milk by homogenizing butter fat, skimmed milk powder and water. Similarly, some areas were supplied with reconstituted milk by dealers during World War II.

*Filled milk* is a compound made up of skimmed milk to which 3 or 4 per cent of coconut oil is added. It is then condensed to approximately one-half its volume. Many states prohibit the sale of filled milk by law.

The importance of sanitary control and proper labeling of such products is obvious.

*Condensed and evaporated milks* are concentrated by partial dehydration. The first really practical method was devised by Gail Borden, of White Plains, New York, who successfully evaporated milk under reduced pressure, and in 1856 obtained a patent for his process.

The *advantages* of total or partial desiccation, whether evaporated, condensed or powdered milk, are manifest. It reduces weight and bulk and saves carrier charges; it improves the keeping quality of a perishable food; and it suppresses the watery environment necessary for microbial activity. There is little danger of these products conveying infection, for they are either made from pasteurized products or steam sterilized. The process of drying permits milk to be produced in parts of the world where it can be made to best advantage. It saves the surplus at the spring

flush. It simplifies the present cumbersome distribution to the householder, and stabilizes the supply for large cities. Transportation difficulties are swept away. Great quantities are made and used. Sanitary control of production, and honest labeling are therefore doubly important.

*Sweetened condensed milk* is heated to about the pasteurizing temperature but is not sterilized, for high temperatures thicken and darken the product. It is preserved with 40 per cent sugar (sucrose). When not produced under sanitary conditions, it may contain many bacteria per milliliter. Condensed milk contains not less than 28 per cent of milk solids and not less than 8 per cent of milk fat (U. S. Government Standard).

*Evaporated milk* is unsweetened and must be processed by heat in order to preserve it; it is therefore sterile, or nearly so. Evaporated milk contains not less than 7.8 per cent of milk fat nor less than 25.5 per cent of milk solids (U. S. Government Standard).

Condensed and evaporated milks may be made from whole milk, skimmed, or partly skimmed milk. These are useful and legitimate products, but they should be labeled as to the grade of milk used, the amount of butter fat, etc. Inspection should be maintained to insure quality and cleanliness. Babies raised on these products are apt to develop scurvy unless given orange juice, tomato juice or other antiscorbutic.

*Dried Milk (Milk Powder)*. Milk may be dried *in vacuo* at moderate temperatures, or on revolving belts or drums in the presence of hot dry air. The presence of the fat has interposed the greatest difficulty to the complete drying of milk. In the Ekenberg process the milk is sprayed under constant pressure on the inner surface of a rotating steam-heated cylinder. The milk is thus dried in partial vacuum at a comparatively low temperature. A more frequently employed process common in the production of cheaper grades consists in spraying the previously concentrated milk on the exterior highly polished surface of revolving steel drums. Here it is almost instantaneously dried at a temperature of 230° F and then scraped off by sharp knife blades. In the Bénévot-de-Neveu process the milk is first concentrated in a vacuum and then sprayed under great pressure into a large drying chamber where the cloud of finely atomized particles is surrounded by a current of hot air, and thereby instantly dried. The result is a powder in which most of the physical and chemical properties of the original milk are retained.

The process has been improved in recent years to such an extent that when milk powder of good quality is mixed with water it makes a product that resembles milk in nearly all essential particulars.

Dried milk powder may be made from skimmed milk, from partly skimmed milk, or from whole milk, rich in cream. The product keeps well, except that the butter fat in powdered whole milk tends to oxidize on protracted storage developing a slightly rancid flavor. It has practically all the nutritive value of the original milk. Vitamins A and B are not materially affected, but the antiscorbutic properties are diminished about one-half. In other words, drying, pasteurizing and age have about the same effect on this vitamin in milk. For general cooking and food purposes, it is about the equal of liquid milk.

Dried milk has all the uses of milk. It is used as a basis of certain proprietary infant foods; it is employed in admixture with cocoa and sugar, with egg powder and sugar as a custard powder, and in various other food combinations. It is exten-

ively used in the baking and confectionery trades. It is convenient in the household and economical so far as waste is concerned.

Babies have been fed on dried milk exclusively with good results, but not all methods of drying have yet been tested. The answer to this question must await a number of years of patient observation. In any case, antiscorbutic accessories, as orange juice, should be used. Dried milk powder makes a good food for growing children and adults.

**Fresh Milk Products.** Cream, butter, buttermilk, ice cream, sour milk, fresh cheese, and other milk products may convey all the infections contained in the original milk from which they are prepared. It is known that tubercle bacilli pass into butter and may live there for months. It has also been demonstrated that infected cream has been the cause of typhoid fever, septic sore throat, diphtheria, scarlet fever, and other milk-borne diseases. Extensive outbreaks of typhoid fever have been traced to fresh or uncured Cheddar cheese and it has been demonstrated that the hemolytic streptococci causing septic sore throat, as well as *Brucella abortus*, will remain viable therein for a month or more. Cheese made experimentally, incorporating cultures of these pathogens, has been shown to contain viable pathogens after many months of storage. Outbreaks of typhoid fever, scarlet fever and other diseases have been traced to ice cream. Cold preserves rather than kills bacteria. Therefore, ice cream may be infected either with the milk or cream from which it is made, or directly from a case or carrier.

Milk products are often made from milk that is left over or otherwise unsalable. This should be controlled by an efficient system of inspection.

The infections in fresh milk products may be guarded against by pasteurization. It is comparatively easy to pasteurize cream, for the reason that it may be heated to a higher temperature than is the case with milk without materially altering its physical properties.

**BUTTER.** Butter is made by churning "gravity" cream or "separator" cream. The cream may be fresh, but is usually ripened, that is, partially sour before it is made into butter. Special cultures of micro-organisms ("starters") are sometimes added to ripen the cream for the purpose of giving the butter a particular flavor.

Butter is usually "scored" in accordance with a score card proposed by Woll in which 45 points are allowed for flavor, 25 for grain (body), 15 for color, 10 for salt, and 5 for packing.

Butter turns acid and rancid in time, owing to the conversion of the fat into fatty acids. Rancid butter may be renovated by washing it with skimmed milk or with water to which bicarbonate of soda or lime is sometimes added to neutralize the acidity. Much butter is made from cream, the acid reaction of which is neutralized with alkalis, the rancid odors and taste blown out with steam, further enzyme action stopped with hydroquinone, and advancing decomposition checked with chlorine or other preservative. Much butter and cream of poor quality are renovated. There is no particular health objection to these processes provided such butter is sold as renovated butter.

Fresh butter contains a great number of micro-organisms (millions per gram). The total bacterial count diminishes with time. There may be a reduction of 85 per cent in two weeks, and 93 per cent in four weeks. Butter may contain tubercle bacilli, typhoid and other pathogenic bacilli. Of 21 samples of market butter ex-

mined in Boston, 2 of them were found to contain tubercle bacilli, being 9.5 per cent of the samples examined. On account of this danger butter should always be made from pasteurized cream and labeled "butter made from pasteurized cream," not "pasteurized butter."

Petri examined 102 samples of butter at Berlin, using 408 animals for inoculation; 16.7 per cent contained tubercle bacilli. Korn found 23.5 per cent of 17 samples of butter at Freiberg to contain tubercle bacilli.

The frequency with which tubercle bacilli are found in butter is shown in a table collected by Swithinbank and Newman. Of 498 samples tested from different sources, 76, or 15.2 per cent, contained tubercle bacilli.

Schroder and Cotton have found that living tubercle bacilli will retain their infective properties for at least 160 days in salted butter when kept without ice in a house cellar.

Butter may also convey typhoid bacilli and other pathogenic micro-organisms.

*Oleomargarine* consists of a mixture of edible animal and vegetable fats churned with milk. Since all of the ingredients are in themselves useful foods, the wholesomeness and nutritive value of the finished product is beyond question. Oleomargarine consisting exclusively of vegetable oils churned with skimmed milk is deficient in the growth-producing vitamins. The principal deficiency is in vitamin A. Since early in World War II manufacturers of oleomargarine have been adding about 9,000 units of vitamin A per pound, which is equivalent to the vitamin A content of butter. The better grade of oleomargarine also contains some milk fat.

Objections to the manufacture and sale of oleomargarine are based rather on the possibility of fraudulent substitution for butter than on nutritive or sanitary considerations. In the United States, oleomargarine has been an object of federal taxation, and its manufacture has been subject to supervision by the Bureau of Internal Revenue. A tax of 10 cents per pound was imposed on oleomargarine which is artificially colored to resemble butter and a tax of one-fourth cent per pound on the uncolored product. During the fiscal year ended June 30, 1924, 229,031,000 pounds of oleomargarine were manufactured, of which about 44 per cent contained no animal fat. In 1954, the total output of oleomargarine was 1,364,339,000 pounds, of which about 99 per cent was made exclusively from vegetable oils. In many sections of the country, the sale of colored oleomargarine is prohibited either directly or by excessive tax. The federal tax on colored oleomargarine has been reduced.

Oleomargarine containing fats derived from the carcasses of cattle, sheep, swine and goats is a meat food product. It is, therefore, subject to Federal Meat Inspection. This inspection insures the use of pure and wholesome materials and the maintenance of cleanliness and sanitary conditions in the establishment. Only animal fats from "U. S. Inspected and Passed" carcasses may be used. Oleomargarine prepared exclusively from vegetable fats is not subject to federal inspection. Pasteurization of milk and other dairy products used is required in all establishments operating under Federal Meat Inspection and is regularly practiced in establishments preparing oleomargarine from vegetable oils. It will be evident, therefore, that the possibility of disseminating disease through oleomargarine is exceedingly remote.

**CHEESE.** Cheese is one of the oldest of the milk products. There are many varieties of cheese, of which Cheddar type is most common. It is a concentrated and valuable food. Roughly speaking, many varieties contain about one-third fat, one-

fourth protein and one-third water. Cheese varies in its richness in calcium depending on the mode of manufacture. In cheese produced from sour milk, much of the calcium is lost in whey. This is not the case in cheese prepared with rennin.

Although pathogens in cheese will become devitalized after long storage at temperatures above zero degrees centigrade, pasteurization offers greater protection. Higher temperatures result in more rapid destruction of pathogens. The cheese should be made from pasteurized products or the cheese should be pasteurized, as in so-called "processed cheese."

### DISEASES SPREAD BY MILK

The disease conveyed through milk are: tuberculosis, typhoid and paratyphoid fevers, gastro-enteritis or food poisoning, diphtheria, streptococcal infections (scarlet fever and septic sore throat), brucellosis (undulant fever), foot and mouth disease, Q fever and milk sickness; also some of the summer complaints of children, and the diarrheal and dysenteric diseases of adults, which are occasionally referable to infected milk. Infantile paralysis may be rarely milk-borne.

Milk becomes infected from human sources, usually on the farm, sometimes at the milk plant, occasionally in transportation, and rarely in the household of the consumer. Sometimes the milk becomes infected as a result of disease of the animal, as in the case of bovine tuberculosis, brucellosis, foot and mouth disease, and Q fever. Furthermore, cows' udders may become infected with human pathogens, particularly Lancefield Group A hemolytic streptococci.

Bussey and Kober in 1895, Baker in 1896, Freeman in 1896, Hart in 1897, Caroe in 1898, Schleghtendal in 1900, and Trask in 1909 reported over 700 milk-borne outbreaks of disease, of which 179 occurred in the United States. Armstrong and Parran (1927) have tabulated additional instances. Experience has shown that many milk-borne outbreaks go unrecognized or unreported. Notwithstanding the great progress made in improving the safety of milk supplies, in 1945 there were 29 milk-borne epidemics reported in the United States which caused 2,161 cases of disease with 17 deaths.

Milk-borne outbreaks of disease are nearly always due to raw milk; often milk of good quality, even certified milk. A few outbreaks have been traced to milk labeled pasteurized which either has not been pasteurized at all, was grossly under-pasteurized or was contaminated after pasteurization with raw milk or with pathogens from cases or carriers. There is no record of a milk-borne outbreak attributable to properly pasteurized milk.

**Tuberculosis.** Milk is the chief vehicle for the conveyance of bovine tubercle bacilli from cow to man. They get into milk either directly as a result of tuberculosis of the udder, which occurs in from 1 to 2 per cent of all tuberculous cows, or indirectly through cow manure. In the latter case the tubercle bacilli are coughed up, swallowed, and passed in the feces. Practically all market milk contains cow feces. Tuberculosis in cattle is still prevalent in some countries. This situation has definitely improved in the United States owing to tuberculin testing of herds on an area basis with the purchase and slaughter of reacting animals, the disinfection of premises and the establishment of accredited herds. The "milk" from a tuberculous udder, when examined under the microscope, may contain as many tubercle bacilli

Table 22-2. Reported outbreaks of milk-borne disease in the United States

Disease and Year	Total Cases Reported	Number of Cases Traced to Milk	Cases Traced to Milk, Per Cent	Number of Outbreaks Traced to Milk
<b>Typhoid fever</b>				
1907-1914	23,482	2,215	9.4	50

\* Scarlet fever only. Septic sore throat not reported until 1915.

† Beginning in 1951 scarlet fever cases were included as streptococcal sore throat.

as are ordinarily found in tuberculous sputum. The milk from a tuberculous udder of one cow may contain sufficient bacilli seriously to infect the mixed milk of 25 or 30 cows. In one case Ostertag found that 0.001 ml. of the secretion from a tuberculous udder was sufficient to cause tuberculosis in a guinea pig. In such a case a child would receive myriads in a gill.

Tonney examined the market milk of Chicago in 1910 for the presence of tubercle bacilli. In 10.5 per cent of 144 samples of raw milk he found tubercle bacilli in sufficient numbers to infect guinea pigs. Of 19 samples of pasteurized milk examined, none contained tubercle bacilli.

Hess in 1909 examined 107 samples of market milk in New York City, with the result that 17 of them, or 16 per cent, were found to contain tubercle bacilli.

Anderson examined 223 samples taken in the city of Washington, and reported 16, or 6.72 per cent, as positive. The tests made by the Bureau of Animal Industry of the milk in Washington disclosed 7.7 per cent infected. Goler reports about 5 per cent of the milk supply of Rochester, New York, infected.

To sum up, we have evidence from four typical American cities. Live tubercle bacilli have not been disclosed in pasteurized milk. A total of 551 samples of raw milk have been examined, in which tubercle bacilli were found in 46, making a percentage of 8.3. This may be taken as representative for the entire country at that time. The situation is improving with many herds accredited free of tuberculosis and much of the market milk pasteurized.

Delépine (1914) reports that the mixed milk of Manchester, England, collected at railway stations or other places than the farm, contained tubercle bacilli in samples examined in the following inclusive periods:

	<i>Per Cent</i>
1897-1899 . . . . .	17.2
1900-1904 . . . . .	10.3
1905-1909 . . . . .	6.8
1910-1913 . . . . .	9.0

It is believed that the figures were an underestimate, for the methods used in the laboratory were not sufficiently delicate to detect a few tubercle bacilli in milk. Unless these micro-organisms are present in considerable numbers, they are apt to escape detection. In any event, it is clear that the raw market milk heretofore furnished large cities and most small towns often contained tubercle bacilli.

Mohler, Washburn and Doane found that tubercle bacilli remained viable in cheese 220 days old. In these experiments the cheese was purposely infected and fed or inoculated into guinea pigs at various times. Tubercle bacilli are frequently found in butter and other milk products, but only if the milk or cream of which they are made has not been pasteurized.

The relation of bovine tuberculosis to man is considered on page 145.

**Typhoid Fever.** Of milk-borne epidemics, typhoid fever takes the lead. Between 1907 and 1954, 510 outbreaks of typhoid fever were recorded in the United States. Typhoid bacilli may swarm in milk without altering its taste, odor or appearance. In Washington, 10 per cent of all the cases of typhoid fever during the years 1907 to 1910 were traced to milk. Despite the decline in the number of cases, the percentage of cases due to infected milk remains relatively high. Nearly all outbreaks occur on raw milk routes. The milk may become infected by a convalescent, a carrier or a missed case. The hazard varies with the level of endemic prevalence in the milk production area.

Typhoid fever has also been traced to cream, ice cream, and other milk products (see typhoid fever, page 198).

Milk-borne outbreaks of *paratyphoid fever* have been described by Levine and Elbersen (1916), Williams (1925), and others (see salmonellosis, page 207).

**Streptococcal Sore Throat (Scarlet Fever and Septic Sore Throat).** For many years outbreaks of streptococcal sore throat have been reported either as scarlet fever or septic sore throat, the diagnosis depending largely upon whether or not a majority of cases did or did not show desquamation. Furthermore, the attempt to identify the etiologic agent by careful cultural methods has caused further confusion. Now there is quite general agreement that this is one disease caused by hemolytic streptococci of Group A (Lancefield) as determined by serological test (see page 13).

Milk-borne outbreaks of streptococcal sore throat are sometimes extensive and serious. This is especially true when Group A streptococci establish themselves in the milk-secreting alveoli of a cow's udder.

In the cow's udder, the Group A streptococcus from a suppurating wound or an infected throat of a milker establishes itself and produces a form of mastitis. The organism has been demonstrated to persist in the udder of an infected cow during

a dry period and the milk to cause a second outbreak when the cow is freshened. In many outbreaks the human pathogens gain access to the cow's udder through the medium of teat injuries treated by a herdsman with a streptococcal sore throat. In one instance, such a herdsman admitted putting the thread in his mouth to knot the end before sewing up the teat torn on a barbed wire fence. It is believed that another avenue is through the medium of teat tubes or dialators placed in the mouths of persons with streptococcal sore throats as the only supposedly clean place they can put them while preparing to insert them in the cow's teat. Such tubes are used to keep the teat canal open for milking in case of a local infection of the membrane of the teat canal tending to close it.

Another known avenue for the transmission of streptococcal sore throat from a human to others is through the direct introduction of Group A streptococci in milk. In one outbreak in New York State, in which no infection could be found in the cows nor Group A streptococci in milk drawn aseptically, a milker with a suppurating wound on his ankle was observed to readjust the bandage on his wound while changing his shoes for boots immediately before starting to milk by hand. This made a direct avenue for organisms in the pus to get into the milk. In another outbreak of streptococcal sore throat traced to hand-separated raw cream, the two cows producing the milk were given a clean bill of health but a woman with a sore throat placed the milk in open cans to let the cream rise and later removed the cream. It was evident that she introduced pathogens under conditions conducive to growth.

The *Boston outbreak*, in 1911, was characterized by its extraordinary virulence and comparative immunity of children, and high mortality among the aged and infirm. In this outbreak there were over 2,000 cases with about 48 deaths. One of the features of special interest was that the milk incriminated had always been a particularly clean, fresh and satisfactory supply. It was obtained from tuberculin-tested cows under veterinary supervision, and the milk itself subjected to frequent chemical and bacteriological tests. The milk was bottled at the dairy, the bottles were sterilized, and many extra precautions were taken to insure its cleanliness. For 28 years not a breath of suspicion was attached to this milk until this catastrophe occurred. It emphasizes the lesson that raw milk is apt to be dangerous milk, and our only protection against these particular dangers is through pasteurization.

Another instructive outbreak, reported by Benson and Sears (1923), occurred in Portland, Oregon, March 24 to 31, 1922. In this epidemic there were 487 cases and 22 deaths. "Almost all of the cases and all but one of the deaths occurred among people who had drunk raw milk from one dairy which had been rated as one of the best in the city." This is the common story.

**Diphtheria.** Diphtheria bacilli in milk practically always come from human sources, either cases or carriers. In a few rare instances ulcers upon the teat of the cow have become infected with diphtheria, and the bacilli thus transferred to the milk. Such an occurrence, however, is unusual. As a rule, diphtheria outbreaks caused by infected milk are more limited both as to numbers and area than milk borne outbreaks of typhoid or scarlet fever (see diphtheria, page 92). Twenty four outbreaks of diphtheria were recorded in the United States between 1907 and 1948. Many milk-borne outbreaks are not disclosed.

**Milk Sickness.** Milk sickness is an acute nonfebrile disease due to the ingestion of milk, milk products, or the flesh of animals suffering from a disease known as

rembles. The disease is characterized by great depression, persistent vomiting, obstinate constipation and high mortality. The picture is that of a poisoning rather than an infection.

Milk sickness is primarily a disease of cattle, secondarily of man. In cattle it is called slows or trembles, and formerly was prevalent in the central part of the United States. The pioneers suffered severely in winning the West. Nancy Hanks, the mother of Lincoln, died from the disease in 1818 after an illness of a week. As forests are cleared and pastures fenced the disease becomes less frequent.

Marsh, in 1926, studied the rayless goldenrod, *Aplopappus heterophyllus*, and concludes that milk sickness is a poisoning due to this plant. Two species are toxic. The white snake root, a poisonous weed, is also responsible. Marsh produced trembles or alkali disease in horses, cattle and sheep by feeding sufficient quantities of the rayless goldenrod. The toxic principle, tremetol, is excreted in the milk, and calves and lambs may be poisoned in this manner. Stock eat this weed only where there is little good forage. The obvious remedy is to see that the animals are well fed. It is entirely practical to dig out the weed in fenced pastures. Knight (1935) describes a case in North Carolina due to white snake root.

**Undulant Fever (Brucellosis).** Brucellosis in milking animals, particularly cows and goats, is commonly called contagious abortion or Bang's disease. The principal manifestation is abortion. The disease spreads rapidly among susceptible animals and constitutes an economic problem. The specific organism is *Brucella abortus* in cows, *Brucella suis* in swine and *Brucella melitensis* in goats. The presence of the organism has been demonstrated in the milk of infected animals by agglutination of the milk serum and by inoculation of guinea pigs.

The organism may be transmitted to man by ingestion of the raw milk of infected animals or by direct contact with such animals. The discharges of infected animals at the time of parturition play an active role in the spread of the disease among animals and human attendants (see brucellosis, page 523).

**Foot and Mouth Disease.** Foot and mouth disease is an infection primarily of cattle and secondarily of man. It is caused by a filtrable virus, and is noteworthy for being the first ultramicroscopic virus of animals to be discovered by Löffler and Frosch in 1898. The infection may be transmitted to man through the ingestion of raw milk, buttermilk, cheese or whey from diseased cows (see page 532).

**Acute Gastro-enteritis.** Milk may occasionally be involved in food poisoning due to contamination with staphylococci or *Salmonella*. It may be the vehicle of dissemination of *Salmonella* infections (see page 216) and *Shigella* infections (see page 224). In the United States, the use of dirty bacteria-laden milk without pasteurization or boiling was formerly one of the chief causes of infant mortality due to summer diarrheas. The improvement in the milk supply has probably been the most important factor in the decrease in infant mortality in recent years.

**Q Fever.** When Q fever was discovered in the metropolitan area of Los Angeles in 1947, extensive epidemiologic studies were undertaken to determine the source of human infection with the disease. Studies were carried out by the National Institutes of Health in cooperation with the California State Department of Health and the Department of Agriculture and by the Los Angeles city and county health departments. Results are reported by Bell and others (1950). They concluded that the most frequent and by far the most important source of human infection is local

dairy cows, their very young calves and some of their raw products, particularly raw milk and hides. The persons most apt to have been infected were those who used raw milk in their households, those whose residence had been located near a dairy or livestock yard, those who had worked in industries handling hides of recently killed dairy cows and young calves, i.e., employees in dairies, in meat packing plants, and fat rendering plants, and employees handling the raw products of such animals, i.e., employees of creameries and hide plants. The causative agent, *Coxiella burneti*, was repeatedly demonstrated in the milk of dairy cows by Huebner and others (1948). It was further shown that commercial pasteurization essentially reduced but did not entirely eliminate the infection from the milk (Huebner and others, 1949) (see Q fever, page 440).

**Erythema Arthriticum Epidemicum or Haverhill Fever.** This clinical syndrome was described in a small but explosive milk-borne outbreak which occurred in the restricted area of Haverhill, Massachusetts, in 1926. The etiologic agent was identified as *Streptobacillus moniliformis*. Clinically the disease was indistinguishable from rat-bite fever due to *Spirillum minus*.

**Infantile Paralysis.** In the past 35 years three small focal outbreaks of poliomyelitis have been reported where the vehicle of distribution seemed to be a milk supply. In two of these, one in Spring Valley, N. Y., reported by Dingman (1916), and one in Cortland, N. Y., reported by Knapp and others (1926) a case of acute poliomyelitis was found on the farm supplying the milk. In the third, and somewhat larger outbreak described by Aycock, at Broadstairs, England, there were 62 cases. Investigation disclosed that practically all of the cases among the residents of Broadstairs were supplied with milk from the same dealer, and the evidence suggested that contamination of only one grade of his milk, which came from a single farm, was responsible for the epidemic.\* In two additional outbreaks, milk has been suspected of being the vehicle of dissemination (Goldstein and others, 1946; Matthews, 1949). The experiments of Lawson and Melnick (1947) on determination of the thermal death points of some mouse-adapted strains of poliomyelitis virus opened up the possibility of survival of the virus even in pasteurized milk. However, with the possible exception of the incidents noted above, in spite of many investigations, conclusive epidemiological evidence has not been presented to indicate that either raw or pasteurized milk is a vehicle for dissemination of poliomyelitis virus.

### SANITARY CONTROL

**Tests.** The objective of control is to give the public safe, clean milk of good quality. The most direct way to measure accomplishments is by making bacteriological, biochemical and chemical tests on surprise samples of the finished products as offered for consumption. Examination of samples of pasteurized milk, cream and milk products by the phosphatase test will indicate the adequacy of the heat treatment. Although the phosphatase test will show recontamination with as little as 0.1 per cent of raw milk, as by leakage, further examination by making a coliform count will show even more slight contamination with raw milk or from ineffective sterilization of containers. Although it is possible that some heat-resistant strain of coliform organism may be encountered, experience with large numbers of tests has shown that such organisms are rarely encountered in practice. The coliform test of

\* The prolonged and careful investigation of the Ministry of Health was not in favor of this assumption, but traced a chain of personal contact between a number of cases in the epidemic (see Annual Report of the Chief Medical Officer of the Ministry of Health for 1927, H.M.S.O., London, 1927, page 92).

pasteurized milk is a good index of possible failures in pasteurization or, more generally, of recontamination after pasteurization.

Bacteria counts on pasteurized milk, cream or milk products alone are of limited value. There is no assurance that low count milk is free from pathogens. However, used in conjunction with the phosphatase and coliform tests, the standard plate count and direct microscopic count give additional information as to the care that has been exercised in the handling of the milk, including refrigeration. Certain field tests, such as the rapid phosphatase test and the reazurin or methylene blue tests, may be used to advantage as screening tests under certain circumstances.

The weaknesses of control by testing the final product are possible sample errors and the fact that, even with the most profuse sampling, only a small portion of the total quantity consumed can be examined. As examples of sampling errors, we have the delivery of samples at the health department office or laboratory permitting selection by interested parties, the collection of samples invariably on the same day of the week, thus opening the way for carelessness the other six days, and the practice of always taking quart samples, which eliminates the possibility of discovering plant operating faults that may occur only when containers of other sizes are being bottled.

The discerning use of the results of field and laboratory tests supplemented by inspection, which also has its strong as well as its weak points, is most likely to result in effective control.

**Inspection.** An efficient inspection service is a preventive measure that strikes at the root of the milk problem. A good inspection service is expensive, but is worth its cost in providing cleaner and better milk.

The inspection of pasteurizing plants is a primary responsibility of the control official. While the laboratory tests of the finished product will indicate weaknesses or failures in plant operation, inspection also may uncover other evidence missed by tests of the final product, because the samples taken represent a very small proportion of the total product. Similarly, inspection has the weakness that the inspector, at best, only a small portion of the total operation. Furthermore, the operator is likely to be on good behavior knowing the inspector is in the plant, and in some instances the inspector may not be alert enough to catch the significance of what is going on before his eyes.

Plant inspection should include the careful examination and auditing of the recording thermometer charts on file, the determination of the accuracy of recording and indicating thermometers and the checking of controls, valves, milk pumps and other parts of equipment performing important functions in insuring pasteurization. Furthermore, such inspections should be so made as to determine the effectiveness of the cleansing and bactericidal treatment of containers and equipment.

Dairy farm inspections are made so infrequently and at such times of the day as to be of little assistance in determining the routine care exercised in the milk handling operations and in the cleansing and bactericidal treatment of utensils. They are of value in determining that favorable conditions for the production of clean milk exist on the farm and offer an opportunity to the alert sanitarian to get acquainted with the dairyman in order to sell his educational program and to secure the dairyman's cooperation in the production of clean milk. Receipt of a copy of the inspection report should be acknowledged by the dairyman's signature and be posted

in the milk house. A satisfactory inspection report may well be endorsed by the inspector so as to constitute a permit for the delivery of milk to an approved plant or receiving station. There is little to be gained in the protection of the public health by regimenting dairymen into providing expensive plants and equipment of any special design. Certain things are necessary to economical operation and generally will be provided for that reason.

As in the sanitary control of pasteurizing plants, most can be accomplished in securing the delivery of good, clean milk consistently from dairy farms by testing the milk periodically as delivered at the receiving platforms of pasteurizing plants or receiving stations and following up all unsatisfactory results promptly to determine and eliminate the conditions on the farms which caused the unsatisfactory results. The direct microscopic count lends itself best to this type of work when used in conjunction with the sediment test. *Reduction* tests are not as informative as the direct microscopic count but may be used to advantage if properly interpreted. The reazurin test is to be preferred to the methylene blue test, particularly because the results may be obtained in not more than two hours instead of a possible eight hours.

Some health authorities require the dairyman to employ a veterinarian to make an annual physical examination of all cows producing milk. This frequently is done by deep palpation of the empty udder to detect the pressure of scar tissue resulting from mastitis. Lack of symmetry in the udder may be an indication of infection. Generally a test such as the brom thymol blue test for alkalinity is applied to a sample of milk from each quarter to confirm the findings. The results must be interpreted carefully as factors other than mastitis may cause alkalinity. However, such things are likely to affect all quarters rather than only one of four.

The sanitary inspector cannot prevent occasional unsanitary conditions. The veterinarian often cannot prevent the occasional infection of milk from cattle diseases. The medical inspector cannot prevent the infection of milk from human sources. There is a safeguard to prevent milk-borne infections and epidemics—pasteurization.

Inspection brings us cleaner, fresher, better and safer milk, but not necessarily safe milk. The limitations of inspection are taken care of by pasteurization.

**Pasteurization.** Pasteurization consists in heating milk to a temperature below that of boiling, holding it at that temperature for a definite time, and then chilling it rapidly. The time and temperature of pasteurization are designed to be sufficient to kill the harmful micro-organisms with the least possible effect upon the milk itself.

Pasteurization is a preventive measure of public health importance. It should be defined legally in the sanitary code so that milk labeled "pasteurized" but which has been processed by improper or incomplete methods may be prosecuted as misbranded. The heat of pasteurization does not alter the taste, appearance or digestibility of milk unfavorably, and does not appreciably diminish its food value except that there may be a diminution of its antiscorbutic property, which in any case should be offset by the use of orange juice or tomato juice. In fact, pasteurization tends to make the curds softer and in this way perhaps easier to digest.

**TIME AND TEMPERATURE.** It has been abundantly demonstrated that heating milk to 140° F. (60° C.) for 20 minutes is sufficient to kill the bacilli of tuberculosis, typhoid fever, paratyphoid fevers, dysenteries and diphtheria, the streptococci

From U. S. Pub. Health Bull., no. 147, 1925.

Fig. 22-1. Time and temperature for pasteurization in the neutral zone which is above the thermal death curves for the pathogenic micro-organisms with minimal injury to the milk.

scarlet fever and septic sore throat, the *Brucella* organisms, the virus of foot and mouth disease and all other nonspore-bearing organisms causing milk-borne infections that are of concern to man.

Temperature and time are both factors in the destruction of pathogens as shown in Figure 22-1. This is a presentation of North's curves. The portion above 160° F for less than two minutes of the thermal death curves for pathogens is in need of further exploration.

The commonly accepted definition of pasteurization is that of the United States Public Health Service Milk Ordinance which reads: "The terms 'pasteurization,' 'pasteurized,' and similar terms shall be taken to refer to the process of heating every particle of milk or milk products to at least 143° F, and holding continuously at such temperature for at least 30 minutes, or at least 161° F, and holding at such temperature continuously for at least 15 seconds, in approved and properly operated equipment. . . ." From the standpoint of safety, any time and temperature combination that lies on or above and to the right of the upper line of demarkation of the neutral zone shown in Figure 22-1 should be satisfactory for pasteurization. For administrative purposes the two time-temperature combinations included in the definition have been selected as the standard. An ample factor of safety is provided as indicated by the portion marked "neutral zone." Heat treatment above this level will affect the creaming properties of the milk.

The effectiveness of heat treatment at 143° F for 30 minutes and at 161° F for 15 seconds in destroying pathogens has been demonstrated by laboratory tests, by the pasteurization in test installations of commercial equipment of milk to which pathogens had been added, and by chance occurrences in which portions of milk supplies consumed raw caused outbreaks and pasteurized portions of the same supplies of mixed milk caused no disease among consumers.

As the result of many years of extensive experience with commercial pasteurization, confirmed by laboratory researches as by North and others (1925) it has been demonstrated that a temperature of 142° to 145° F, with a holding period of 30 minutes, serves the purpose of protecting the public health and preserving the integrity of the milk. Later research showed that by subjecting every particle of milk to 160° F or more for not less than 15 seconds in approved equipment gave equivalent results. Pasteurizing machinery is not foolproof, and even the best designed apparatus must be operated with intelligent watchfulness. The thermoregulator should be responsive, the thermometers accurate and frequently standardized, for they are apt to be injured by the steam used in cleaning. The process should be done under official supervision. Automatic records of the temperature and time should be kept for each run.

**ADVANTAGES AND DISADVANTAGES.** Pasteurization prevents sickness and saves lives. Pasteurization is not ideal, but only an expedient. It is advocated because milk is likely to convey the viruses of a number of diseases harmful to man. Pasteurization effectively prevents this hazard. It implies precaution, protection and prevention. It is the best insurance both for the industry and the consumer, and the simplest, cheapest, least objectionable and most trustworthy method of rendering infected milk safe. Next to water purification, pasteurization is the most important single preventive measure in the field of sanitation.

Pasteurization does not claim to replace sanitation and common decency. It cannot atone for filth and should not be used as a redemption process. Stale, weak and dirty milk is still stale, weak and dirty after it has been pasteurized. A pure milk is better than a purified milk. However, no one should drink raw milk that cannot be guaranteed by the health officer as safe and free from danger. Even certified milk or milk of equally high character is only reasonably safe without pasteurization. Less than one per cent of all the milk found upon the market is certified. Therefore, raw milk of this honor class is not a public health problem of any magnitude, although

It has been responsible for outbreaks of diphtheria, scarlet fever and other diseases. There is no authentic record of any milk-borne epidemic caused by properly pasteurized milk.

It is sometimes alleged that pasteurization destroys nature's danger signal, souring. Milk pasteurized at the temperatures recommended ( $142^{\circ}$ - $145^{\circ}$  F) sours as a result of lactic acid fermentation just as raw milk does, although somewhat more

#### TUBERCLE BACILLUS KILLED

(NORTH - PARK - 1926)

From Am. J. Hyg., 7:147, 1927.

Fig. 22-2. Thermal death curve of tubercle bacillus.

lowly. Nature has no danger signal for infected milk. Milk may be teeming with typhoid bacilli and other pathogenic micro-organisms without its taste, odor or appearance being changed.

One objection to pasteurization has always been the claim that it will put back the cause of clean milk and good dairy methods, because pasteurization will make cleanliness unnecessary and will put carelessness at a premium. Experience has proven the fallacy of this argument; in fact, the general milk supply of large cities has been materially improved despite pasteurization.

Pasteurization is not proposed as a substitute for, but as an adjunct to, inspection. Inspection gives us cleaner and better, but not necessarily safe milk. Inspectors cannot be present all the time, and furthermore, even if they were Pasteurs, they could not see missed cases and carriers. Pasteurization destroys the dangers inspection cannot see. The combination of inspection and pasteurization corresponds in all respects to the modern principles of furnishing a safe water supply to a large city. The watershed, through inspection, is kept as clean as practicable, but the water is filtered or chlorinated to protect the consumer.

There can be no more objection to the heating of milk for the use of adults or children above the age of one year than there is to the cooking of meat. Infants

should receive breast milk. There is no adequate substitute. When this is not possible, they should have the best and freshest cow's milk that can be obtained. Whether such milk is to be pasteurized, modified, boiled or otherwise treated rests with the pediatrician. Pasteurization has the well-nigh unanimous endorsement of sanitarians and pediatricians.

**The Effects of Heat upon Milk.** The changes produced in milk by heat depend upon the degree of heat, the length of time of exposure, the access of oxygen, the pH and other factors. Milk heated to 145° F for 30 minutes does not undergo any appreciable physical or chemical change. Heat above 145° F for any length of time affects the creaming ability and the properties as exposure increases. The boiling of milk, however, produces pronounced changes. In the main, these consist of a partial denaturing of the proteins and other complex nitrogenous derivatives; diminution of the organic phosphorus and an increase of inorganic phosphorus; changes of form of the calcium, phosphorus and magnesium salts; expulsion of the greater part of the carbon dioxide; caramelization or burning of a certain portion of the milk sugar, causing the brownish color; partial disarrangement of the normal emulsion, and coalescence of some of the fat globules; coagulation of the serum albumin, which begins at 75° C; the ferments are killed; vitamin C is reduced 20 to 50 per cent; vitamins A and B<sub>2</sub> are not affected.

Boiled milk has a cooked taste which appears at about 70° C. This is due perhaps to the decomposition of certain of the proteins in the milk. The loss of certain gases also alters the taste. Heating milk openly drives away off-flavors.

Milk heated in the open air forms a pellicle which renews if it is removed. This scum forms when milk reaches about 60° C. It consists of:

	<i>Per Cent</i>
Casein and albuminoid . . . . .	50.86
Fatty matter . . . . .	45.42
Ash . . . . .	3.72

Milk heated in closed vessels does not form a pellicle, even when the temperature reaches the boiling point. It seems that this pellicle is due mainly to the drying of the upper layer of the liquid.

Heat causes a progressive decline in the hydrogen ion concentration of the milk as the temperature rises. Evidently, the heat modifies the balances of colloids in the milk.

It is claimed that heat influences the availability of calcium and phosphorus of the feeding mixture. Boiled milk for infant feeding has its advocates both here and abroad.

**RELATION OF PASTEURIZATION TO SCURVY AND RICKETS.** Milk contains but a moderate and variable amount of antiscorbutic property, vitamin C. The amount of this dietary factor depends upon the quantity contained in the feed of the cow. Stall-fed cows in winter furnish a milk almost devoid of antiscorbutic property. This vitamin is influenced by age, oxidation, and, to a certain extent, by heat. Experiments have shown that the temperature of pasteurization recommended decreases this property in milk about one-fifth to one-half. In any case, cow's milk cannot be depended upon to protect children against scurvy, and they should, therefore, receive orange juice or tomato juice, whether the milk is raw or pasteurized.

Milk at best has but moderate antirachitic property, vitamin D, which is not affected by heat. Rickets, therefore, cannot be laid at the door of pasteurization. It may readily be prevented by the use of cod-liver oil and the benefits of sunshine.

**CARE OF PASTEURIZED MILK.** Pasteurized milk must be handled at least as carefully as raw milk. It is just as apt to become infected if exposed. Bacteria grow even more rapidly in heated than in fresh raw milk. The bacteriostatic properties of milk are destroyed by heating above  $158^{\circ}\text{F}$  ( $70^{\circ}\text{C}$ ) but are little influenced at  $142\text{--}145^{\circ}\text{F}$  for 30 minutes (see page 878). There is a plentiful lack of understanding concerning the relative growth of bacteria in raw or heated milk. From a practical standpoint, this question can be disregarded, for the pathogenic germs that concern us particularly are just as harmful if taken in raw milk as in heated milk.

Pasteurized milk should be cooled and transferred to the bottler through a closed system, bottled and capped by machinery immediately following the process, kept cold and delivered promptly. The bottles should first be disinfected with steam or scalding water. All milk, whether raw or pasteurized, should be kept *clean, cold and covered*.

**OFFICIAL CONTROL.** Pasteurization is too important a public health measure to leave to individual caprice. The process should be under official supervision. The operator should be trained and licensed. The sanitary code should clearly define the requirements, and pasteurized milk should be labeled as such. Action for misbranding may be taken for milk labeled "pasteurized" but which has been processed by improper or incomplete methods. Milk should not be pasteurized twice.

Milk should be pasteurized at some central station where it may be done scientifically under official surveillance. In other words, it should be done for the householder just as in the case of central water purification plants. If water needs filtration or chlorination, experience teaches that it is inadvisable and expensive to depend on the householder to carry out the process. The same is true with pasteurization.

Pasteurizing machinery must be of a type approved by the state health authorities, well designed, properly run and kept clean and in good order. It should have automatic temperature control and automatic temperature recording devices, and the records should be kept for official inspection. From time to time the thermometer and thermoregulators should be standardized and the process controlled by physical and bacteriologic methods to insure its effectiveness.

**METHODS OF PASTEURIZATION.** There are six methods of pasteurizing milk: (1) the flash method, (2) the high temperature-short time method, (3) the holding method, (4) continuous flow, (5) the vat method and (6) in the final container.

*The Flash Method.* The flash method consists of heating milk momentarily to a temperature of about  $158^{\circ}\text{F}$  and chilling at once. This is done by allowing it to flow as a thin film on the outside of a steam coil, and then over cold metal. The temperature is uncertain and the holding time is left to chance. It does not give uniform results and is not entirely reliable, and hence does not meet with the approval of the sanitarian. The method, however, is rapid and cheap.

*High temperature-short time methods* of pasteurizing milk have been devised that are recognized by the U. S. Public Health Service and a number of states. Every article of the milk should be heated to not less than  $161^{\circ}\text{F}$  and held at this temperature or higher for not less than 15 seconds. Some of the milk may be heated by steam or by an electric current. A rapid method known as Electropure depends

upon an electric current heating a column of milk as it flows between two electrodes. The heating effect is uniform and rapid, the rate can be controlled and the milk can be held before cooling. Temperature control is precise, and a flow diversion valve functions automatically to return any unheated milk for heating to 161° F. Any mechanical failure results in stopping the flow of milk.

*The Holding Method.* The holding method consists of heating the milk to the desired temperature (142°-145° F) and holding it in a suitable tank at that temperature for a given time (30 minutes). In this way none of the milk escapes the disinfecting power of the heat, and the pathogenic bacteria in question are killed with certainty. The use of leak-protected inlet valves with an air relief, leak-protected and close coupled outlet valves, air space heaters, accurate and easily read indicating and recording thermometers, and automatic temperature controls have eliminated the questionable features of old pasteurizers of this type. This method has proved satisfactory in practice under commercial conditions. From the holding tank the milk should be run directly to the cooler and thence to the bottling machine through a closed system.

*Continuous Flow.* In this method the milk is first heated to 143° F or more and then permitted to flow through a series of tanks or coils of metal tubes. The rate of flow is adjusted so that the heated milk remains for 30 minutes in the apparatus. Experiments have shown that there may be mixing and irregularity in the time of flow unless the apparatus is well designed; the method is not extensively used.

Continuous flow pasteurizers also have been devised consisting of a series of four or more holding vats or pockets, in two or more of which milk is held at 143° F while one is being filled and another emptied. The inlet and outlet valves are operated either mechanically or manually to provide a continuous flow with 30 minutes holding. When dead ends are eliminated, and all valves protected against leakage and air binding, this equipment is satisfactory.

*Pasteurization in the Final Container.* In order to heat milk in bottles, they should be well sealed with an effective stopper. They may be heated by a shower of hot water or by steam. The simplest method, which is useful in an emergency, is to place the milk bottles in a water-bath brought to the proper temperature, held there a sufficient length of time and then chilled. Several types of machinery are in use for this method. One borrowed from the beer industry consists of a revolving drum in a metal cylinder, in which the filled bottles are subjected to a spray of hot water, and before completing the revolution are chilled. Another type of device is by endless conveyors, which carry the bottles through first a trough of hot water and then cold. Pasteurization in the final container is called the perfection of the art. It has the theoretical advantage that contamination after pasteurization is entirely eliminated. Practical disadvantages have been that temperature stratification occurs in heavy weight glass milk bottles and applied temperatures have not been uniform where solid bottle crates have been used and steam or hot water applied through perforations. Efficient equipment has been devised using light weight glass bottles, welded wire crated and a deluge of temperature-regulated, circulated hot water.

**HOME PASTEURIZERS.** Freeman's pasteurizer for heating milk in individual feeding bottles in the home is most serviceable. The modification of Nathan Straus is shown in Figure 22-3. It is used as follows:

Fig. 22-3. Straus home pasteurizer.

After the bottles have been thoroughly cleaned they are placed in the tray (A) and filled with the milk or mixture used for one feeding. Then put on the corks or patented stoppers without fastening them tightly.

The pot (B) is now placed on the wooden surface of the table or floor and filled to the supports (C) with boiling water. Place the tray (A) with filled bottles into the pot (B) so that the bottom of the tray rests on the supports (C), and put cover (D) on quickly.

After the bottles have been warmed up by the steam for five minutes, remove the cover quickly, turn the tray so that it drops into the water, replace the cover immediately. This manipulation is to be made as rapidly as possible to avoid loss of heat. Thus it remains for 25 minutes.

Now take the tray out of the water and fasten the corks or stoppers airtight. Cool the bottles with cold water and ice as quickly as possible, and keep them at this low temperature until used.

Use the milk from the bottles and by no means pour it into another vessel.

The milk should not be used for children later than 24 hours after pasteurization.

Emphasis is laid on the fact that only fresh, clean milk, which has been kept cold, should be used.

**The Essential Requirements for a Safe and Satisfactory Milk Supply.** 1. Cows should be healthy and free especially from communicable infections, or any febrile disease, or inflammatory condition of the udder.

2. All persons who in any way come in contact with the milk or milk apparatus should be free from communicable diseases and not be carriers. A minimum of human contact should be insisted upon.

3. The milking should be done in clean surroundings, the udders washed; the

hands of the milker should be clean and dry; the fore milk should be discarded and good dairy technic observed.

4. The milk should be received into clean, sterilized pails, seamless and with a small mouth so as to keep out dust and dirt which fall from the udder and belly of the cow. Strainers should be cleaned and boiled morning and evening. Cans and pails should be cleaned with washing soda or alkaline powder (not soap), rinsed in clean water, and then steamed or boiled or chlorine sterilized.

5. The milk should be chilled to 50° F or under at once, and kept protected from flies, dust, odors, and contamination, in a clean milk house until collected.

6. The milk in transit to the city should likewise be kept protected and cold, not higher than 50° F, and guarded against tampering en route. The lower the temperature the easier it will be to keep the bacterial count down. Milk should not be frozen.

7. All apparatus at the city dairy, such as tanks, clarifiers, separators, pasteurizers, and bottling machines, should be kept scrupulously clean and sterilized daily with steam or chlorine.

8. Pasteurization should be followed by rapid chilling and the milk kept below 50° F until delivered to the consumer. Milk and cream used for making milk products should also be pasteurized.

9. The pasteurized milk should be bottled and capped by machinery in sterilized bottles, well sealed; and delivered promptly to the consumer.

10. All bottles and cans, after use in city delivery, should be washed and sterilized before being returned to the producer in order to prevent the conveyance of infection to the dairy or country farm.

11. The milk must be graded, even if there is only one grade. In this way the producer is paid for care and cleanliness and the consumer has a ready means of knowing the sanitary character and nutritive value of the milk he purchases. Grading and labeling help the official control.

12. Laboratory aid is essential, including frequent bacterial and chemical analyses. Sanitary surveys and inspections from the producing farm to the consumer are a fundamental part of the program.

13. A sanitary code based upon good milk laws, which include milk products, should be enforced.

14. A system of licensure, inspection and education to insure the above requirements should be followed.

## MEAT, FISH, EGGS, AND PLANTS

### MEAT

Meat (Edelman, 1933) is an important item of diet throughout the world. Man selects his meat from a wide range of animal life. Herbivorous mammals and certain omnivorous animals are the chief sources, while the flesh of carnivora is distasteful to civilized peoples. Next to mammals, birds and then fish supply our food.

In some countries the flesh of horses, dogs and cats is eaten. In Germany horses and dogs are slaughtered and regularly inspected for human food. The meat of these animals is also used in other countries that have long been flesh hungry. There is no sanitary objection to the use of such meat if derived from healthy animals. Horse meat, when eaten for beef, makes no unpleasant impression. In Paris, Vienna and other cities large numbers of horses, mules and donkeys are slaughtered for food.

**Structure and Composition.** Meat is composed of muscular fibers and associated structures, such as connective tissue, blood vessels, nerves, lymphatics and more or less adipose tissue. The muscle (flesh) of an animal consists of highly specialized contractile tissue. It is also a storage organ in which glycogen and fats are held for reserve. It contains little of the cell structures of such glands as are found in the liver, kidney and pancreas. Chemically, muscle consists principally of protein, salts and water and the reserve foodstuffs. Muscle tissue contains less nucleic acid by weight than the glandular organs. The inorganic content of muscle tissue resembles that of the seed rather than the leaf of the plant, both in amount and in relative proportions among the elements. Muscle contains about 25 per cent solid matter, of which four-fifths is protein, one-fifth extractives and inorganic salts. About 75 per cent of the protein is made up of a coagulable albumin (myosin). The non-nitrogenous extractives are glycogen, hexosephosphate, lactic acid, inositol and fat; and the nitrogenous extractives are creatine, purine bases (xanthine, hypoxanthine), uric acid, adenylic acid, inosinic acid, carnosine (ignotine) and carnitine (novaine). Potassium phosphate is the predominating salt of muscle. Iron exists chiefly as hemoglobin, belonging in part to the muscle cells and in part to retained blood.

The toughness of meat is due to the thickness of the walls of the muscle tubes and excess of connective tissue which binds them together; hence, the flesh of young domesticated animals is usually more tender than that of old or wild animals. Freshly dressed meat is alkaline in reaction. Soon after death rigor mortis sets in and the reaction becomes acid due to the development of lactic acid, called in meat sarcolactic acid. During this process the connective tissue and muscular fibers become softened, thus rendering the muscular structures more tender.

The flavor of meat varies more or less with the age of the animal, its food, breed

and condition at time of slaughter, and the handling of the meat after slaughter. The flesh of sexually mature male animals is usually stronger in odor than the meat of females or young or castrated males. This is particularly true of goats and swine.

**Nutritive Value.** The nutritive value of meat depends mainly upon the presence of proteins and fats. Nitrogenous extractive matters, such as creatine, xanthine and similar substances, sometimes called meat bases, which are formed by cleavage of the proteins, are of little value as foods. These nitrogenous extractives are present in about the same amount in both red and white meats; in fact, there is no essential difference between red meat and white meat except for the presence of pigment.

Animal tissues fall into two groups: (1) glandular organs as the liver and the kidneys; (2) the highly specialized muscle tissue. The proteins of muscle and the glandular organs are complete as sources of amino acids.

The dietary properties of meat are comparable with the seed rather than the leaf of plants; in fact, muscle tissue differs markedly from the seed in only one respect when considered as a foodstuff, namely, in the quality of its proteins. The proteins of meat are complete, those of seeds incomplete. Both meats and seeds are poor in mineral salts, which are necessary in the diet. Both muscle and seeds are relatively poor in vitamin A as compared with such foods as milk, egg yolk and the leaves of plants. Meat is an admirable source of protein of good quality. It is appetizing, satisfying and stimulating. The condimental value of meat is high. Meat is an essential part of an optimum diet. On the other hand, growth and nutrition cannot be maintained on meat alone because it is so deficient in many of the necessary dietary factors. Carnivorous animals in the wilds make up this deficiency by drinking the blood, gnawing the bones and eating the liver of their quarry.

There is little difference in the composition and nutritive value between the meats of mammals, birds and fish. Meats from different sources and even from the same source differ chiefly in the amount and character of the fat they carry. The flesh of fish ordinarily is not classed as meat, but it has the same muscular structure and similar chemical composition and nutritive value as mammals and birds (see page 904).

**Beef Extracts.** Beef extracts are nothing more or less than a soup or soup stock specially prepared. They first became generally known through the researches of Liebig and are now an important article in commerce. The ordinary beef extract found on the market contains from 15 to 20 per cent of moisture, from 17 to 23 per cent ash, and from 50 to 60 per cent of meat bases, and but a trace of soluble albumin, albumoses and peptone. Meat extracts contain little nutritive matter, although this being soluble is readily digested. These extracts may be useful as stimulants or as condiments, or as a means of speedily introducing a small amount of nutriment in the case of disease.

A distinction should be made between beef extract and beef juice. *Beef juice* is obtained by strong pressure of fresh lean meat which is concentrated *in vacuo*, or it may be freshly prepared in the household. Beef juice contains much more albuminous nutrient material than beef extract, provided the protein is not coagulated by heat and separated out.

**Differentiation of Meats.** The meat of any species may be determined readily by means of the specific precipitins; also by physical, microscopical, chemical or biological tests. Meats from different animals usually may be distinguished by their

odor, taste or appearance. Microscopically the fibers resemble one another so closely that this test is not reliable. There is some variation chemically in meat from different species, from different animals of the same species, and even from different muscles in the same animal. Meats from animals of different species differ principally in glycogen and fat content. The glycogen content may be changed as a result of bacterial action, hence the test for fat is the more satisfactory. The fats of different animals have different physical and chemical characteristics; they crystallize in different forms and have different melting points, as also the fatty acids derived from them. A careful examination of the fat will determine approximately the character of the flesh from which it has been derived.

**Raw Versus Cooked Meat.** Meat should not be eaten raw. Individual cysticerci (tapeworm larvae) are easily overlooked, and one is enough to bring forth a tapeworm. It is also not practicable to examine the flesh of all hogs for trichinae, and even though this were done with care the method does not afford complete protection. It is again emphasized that some of the more serious bacterial infections do not alter the color, taste or appearance of the meat in any way. Raw meat does not have a higher nutritive value than cooked meat. Thorough cooking is our ultimate safeguard against infection.

#### MEAT INSPECTION

**Importance of Meat Inspection.** The flesh of food animals may be objectionable or harmful through disease or parasitic infection; the meat of a healthy animal may develop noxious qualities after slaughter through deteriorative changes, or infection through unsanitary handling. Not every disease makes the flesh of an animal unsafe or unfit for food. Thus, in order that the established principles of pathology may be accurately applied so far as practicable, a skilled inspection and supervision of food animals and their products becomes necessary to protect against possible dangers. This obligation is assumed by the state or national government.

An efficient meat inspection service, in addition to being a protection to man, is an effective agency in locating and eradicating dangerous diseases from food herds. Competent inspection at places of slaughter will discover the first appearance of rinderpest, foot and mouth disease, Texas fever or other epizootic; or herd diseases, such as tuberculosis, actinomycosis and hog cholera. Effective measures may be instituted at once and great economic loss averted.

The practices of meat inspection vary in different countries. Thus, in countries which have long had a scarcity of meat, much is passed for food that would be condemned under the federal system in the United States. Where lack of abundance prevails a sharp watch must be maintained to prevent the people from eating meat known to be injurious. In America, where meat has been plentiful, the attitude is different and even meat known to contain a harmless parasite may be repugnant to some. Scarcity and higher prices will overcome this supersensitiveness. The need of conservation during and since the World Wars has placed our national meat inspection service on a more practical basis, without sacrificing good standards.

The prevention of infections and poisoning from meat and meat food products depends first of all upon the health of the animal, next upon the mode of death, and finally upon the methods of butchering, preserving and handling the flesh. Careful attention to every detail is necessary throughout. Cleanliness approaching surgical

methods during the preparation, transportation and handling of the meat is called for.

A corps of thoroughly trained meat inspectors is one of the most important links in the chain of an efficient meat inspection system. A meat inspector should be a qualified veterinarian having special training and experience. He should know the anatomy of the various food animals and be acquainted particularly with the infectious diseases which prevail in the district where he is situated.

**The Public Abattoir.** The first essential of a good meat inspection service is to concentrate all slaughtering in central abattoirs. This simplifies inspection and sanitary control and protects the consumer. In Germany, England, Australia and New Zealand municipal public abattoirs have been established. Each person who wishes to slaughter must obtain a permit and pay rent. The erection and maintenance of well-controlled, modern public slaughterhouses is one of the needs of our country, especially in the smaller towns.

The building must be especially well constructed and kept clean. Only good and wholesome water and ice should be used in the preparation of the carcasses, and the wagons and cars and all surfaces with which the meat comes in contact should be kept clean and in good sanitary condition. Slaughtering and butchering involve more or less blood and refuse matter, hence the necessity of frequent and repeated cleaning. The inedible products tanking department, fertilizer department, hide room, casing room, toilet rooms and dressing rooms should be entirely separate. Sources of odor that may contaminate the meat or be otherwise objectionable must be eliminated, and every effort made to keep out flies and other vermin, especially rats and mice. Dogs should not be allowed within slaughterhouses on account of the danger of spreading the *Echinococcus* and other parasites. The uncooked refuse of slaughterhouses should not be fed to hogs.

The employees must be free from infections that may contaminate the meat, be cleanly and wear outer clothes that may be laundered readily. The hands should be washed before beginning work and after each visit to the toilet. Butchers should thoroughly cleanse their hands after handling a diseased carcass. Implements used on such carcasses should be sterilized in boiling water.

The spoiled portions of meat that fall upon the floor or otherwise become soiled should be condemned. All carcasses, parts of carcasses, and meat products that have been condemned for food purposes should be destroyed.

#### THE UNITED STATES FEDERAL MEAT INSPECTION SERVICE

The U. S. Federal meat inspection law, approved March 18, 1907, and as amended at various times since, provides for the inspection of cattle, sheep, goats, swine, and, in a restricted way, of horses, the meat or products of which animals are to enter interstate or foreign shipment. The law is administered by the Bureau of Animal Industry, U. S. Department of Agriculture.

The purpose of a meat inspection service is to eliminate diseased or otherwise unsound meat; to require cleanly and sanitary precautions in the preparation and processing of foods composed wholly or in part of meat; to prevent the use of harmful dyes, preservatives, chemicals or other deleterious substances, and false and misleading labels and statements.

In magnitude, the U. S. Federal Meat Inspection Service stands alone among the meat inspection systems of the world. The government is expending annually

about \$14,325,000 toward supplying wholesome, clean and unadulterated meat and meat food products. During the fiscal year 1955, federal meat inspection was maintained in 1,149 slaughtering, packing, rendering and meat-preparing plants located in 446 different towns and cities, and included most plants of considerable size or importance in the United States. The year's slaughter of these inspected establishments was in round numbers 18,643,780 cattle, 7,563,234 calves, 14,432,021 sheep, 86,205 goats, 56,951,433 swine and 236,424 horses, a total of over 97,913,097 animals. The federal system may be regarded as consisting of five continuous and coördinating inspections, namely, (1) sanitation, (2) the ante-mortem or live-animal inspection, (3) the postmortem or slaughter inspection, (4) the products inspection or supervision of processing and manufacturing meat food products, and (5) the laboratory inspection.

**Sanitary Inspection.** The federal regulations require certain definite and important requirements to be met satisfactorily before sanctioning an establishment. There must be adequate light and ventilation, pure water supply, efficient floor drainage and modern plumbing and sewerage. Smooth and impervious material must be used in the construction of building and equipment. Separate modern and sanitary toilet and dressing rooms, lavatories for cleansing hands, and equipment for disinfecting utensils must be provided. All rooms in which meat and products are stored or handled must be separate from those in which inedible products are stored, handled or treated. Cleanliness must be observed throughout.

**Ante-Mortem Inspection.** Animals about to be slaughtered, if found affected, or suspected, are separated from the rest. Those which show symptoms of particularly virulent diseases and those in a moribund condition are condemned outright, and the remainder are slaughtered separately and given expert veterinary postmortem inspection.

**Postmortem Inspection.** The postmortem inspection is an autopsy performed during the process of dressing the carcass. It consists of an examination of the principal groups of lymphatic glands, of the head, viscera, tongue, lungs, heart, liver, spleen and kidneys, the peritoneal and thoracic membranes, exposed bones, joints and surfaces of the carcass. Abnormal or diseased carcasses are subjected to expert veterinary inspection. Carcasses or parts were condemned by the Federal Meat Inspection Service during the year 1949 for more than 40 diseases and conditions, among which were anthrax, tuberculosis, hog cholera, pyemia and septicemia, actinomycosis, caseous lymphadenitis, cysticercosis, emaciation, carcinoma, leukemia, icterus, immaturity, pregnancy, sexual odor, parasitic infestations, abscesses, bruises, dropsical conditions and asphyxia. A few of the more significant of these diseases are discussed below. In 1955, nearly 98,000,000 animals passed post-mortem inspection and 281,664 were condemned as a result of such inspection.

**Products Inspection.** Meat products are inspected and passed in the same manner as meats. The inspection covers all such processes and operations as rendering, curing, smoking, cooking, mixing, canning, manufacturing and labeling. In the year 1955, this amounted to 16,373,853,029 inspection pounds. All meats and products are subject to inspection and reinspection at any time to determine whether they have remained sound. The purpose of this inspection is to see that sanitary conditions are maintained; that harmful substances are not used; and that the meat products shipped are sound, wholesome and correctly labeled.

Under federal requirements all condemned carcasses and parts are effectually destroyed for food purposes under direct supervision of inspectors. Carcasses and organs passed for food are marked "U. S. Inspected and Passed."

The regulations of the United States Department of Agriculture permit the addition to meat or meat food products of the following substances: common salt, sugar, wood smoke, vinegar, pure spices, saltpeter, nitrate of soda and nitrite of soda. Benzoate of soda may be added to meat and products only when declared on the label with percentage used. Only such coloring matters as may be designated by the Secretary of Agriculture may be used under prescribed limitations and declarations. The adulterants most commonly used in meats are boracic acid, borax, sulphite of soda, and benzoic acid.

**Laboratory Inspection.** The government maintains well-equipped district chemical laboratories at convenient points throughout the country. In these laboratories analyses and examinations are made of meats and meat food products, as well as of the water supplies, curing materials, spices, cereals, denaturing oils and other substances.

**Need of State and Municipal Inspection.** About one third of all animals slaughtered for food in the United States do not have federal inspection. A few of the states and a number of municipalities maintain meat inspection services varying considerably in enforcement, but in many places there is practically no control over meat that does not cross the state border.

#### DISEASES FOR WHICH ANIMALS ARE CONDEMNED

**Tuberculosis.** A nation-wide campaign against tuberculosis in cattle and swine has resulted in decreased prevalence of the disease and a marked reduction in the number of carcasses of these animals condemned on this account. During the fiscal year 1955, 580 cattle or 0.003 per cent, 7,311 swine or 0.11 per cent of the total killed and inspected were condemned on account of tuberculosis. This is a marked reduction over the figures for the year 1924, when 56,760 cattle or 0.618 per cent, and 100,110 swine or 0.184 per cent were condemned; and 7,184 cattle and 125,000 swine with limited tuberculosis were passed for cooking.

The line of demarcation between localized and generalized tuberculosis from the standpoint of meat inspection is frequently difficult to determine. If the lesions are not numerous, if there is no evidence of distribution of tubercle bacilli throughout the blood, and if the animals are well nourished and in good condition, there is no reason to suspect that the flesh is unwholesome, and it is permitted to be used after the removal of the affected parts. Evidence of generalization of the process is indicated by fever before slaughter, anemia, cachexia, emaciation; generalized or extensive lesions in one or both body cavities; or lesions in the muscles, intermuscular tissues, bones or joints; or multiple, acute or actively progressive lesions. Fortunately, tuberculosis of muscle is exceedingly rare and thorough cooking is sufficient to kill the tubercle bacilli. The relation of bovine tuberculosis has been discussed on page 145.

Tuberculosis of cattle shows itself in four primary lesions: (1) the retropharyngeal lymph nodes, (2) the lungs and associated lymph nodes, (3) the mesenteric lymph nodes and (4) the liver. From the retropharyngeal nodes the process extends to the cervical lymph nodes and also to the anterior mediastinal lymph nodes. When

this group of glands alone is infected the disease may be considered as localized. From the mesenteric lymph nodes the infection frequently reaches the peritoneum, and from the bronchial lymph nodes the pleura. The newly formed growth in the peritoneal or pleural cavities may be enormous in amount. It is often suspended from the omentum in great grape-like masses (Perlsucht), or the intestines may be plastered with tubercles. In these cases the animal otherwise may be in good condition; that is, the disease is still outside the vital organs and the tubercle bacilli have not invaded the blood stream. In Germany it is permitted to cut off such growth and allow the meat to go into consumption. In the United States, the meat of such animals is condemned. Carcasses which cannot be passed, but which are not sufficiently severely infected to be condemned, may be rendered into lard or tallow or otherwise cooked, provided the parts containing tuberculous lesions can be removed.

In Germany tuberculous and trichinous meat is cooked and sold as second quality meat in accordance with the third class or "*freihank*" meat system. There is no known sanitary objection to this practice, provided the cooking is complete and the label represents the true nature of the product.

**Anthrax.** All carcasses showing lesions of anthrax, regardless of the extent of the disease, are condemned and immediately destroyed. This includes the hide, hoofs, horns, viscera, fat, blood, and all portions of the animal. The killing bed upon which the animal was slaughtered must then be disinfected and all knives, saws and other instruments that have come in contact with the infection must be boiled or otherwise disinfected.

**Hog Cholera.** Carcasses showing well-marked and progressive lesions of this disease in any organ or tissue are condemned. If the lesions are slight and limited they may be passed for cooking. Man is not susceptible to hog cholera.

**Actinomycosis.** If the animal is in a well-nourished condition and the disease has not extended from a primary area of infection the carcass may be passed for food after condemnation of the infected organs or parts; but if the disease is generalized the entire carcass is considered unfit for human use and should be condemned.

**Tapeworm Cysts.** Carcasses of animals affected with tapeworm cysts are condemned if the infestation is excessive. Carcasses of cattle showing a slight infestation may be passed for food after removal and condemnation of the cysts, provided complete destruction of any hidden cysts is insured. Cold storage or pickling for not less than 21 days, or storage for six days at a temperature not exceeding 15° F will destroy the cysts. Such carcasses may also be passed for cooking.

Carcasses or parts of carcasses found infected with hydatid cysts (*Echinococcus*) may be passed after condemnation of the infected part or organ.

**Septic and Pyemic Conditions.** Carcasses of animals so infected that consumption of the meat or meat food products may give rise to meat poisoning should be condemned. For the information of the inspector the following conditions are specified: (1) acute inflammation of the lungs, pleura, peritoneum, pericardium or meninges; (2) septicemia or pyemia, whether puerperal or traumatic or without any evident cause; (3) severe hemorrhagic or gangrenous enteritis or gastritis; (4) acute diffuse metritis or mammitis; (5) polyarthritis; (6) omphalophlebitis; (7) traumatic pericarditis; (8) any other inflammation, abscess, or suppurating sore, if associated with acute nephritis, fatty and degenerated liver, swollen soft spleen.

marked pulmonary hyperemia, general swelling of the lymphatic glands, and diffuse redness of the skin, either singly or in combination.

Immediately after slaughter, the premises and implements used must be thoroughly disinfected. Any carcass which has been exposed to contamination should also be condemned.

**Poisons in Meat.** Meat may occasionally be injurious to health from a variety of miscellaneous causes. Thus, an animal that has died of arsenic or other poisonous substance may contain sufficient of the poison in the tissues to affect the person who eats part of the flesh.

The belief that sickness in man can follow the consumption of the flesh or milk of animals which have previously fed upon poisonous plants is not unfounded. Chesnut states that poisons from various plants have been isolated from honey, which may also contain as much as three grains per liter of formic acid.

**Bob Veal.** Bob veal is the flesh of calves less than two or three weeks old. Bob veal is not objectionable from a health standpoint, and the prejudice against it is illogical. There is no similar prejudice against eating suckling pig or the immature of other animals. The meat is flabby, edematous, soft. The connective tissue is gelatinous and is present in greater quantity than in mature animals. The fat is reddish-gray and soapy, the meat less nutritious in value, as it contains a large proportion of water. The digestibility of the protein of bob veal is the same as market veal, namely, 93 per cent. On account of its moist and soft condition, bob veal has a greater tendency to spoil than the flesh of mature animals. Young calves are highly susceptible to a number of infections, particularly diarrheal diseases and infections which enter through the navel, but trouble has seldom been traced to bob veal. Bollinger and also Ostertag have reported a few cases of illness due to eating the meat of diseased animals. Infections may be guarded against by care, inspection, and thorough cooking.

## ANIMAL PARASITES TRANSMITTED TO MAN

GILBERT F. OTTO, Sc.D.

**Trichinosis, Trichiniasis, or Trichinelliasis.** *Trichinella spiralis*, commonly known as trichina, is a nematode (roundworm) which passes its entire life cycle in a single mammal. It differs from most other metazoan parasites of man in at least two significant aspects: (1) it is an obligatory parasite throughout its entire life history and has no free-living stage; it survives for relatively short periods after the death of the host only when encapsulated within the skeletal musculature; and (2) it is lacking in host specificity; it will develop similarly in any mammal so far as is known; certainly there are no records of failure in adequate attempts to infect any species of mammal and over 25 species have been found naturally or experimentally infected. In addition, with proper preparation, birds and amphibians have been experimentally infected but none has ever been found naturally infected.

Trichinosis is a common and important infection but the means of prevention are, and have been for many years, readily available. Fortunately the mortality rate in this country is very low, ranging from 0 to 5 per cent in localized outbreaks, and confined to those who have a very heavy initial infection. When the

disease was first recognized in Germany, shortly after the middle of the past century, mortality rates as high as 30 per cent were reported.

**LIFE CYCLE OF *Trichinella spiralis*.** Infection is acquired by ingesting the raw or inadequately cooked skeletal musculature of infected mammals. The larvae coiled within a fibrous capsule within such muscle, escape within a few hours after ingestion, become attached to the mucosa of the upper part of the small intestine, mature and mate within two or three days. The male worms are thereafter quickly discharged in the feces while the females burrow deeper into the mucosa. Within a week they begin discharging larvae into the lymphatic spaces and continue the process until a few hundred to over a thousand are produced in the succeeding two to six weeks. These larvae, which are about 100 $\mu$  long and smaller in diameter than a red cell, upon reaching the heart are discharged through the systemic circulation to all parts of the body. Only those which reach the striated muscles are capable of further development; this development is completed within a month. By this time the larvae are encapsulated by host fibrous tissue, and are infective when eaten. Within two months the inflammation in the muscles has been resolved, except in very heavy infections, and only the fibrous capsules containing the larvae remain. Ultimately the capsule becomes calcified but that process in rats does not begin in less than six to eight months while in dogs and cats, and in man it may not begin for years. The calcification does not involve the larvae nor does it produce any discernible injury to them for some time; living and infective larvae may be recovered from capsules which have become completely calcified naturally or in which calcification has been induced by overdoses of parathormone or irradiated ergosterol and calcium salts (von Brand and others, 1938).

Larvae may leave the blood stream apparently in any organ or tissue of the body but are unable to complete their development in sites other than striated muscles. It appears from experimental work on mice that even transient penetration of tissues other than striated muscles is rare, about one larvae in 10,000 (Mauss and Otto, 1942) and that logically enough even these few are more commonly seen in the myocardium than in nonmuscular tissues.

**PREVALENCE AND GEOGRAPHICAL DISTRIBUTION.** Human infection is confined to those who eat the uncooked or inadequately cooked flesh of infected mammals. Hence it occurs as a disease entity only in those areas where such food habits are common. Thus the disease is all but unknown in the tropics and in the Orient. While fish is eaten raw as a delicacy in localized areas of the Orient, pork and the flesh of any other mammals are habitually cooked more thoroughly than is done by most Caucasian races. The writer distinctly recalls the visit of a distinguished Japanese parasitologist with decades of experience in Japan, Formosa, and the mainland who had never seen trichina. Except for a few outbreaks in South America (e.g., Chile) little evidence of the disease has been reported from the Southern Hemisphere; Australia, for instance, is notably free of the infection.

The disease is, therefore, of widespread public health concern at the present time only in the Northern Hemisphere. The most severe epidemics of this disease known were those which occurred in Germany 75 to 100 years ago, in the intervening century the disease has been brought under control in that country so that today it occurs only sporadically. Outbreaks of varying severity are reported from

austria and the Italian Tyrol, but elsewhere in Italy, Spain, France, Portugal, and the British Isles it is uncommon. Relatively little is known concerning its prevalence in Eastern Europe, but recurrent reports suggest that it is comparatively common in Czechoslovakia, Poland, and Russia. The infection, however, appears to be most common in the temperate zone in the United States. Numerous post-mortem surveys in the past two decades have indicated that about 15 to 20 per cent of the adult population harbor the infection. Most of such surveys have been made by the examination of a single small sample of the diaphragm, but Evans (1938) has presented evidence that the prevalence may really be much higher. Direct microscopical examination of two different samples of the diaphragm revealed, respectively, eight and nine positive in 100 consecutive autopsies. The complete digestion of the gastric and tendinous portions of the same diaphragms revealed, respectively, 16 and 17 positive. The increasing figures were not simple summations, however, and the total number of diaphragms positive was 20. Furthermore, when up to 75 gm. of sternomastoid and up to 100 gm. of intercostal muscles were digested, 16 new infections were revealed, bringing the total to 36 per cent infected. Such figures demonstrate that a very large portion of our population is infected, but, in addition, the more comforting fact, that most of the infections are apparently very light. Only 4,543 human cases of clinical trichinosis were reported to the United States Public Health Service between 1842 and 1936 (Sawitz, 1938). Since reporting of this disease is incomplete, we can safely assume that more actually occurred, and there may even have been more than the 5,000 to 6,000 which Schwartz (1938) estimated. It seems extremely unlikely, however, that there are "several hundred thousands who have had clinical trichinosis never diagnosed as such, and possibly several thousand deaths annually from this cause" as Hall and Collins (1937) estimate. Evidence has been presented (Hall and Collins, 1937) which suggests that the infection is much less in the deep south (3.5 to 6 per cent in New Orleans) and most common on the North Atlantic Coast (e.g., Queen, 27 per cent in Boston) and California (e.g., McNaught and Anderson, 1944, 4 per cent in San Francisco). These same authors, furthermore, call attention to the fact that the reported morbidity and mortality from this infection follow the same geographical distribution.

In Mexico the infection has been found recently to be much more common than hitherto expected, but it is still not comparable to the infection rate in the United States.

Canada is usually considered to be relatively free of the infection, but Cameron (1938) suggests that it may be much more common than realized, and, recently, has been reported as common in Vancouver, British Columbia.

Of considerable interest are the recurrent reports of trichinosis in the Arctic and nearctic regions, in Alaska, Northern Canada, Greenland, Iceland, the Northern parts of Scandinavia, Finland, Russia and Siberia. Clinical outbreaks have been reported from these areas (e.g., 33 deaths among 300 cases in Northern Greenland), and in 1949, 7 per cent of the Eskimos in the Bethel Area (near Anchorage), Alaska, gave positive reactions to the intradermal use of trichina antigen.

**SOURCES OF INFECTION.** In the temperate zone the principal source of human infection has been, and still is, raw or insufficiently cooked pork. It was raw pork which was the cause of most of the fatal infections in Germany a century ago,

and it is raw or insufficiently cooked pork which accounts for most of the present-day infection, i.e., roasts, chops, *fresh* ham, etc., but the commonest source appears to be *fresh* pork sausage. Furthermore, severe clinical outbreaks involving whole families or other, even larger, groups of people are almost invariably traced to a single hog which is eaten without mixture with other pork; or from sausage made from, at most, two or three hogs, one of which is infected. Since usually only a small percentage of hogs are infected, and most of them lightly, trichina are diluted in sausage made at large abattoirs. Since most human infections are subclinical or mildly clinical, it is probable that the latter sausage is one source of these infections; sporadic clinical cases have also been traced to such meat. Other sources are probably inadequately cooked roasts, chops, sausages, etc. in which many, but not all, trichina are killed. While it is not impossible that an occasional light infection may be acquired from processed meat such as smoked ham, no such meat has ever been directly incriminated as a source of infection, and the examination of over 16,000 one-half pound samples of various processed pork products has failed to reveal that any of them contain infective larvae (Harrington and others, 1950; Zimmerman and others, 1955).

Since Leidy's discovery in 1846 of trichina in pork, identical to that in man, there has been much study, and even more speculation, on the source of the porcine infection. The finding of 1.4 per cent infection in the routine microscopic inspection of 8,000,000 hogs killed under federal inspection from 1898 to 1906 does little more than indicate the scope of the problem. Many continued to subscribe to the theory Leuckart had earlier advanced in Germany that hogs became infected from eating rats. To this was added the refinement that such infections took place in abattoirs where rats are heavily infected. We may safely discard these theories; the abattoir as a source of infection is of no concern since hogs are not held there more than a few days; and a minimum of three to four weeks are required for the maturation of the infection. It may be that rats are the source of some of the comparatively few infections reported in grain-fed hogs, but this has yet to be demonstrated. It is more probable that the rat is another victim of the disease rather than a source of infection for hogs.

The real source of porcine infection in the United States was demonstrated in 1888 by Mark in Boston. In the preceding five years the examination of over 3,000 hogs from garbage feeding piggeries in the vicinity of Boston had revealed 9 to 16 per cent infection in the several lots with an average of 13 per cent, whereas the examination of 500 "Chicago hogs," largely grain fed, had revealed only 2 per cent infection. Even more striking was his report, 1894, from the experience of North Hampton Lunatic Asylum. Up to 1887, hogs there had been fed upon kitchen garbage and slaughterhouse refuse with the result that 26 and 63 per cent of the hogs killed in 1885 and 1886, respectively, were infected. After January 1, 1887, the practice of feeding slaughterhouse refuse was terminated and only cooked kitchen garbage was fed, with the result that the infection rate dropped rapidly to 0 in 1893 to 1894, and it was ascertained that a number of the 25 positive hogs killed from 1887 to 1893, including the one positive in 1893, were born during the garbage feeding practices of 1885 to 1886.

More recently, Schwartz (1939) reports 4.4 per cent infection in a miscellaneous group of over 6,000 garbage-fed hogs and 0.9 per cent in similar group of

grain-fed hogs, and 0.6 per cent in over a thousand hogs fed on cooked garbage. Kerr, 1940, reported less than 0.5 per cent infection in California grain-fed hogs, and over 6 per cent in raw-garbage-fed, with the latter running over 12 per cent in some groups of hogs from the northern part of the state; interestingly enough, no infection was found in hogs fed on cooked garbage. Similar reports have come from Vancouver, B. C. It seems evident then, that the bulk of the porcine infection is associated with the practice of feeding raw garbage, but the source of the occasional infection in grain-fed hogs is not at once evident. It has been suggested that rats may be the source of the infection of such hogs, but Mark pointed out the difficulty of tracing the full history of any given hog. Kerr did succeed in tracing the history of some of the grain-fed hogs. He found that they had only been fattened on grain after having been raised on raw garbage and that such hogs had three times the infection rate of the remaining group of grain-fed animals. Furthermore, he was unable to find any trichina in rats or other rodents trapped around the grain feeding pens, but those trapped in raw-garbage feeding pens harbored about the same infection rate as the hogs feeding there. This would seem to support the earlier statement that the rat is another victim of the infection and not an indirect disseminator to man.

Although garbage-fed hogs are the primary source of infection in the United States, there have been small outbreaks traced to inadequately cooked meat of other animals, notably the bear. Bears, near common picnic or camping grounds, have had easy access to garbage.

Further, while pork was apparently the primary source of infection in Germany up to a half century ago, there is now relatively little infection found in German pork. Fischer, 1934, reported one to eight infections per year since 1924 out of an average of 30,000 hogs killed and subjected to routine microscopical examination in Linz each year; Mayer in 1939 reported the *first* positive in the 100,000 hogs killed and inspected in Heidelberg in the preceding five years. Todd, 1948, reported that of the total of 79,000,000 hogs butchered and inspected in all of Germany from 1934 to 1937 less than 0.0005 per cent (actually 44 per 10,000,000) were found to be infected. Similarly, Hjortland, 1935, reported routine microscopical inspection of pork in Denmark has failed to reveal a single trichina infection in the last five years and only 45 in over six million hogs examined in the last 25 years. Although this is lower than the swine infection rates in the United States during the same period, it seems evident that the infection was never as frequent in swine in Germany as in American garbage-fed hogs. Although rates of 1 to 2 per cent have been reported in small groups of hogs in Germany, the rate for the 2.5 million hogs in the first year of inspection in Prussia (1878) was less than 0.1 per cent, and no figures materially higher have been found for any period since. Since raw pork sausage is considered a delicacy and commonly eaten when available in a number of places in Germany, there was ample opportunity for infection through the eating of pork despite the low infection rate in hogs. Evidence is accumulating that at least the severe outbreaks in Germany in recent years have resulted from meats other than domestically raised pork; wild boar and other game animals have been incriminated a number of times.

In the Arctic and Nearctic regions man is infected almost exclusively from the meat of wild animals. Of these the polar bear appears to be the commonest source

of human infection; this bear is both a scavenger and a predator on small animal and has ample opportunity for infection. A number of outbreaks have been traced directly to these animals, and the microscopical examinations in limited survey have revealed as high as two out of three infected. A wide variety of other Arctic mammals have been found infected and a number, such as the walrus, seal, and even the white whales, have either been directly incriminated or are under serious suspicion as the source of infection and disease in man.

**CHARACTERISTICS OF THE DISEASE.** Not everyone who becomes infected suffers the disease. The occurrence and severity of the disease are apparently almost entirely dependent upon the number of infective larvae ingested in the case of an initial infection. Since, in the United States, most infections appear to be acquired from inadequately cooked, rather than raw pork, and in the case of sausage, the trichinous pork is usually heavily diluted with nontrichinous pork, the resulting infections are light. It is probable that most of them are subclinical. The exact number of larvae necessary to produce disease in man is not known. There are some interesting experimental observations, however, which indicate that the severity of the reaction to the same dose varies with the species of host, but that within a species, size of dose is an extremely important if not the principal factor in determining the severity. For instance, rats tolerated without demonstrable ill effect doses of 10 to 20 larvae per gram, but are nearly all killed in 12 to 35 days by doses of 40 gm. and in two to seven days by 70 gm. (McCoy, 1931). Swine, on the other hand, while not injured by less than 1 gm. were all made ill by as little as 1 to 4 gm., and at this dose 8 of 14 died in 7 to 24 days (Schwartz, 1938). Even one larva per gram would mean between 60,000 to 70,000 larvae for a 150 pound man, which would require the eating of more than 150 pounds (60-70 kg.) of infected pork since rarely do hogs, i.e., garbage-fed hogs, have as many as one larva per gram of meat.\* It seems probable then that man is injured by these worms much more even than swine, but unless man is more than a hundred times as susceptible, he would rarely ingest enough infected pork at one time in the United States to suffer from trichinosis. This is in accord with the finding that individual clinical cases or more extensive outbreaks are always traced to concentrated doses of infective larvae.

The light infections harbored by so many Americans may not be without some benefit in terms of immunity. Ducas in 1921 first reported that a protective immunity develops in rats as a result of a single infection, and this has been verified and amplified by many workers. McCoy has shown that as low an initial dose as two or three larvae per gram will stimulate a demonstrable immunity, and that 1 to 20 larvae per gram will protect a rat from several times the otherwise lethal dose. There is some limited evidence that an initial infection in man will confer complete protection for at least months thereafter. Such protective immunity may not prevent some clinical manifestations from exposure to reinfection. An immunized animal, upon receiving a subsequent challenge dose, may develop allergic manifestations characterized by pronounced edema of the intestinal mucosa with resulting diarrhea, although none of the worms from the challenge dose becomes established.

\* Although Mark, 1888, found much higher infections (10-100 larvae/gm. and one case with 15,000 larvae/gm.) in hogs fed on meat trimmings from the abattoir as well as kitchen garbage, no infections of this intensity have been reported since in swine.

ch a condition in man may be classified as "intestinal flu," food poisoning, or receive some other nonspecific classification.

Although trichinosis is commonly ushered in with a gastro-intestinal episode, the earliest physical sign which points to the nature of the disease is commonly angioneurotic edema of the upper eyelids; this is commonly followed by muscular tenderness and pains; an eosinophilia is characteristic and suggestive. A variety of other signs and symptoms may develop, such as bronchopneumonia (about 15 per cent according to Minot and Rackemann, 1915), transient neurological signs, and myocarditis. Only the myocarditis may leave permanent damage, but even that clears up completely unless the damage is severe. The failure to find larvae in the blood and spinal fluid is meaningless since even at the height of the migration they cannot be regularly detected. Bachman (1928) developed an intradermal test, using a saline extract of the trichina larvae, which has proved to be very useful. The test usually is not positive until the second week of the infection and the recovered subclinical case may be positive for years. The precipitin test is usually positive only during the active infection but, unfortunately, does not become positive regularly until the third week of the infection. Only the closely related *Trichuris trichuria* regularly produces a nonspecific or cross reaction with the intradermal test. In areas where this infection is common it is important to check the validity of the positive intradermal test by repeated stool examinations for *Trichuris* eggs.

**TREATMENT.** Treatment is largely symptomatic, including rest. Harwood and Cutler have shown that calcium salts will relieve the toxicity of tissue destruction but do not alter the course of the infection in rabbits; its possible value in human trichinosis has not been demonstrated as yet. Most attempts at specific therapy have been useless, but not infrequently they have contributed unfavorably to the disease. Recently Oliver-Gonzales and Hewitt (1947) have found that hetrazan given very early in the course of experimental infections in rats may reduce the number of worms ultimately developing but its possible value in human trichinosis is yet to be demonstrated.

**PREVENTION.** The procedures for the prevention of this infection may be classified under two main headings, individual and community, or personal and public.

At least for the present it is of fundamental importance to stress the role of the individual in the prevention of disease. Until such time as there is universal abstinence from the currently common practice of feeding raw garbage to hogs, there can be no assurance that any particular hog is free of the infection. Accordingly, in the United States only the individual can insure his own protection by making certain that any fresh pork he or she eats is adequately cooked. Carefully controlled experiments have shown that all trichina larvae are quickly killed at  $50^{\circ}\text{C}$  ( $131^{\circ}\text{F}$ ) and instantly killed at temperatures less than  $60^{\circ}\text{C}$  ( $140^{\circ}\text{F}$ ) (Ransom and Schwartz, 1919; Otto and Abrams, 1939). Either higher temperatures or continued exposures to these temperatures are required to give the meat a cooked appearance. Thus, any fresh pork which has lost its natural pink color and has turned gray or brown with cooking would contain no living trichina larvae. The difficulty, however, comes from the fact that it may take some little time for heat to penetrate to the center of a piece of meat. Frying or roasting particularly tend to produce an insulating layer, the brown crust, so that a large roast which

looks well done may be pink and infectious in the center. Although fresh sausages are usually small, quick frying will even more quickly produce an insulating layer on the outside. We have seen such sausages with a very hard brown crust containing a core of fresh uncooked meat. This is apparently why fresh pork sausage is so commonly the source of infection. The same admonition applies not only to pork but to the flesh of any carnivorous or omnivorous animal, such as the bear.

Community or public activities in control of trichinosis should center on the prevention of infection in the animal which is the primary source of infection for man. Certainly in the United States and probably in most areas other than the Arctic or Nearctic regions pork is the principal source of infection. The principal source of the porcine infection in *all areas* of the world where it has been studied is raw garbage or other meat scraps in feed lots and fattening pens *before* the animals are brought to the abattoir for slaughter. Either uniform state regulations or federal regulations are, and have for many years, been so obviously needed for the control of garbage feeding that one is forced to wonder why they have not been established. The initial and anticipated operating costs and fear that cooked garbage will be less nutritional for hogs has resulted in active and organized resistance by some garbage feeders to such legislation. It should be noted that the provisions in England and Canada for feeding only cooked garbage has not brought financial ruin upon the swine industry in these countries and has offered significant protection. Continued lapses in the enforcement of the laws in a few instances in Canada has resulted in trichinosis. The recent evidence that vesicular exanthema and perhaps other virus diseases of swine are spread through the feeding of raw garbage has been more effective than the evidence that it is the basic source of human trichinosis in curbing this practice. At least 41 states now have laws or regulations requiring the cooking of garbage used as swine feed.

Other public measures, however valuable in themselves, must be considered as auxiliary measures, even the present federal regulations on heat and cold processing and the continental practice of microscopical inspection of pork. Present federal regulations apply only to pork products which are "customarily eaten in the form in which they are purchased." The regulations are based on carefully conducted experiments and as indicated above it has since been demonstrated that "processed pork" products do not contain living trichina larvae. Such products as wieners, smoked sausage, and even smoked hams commercially prepared either in federally inspected or noninspected processing plants are almost invariably safe for consumption. Although it is possible that some trichina may escape destruction in such products as smoked hams, in which the curing process may be shortened, it is hardly conceivable that enough to produce disease would survive. Federal regulations covering such pork products are set forth under three main headings. (1) In heat curing, all parts of the meat must reach a temperature of 137° F. (2) In cold curing, meat must be held at temperatures of not higher than 5° F for less than 20 days; -10° F for not less than 10 days, or -20° F for not less than six days. More recent studies have indicated that much shorter time at lower temperatures are equally effective (Gould and Kaasa, 1949) but they are not yet written into the regulations. (3) Special curing methods include drying, salting and smoking under sharply specified conditions. It is significant to note that these conditions do not exceed the procedures commonly in use in curing the various dried or smoked pork products.

Recent work has shown that gamma rays will render trichinous pork noninfectious and safe for human consumption. However, its practical value is debatable.

Microscopical inspection of pork for trichina is routinely practiced in Germany and Denmark and locally elsewhere in Central Europe. Such federal inspection was maintained in the United States from 1892 to 1906 for pork intended for export. As Schwartz points out, this was an economic rather than hygienic measure. At no point was serious consideration ever given to its general application in the United States. Although it is commonly believed in Germany that inspection is responsible for reduced human infection, the data are not without ambiguity. For instance, files, 1901, traced 32 per cent of more than 6,000 cases of trichinosis to pork which had passed the German Government Inspection. Deaths from trichinosis still occur in Germany. Thus, the view, both scientific and official, generally held in the United States is that microscopical examination of pork would give a false sense of security. Schwartz (1941) has estimated that the cost of this false sense of security would be about \$10,000,000 a year, almost twice the cost of all other meat inspection combined. It may be noted also that only about 60 to 70 per cent of the pork killed in the United States is killed under federal supervision.

Thus, the two points to be emphasized are: (1) do not eat the fresh meat of dogs or any other omnivorous or carnivorous animal without thorough cooking, i.e., until the natural pink color turns to gray or brown in all parts of the meat; and (2) take advantage of the swine industry's concern over the spread of swine diseases by raw garbage feeding to support the extension and enforcement of laws and regulations against this practice.

**The Beef Tapeworm.** *Taenia saginata*. *Taenia saginata* occurs as an adult tapeworm only in the intestine of man. The larval stage, or bladder worm, known as *Cysticercus bovis*, occurs only in the tissues of cattle and produces a condition known as "measles" in beef or "measly beef." The infection in man may be more common than is generally realized. Penfold \* reports that it was the only large tapeworm of man in Melbourne, Australia, and through painstaking efforts found many unreported infections. It is by far the commonest of the large tapeworms of man in the United States but it is even more common in Mexico. However, it occurs to even a greater extent in other beef-eating countries. It is reported to be particularly common in Syria, Africa, and parts of the subcontinent of India among Mohammedans, who customarily eat beef raw. In Baltimore the tapeworm is found in man most commonly among the professional group or other higher economic groups, such as the legal profession, and business personnel. The possible significance of these limited observations is not clear. It may be that the higher economic groups are more likely to seek medical attention for minor complaints or that such groups eat the better cuts of beef and thus more commonly eat them raw. Intestinal discomfort, particularly epigastric pain, occurs during the course of the development of the worms and apparently is more severe about six or eight weeks after infection when the worm is maturing. Thereafter most infections may be asymptomatic except for episodes of gastric distress. These are most likely to occur when a meal has been delayed or missed and may give rise to giddiness

\* The careful studies of Penfold and his collaborators on the biology, epidemiology, control and medical aspects of *T. saginata* infection are reported in a series of papers from 1935 to 1938 in the Medical Journal of Australia and the Journal of Helminthology.

at those times. The Australian workers could find no evidence in support of the common belief that the worm causes chronic hunger, massive appetites, or failure to gain weight. It does not produce anemia or any other constitutional symptom.

Man is infected exclusively by the eating of raw or rare beef containing the living cysticerci while cattle are infected by the ingestion of feces or food or water contaminated with feces from infected humans. Meat inspection as practiced in the United States has disclosed scarcely more than 0.1 per cent infection in cattle. However, the infection is far from uniformly scattered. Sussman and Prechal (1950) have recently shown an average of 3.0 per cent infection in cattle fattened in the feed lots of the Salt River Valley in Arizona but much of this infection was in the cattle from one ranch which had an infection rate of 12 per cent. Very often the cysts are dead and calcified. In an experience with a herd of 900 cattle harboring 10 to 25 per cent infection practically all the cysts were calcified. Penfold has shown that the cysticerci in the tissues of cattle live only a matter of months, usually not more than two or three months, and have begun to calcify within six months. Even the calcium is resorbed within two to three years. Furthermore, cattle once infected are immune to reinfection, at least for a matter of years thereafter. For instance, cattle grazed continuously for two years on pasture fertilized with raw human sewage harbored no living cysticerci, although it was shown that most of the cattle became infected. It was accordingly recommended that no attempt be made to curtail the dumping of sewage in pastures but that where such practices exist in Australia the calves be intentionally exposed to the heaviest source of human feces to insure early infection and not slaughtered under two to three years thereafter. It is visualized that at the end of three years, even the calcified cysts will have become resorbed. It seems probable that this method of control alone could do no more than provide a biological balance and could not be expected to completely break the chain of transmission. Certainly it has no application in the United States since the source of infection in cattle is the careless defecation, as Sussman has shown, by relatively few infected individuals. Such individuals may habitually or intermittently defecate in pastures, drainage ditches, feed lots, and even in silage tanks. The prevention of infection in cattle in the United States is a simple matter of educating cattlemen and cattle handlers of the necessity of enforcing simple sanitary concepts. The examination of all help and the treatment of the infected individual has proven of value; the greatest value, perhaps, results from the collateral discharge of noncooperative personnel.

Since the source of infection in cattle is individual and not readily controlled by community activity it is necessary to have inspection of beef. Since the cysticerci are readily visible to the naked eye and are concentrated in the heart and the region of the heart, gross inspection of the carcass as practiced in federally supervised abattoirs is a comparatively simple and effective method of eliminating infected beef. While inspection cannot give absolute assurance of protection, the difficulty arises primarily from the fact that about one-third the cattle in this country are slaughtered without benefit of federal inspection and local inspection regulations are quite varied and in general unsatisfactory. Thus, absolute protection from infection, particularly if the inspection status of the meat is unknown, depends upon the handling of meat. The principal source of infection appears to be raw meat

ut rare beef cannot be eliminated. The cysticerci are killed quickly at 55° C (131° F) and within a month by freezing.

In conclusion, it seems desirable to emphasize again that the problem is simply one of the adherence to the elementary principles of fecal disposal—the provision of easily available privies near cattle lots and the enforcement of their use.

**The Pork Tapeworm. *Taenia solium*.** This tapeworm has a life history essentially the same as that of *T. saginata* except that pork replaces the cattle in the above life cycle. The cysticerci in pork produce “measly pork.” It is, however, a greater danger to man because of the fact that man may play a dual role. Man is normally the host for the adult tapeworm in the intestinal tract and pigs for the larval stages (*Cysticercus cellulosae*) in the muscle of that animal. However, when the eggs of *T. solium* from man are ingested by the same or another human the larval stages may develop in a manner somewhat similar to that in the pig. However, man is an abnormal host for this stage and accordingly there appears to be a wider dissemination of these larvae in the tissues of man beyond the musculature than is the case with the pig.

Thus, *Cysticercus cellulosae* in man may commonly involve the central nervous system and be the source of serious disturbance, including the manifestations of Jacksonian epilepsy. It is perhaps important to note that even here the cysts die early and are calcified so that if the patient recovers from the acute manifestations he usually is thereafter without any serious impairment. There has been a great deal of confusion on the source of human infection with this larval stage and not infrequently time is wasted in looking for the parent worm in the intestine of the same individual. No evidence has been presented to support the statement that internal auto-infection with *Cysticercus cellulosae* results from an adult tapeworm in the intestine, and it is difficult to visualize such a process. Man may become infected with cysticerci by ingesting eggs in his own feces but probably more commonly obtains them from eating contaminated food. Thus, we find this infection with the larval stage most common in areas where widespread fecal contamination occurs including areas where human feces are used for fertilizer. It became a problem with certain regiments of the British Army some years ago. There have been a number of cases of *Cysticercus cellulosae* infection reported in the United States, many of which, however, were acquired outside of the country. In this hemisphere the infection in both adult and cysticercoid stages is more common in Mexico and points south, and is fairly common in Mesopotamia on the other side of the world. Again, although freezing, heating, or various processing will kill the larval stages in pork, they are so readily visible that federal meat inspection includes direct examination for them just as it does for *Cysticercus bovis* in cattle, and federally inspected pork may be considered to be free of this infection although it may not be free of trichina. As already noted a significant portion of the swine is killed outside of federal inspection and this constitutes a potential hazard of infection.

As with *Taenia saginata* the prevention of infection is basically one of proper fecal disposal. Care of the disposal of human feces in and around swine raising establishments will prevent infection of swine. Furthermore, the feces of humans infected with *Taenia solium* are the direct source of *Cysticercus cellulosae*, the larval stage of this tapeworm, in man.

**Hydatid Disease. Echinococcosis.\*** Hydatid disease is caused by the larval stage of a tapeworm, *Echinococcus granulosus*. The adult is a small tapeworm, with only three segments and a total length of 3 to 6 mm., which lives in the intestine of dogs or related carnivores. The larval stage or hydatid develops in the liver of a number of domesticated and wild ruminants and even in the rabbit, but sheep are by far the most important host of this larval stage. The larval stage, i.e., the hydatid, is not only larger than the adult stage, but develops slowly and seems to have an almost unlimited capacity for growth and asexual reproduction, by budding. Carnivores are infected by eating the larval stage with the livers of these intermediate hosts. Man is infected as are the sheep or other intermediate hosts by ingesting the eggs from the feces of the carnivores. Thus, man is a blind alley intermediate host since carnivores have normally no chance of eating the infected liver (or other organs) of man. This was formerly a very important endemic disease in Iceland and has been an important disease in New Zealand and Southern Australia for many years. It is of growing importance in the sheep raising areas of Argentina, Paraguay, and Uruguay. It also occurs in widely scattered parts of Europe and in Siberia, the Near East, Asia, and the southern tip of Africa. It is a highly endemic infection in man only where the sheep-dog-man contact is intimate and common. The infection has apparently not become established in domesticated animals in the United States and Canada. The larvae have been reported in swine and cattle livers, up to 12 per cent in some lots of swine, and have even been found in sheep. However, the adult has been found less than half a dozen times in dogs. However, over 20 years ago Riley demonstrated that this parasite occurs as an endemic sylvatic infection in Minnesota, involving the moose and the timber wolf. Recently it has been shown that the sylvatic infection is common in northwest Canada and in Alaska. However, there is no evidence that this sylvatic infection has ever produced any center of infection in domestic dogs and sheep, cattle, or swine. Thus, while over 500 human infections have been found in the United States and Canada, over 95 per cent are directly traceable to endemic areas abroad. Magath (1937), in reviewing the 482 cases up to that time, found that 460 of them had previously lived in endemic areas abroad. The remaining 22 had never been outside of the continental limits of the United States or Canada and must thus have acquired infections within one of these countries. It is not known whether the sources of these infections were wild carnivores or undiscovered infections in dogs. Since Eskimos in Alaska have apparently acquired hydatid from their sledge dogs, there is increasing concern over the possibility that dogs brought from Alaska may become the source of human infections in the United States. The extent of this possible danger has not been determined and should be investigated (Magath, 1954). The disease develops slowly; more commonly than not the subject is asymptomatic for 10 or more years after becoming infected so that it is almost impossible to pinpoint the individual source of infection.

The control and prevention of human infection centers around preventing the infection of dogs. This has been dramatically accomplished in Iceland where a century ago there was over 15 per cent human infection, essentially 100 per cent infection in sheep and cattle, and over 25 per cent of the dogs harbored the adult

\* *Echinococcus* is conveniently treated here with the other tapeworms although man does not contract it by eating meat.

orm. Now (Dungal, 1946) autopsies have failed to reveal any infections in those under 20 years of age (Table 23-1).

Table 23-1. *Echinococcus* discovered at autopsy in Iceland (Dungal, 1946)

Age	Number of Autopsies	Cases of <i>Echinococcus</i>	Per Cent Positive
0-20	239	0	0
20-30	193	1	1
30-40	199	1	1
40-50	170	4	2
50-60	179	13	7
60-70	153	21	14
70-90	98	20	20
TOTAL	1,231	60	45

Only in those over half a century old was any appreciable infection found and was highest in those approaching the century mark. Of the 60 cases, 34 were males and 26 females. The dramatic reduction has been accomplished by the education of the people and enlisting their cooperation in instituting control procedures. The practice of feeding viscera of slaughtered animals to dogs has stopped and every effort has been made to destroy the carcass of any sheep which dies. This has been facilitated by a shift from home slaughter and slaughter in small community abattoirs to the utilization of large central abattoirs from which dogs are restricted. Accidental infection of dogs has been further reduced by a marked change in age of animals slaughtered for food. A century ago older sheep (three to four years old), with hydatids sufficiently developed to be infectious for dogs, were the commonest source of mutton whereas today five- to six-month old lambs constitute the bulk of the sheep slaughtered. Even if such young animals are infected the hydatid is likely to be acephalic (immature) and noninfectious. When the organized control program was initiated it included the annual treatment of all dogs with a powerful taenicide and the regular use of such treatment (Arecoline hydrobromide) still continues. Whether or not this is a continuing necessity appears not to have been determined but one would hesitate to discourage the practice until it is clearly demonstrated to be unnecessary.

In Australia, also, attention to preventing infection in dogs has brought a reduction in human infection. This is most evident in the City of Melbourne where stray dogs, with free access to multiple small abattoirs, were formerly 100 per cent infected but now constitute no serious hazard to man. This change was accomplished by consolidation of the abattoirs and the enforcement of restrictions on dogs around such abattoirs together with the impounding and killing of stray dogs. In the smaller towns and less populated rural areas progress has been slower but attention continues to be focused on unprocessed sheep offal and the destruction of sheep which die on the range. Thus control is basically a matter of not permitting dogs under any circumstance to have access to the raw viscera of any of the intermediate hosts, but primarily of sheep; and the destruction of stray dogs.

## FISH

In nutritive properties, there is little difference between the muscle of fish and that of beef. In other words, fish is meat although ordinarily not so regarded. Drummond found that the coagulable proteins of muscle tissue of the cod, herring and canned salmon have a nutritive value as high as those derived from beef. Fish also resembles meat in that both are poor in vitamin B.

The percentage of fat in different species of fish varies greatly. The unique quality of fish oils as a source of vitamins, especially A and D, suggest the importance of fish in the diet. The livers of fish do not serve as a storehouse of glycogen as do the livers of mammals, but are loaded with fat. All liver oils from fishes thus far studied are excellent sources of growth-promoting vitamins. The liver of the cod is a veritable storage battery of radiant energy, which gives to cod liver oil its well-known antirachitic properties. Some of the fat-rich sea fish, such as sardines, salmon and shad roe, have an energy value equal to that of hearty foods such as veal, milk, sirloin steak and baked beans. Salt-water fish and shellfish generally contain much iodine and are prophylactic against goiter. Fish also are fair sources of various mineral elements.

Fish poisoning or *ichthyotoxismus* is most frequent in Russia, Japan and the West Indies, and other seacoast countries in which fish forms a large part of the diet. It occurs especially in warm countries.

**Physiological Fish Poisoning.** Some fish are always poisonous, that is, normally contain a substance toxic to man; usually the poison is developed only during the spawning season. Various species of the *Tetrodon* and *Diodon*, which include the puffers, balloon fish and globe fish, frequently cause serious and fatal poisoning in Japan. The most poisonous is perhaps the fugu. In Tokyo alone, 680 fatal cases out of 933 were reported as occurring from 1885 to 1892 from the so-called "*fugu*." In China and Japan such fishes are sometimes taken for suicidal purposes. The active principle in fugu poisoning resembles curare. The poison is found mainly in the head, liver and ovaries, and called "*fugin*." It is not destroyed by boiling. Its chemical nature has not been determined. The symptoms produced are: dyspnea, cyanosis, dilatation of the pupils, relaxation of the sphincters, paralysis of speech, dizziness, salivation and vomiting. Death may result in one or two hours.

Few fish containing physiological poisons are found outside of the tropics. Some fish, such as shad and smelts, are preferred during spawning season. However, during spawning season the roe of different members of the sturgeon family, of the pike, and the barbel have been said to cause pronounced and even fatal intoxication; the symptoms resemble those of gastro-enteritis. Anchovy belassa and the meltite of the Indian Ocean are both said to be poisonous, the former causing death when only small amounts are taken, the latter causing violent vomiting. The Greenland shark causes an intoxication in dogs similar to that caused by alcohol. A certain degree of tolerance can be produced by feeding graded amounts. The roe of the European barbel produces the so-called "*barbel cholera*," while the roe of the pike is said to be poisonous during the spawning season. The toxic symptoms are said by Pozzi-Escot to occur in not less than 24 hours after ingestion. The smooth puffer (*Lagocephalus levigatus*) is considered by fishermen to

are the most poisonous of the fishes of Brazil. Little is known concerning the nature of physiological fish poisons.

**Bacterial Poisons.** Bacterial poisoning from fish occurs. The fish may be diseased, or when caught may be healthy, but the bacteria gain access and grow throughout the meat as the result of contamination or imperfect preservation. Bacterial diseases among fish are rather common and often occur as epizootics. In almost all the reported instances of injurious action resulting from bacteria the fish has been eaten raw. Bacteria may form poisonous substances in fish closely resembling botulinus. Fish caught by the gills in nets die slowly and decompose rapidly. They are of inferior flavor and value and are more liable to be injurious than fish taken from the water and killed at once; under such circumstances they remain firm and retain their flavor longer than those that die slowly. In some parts of the world live fish in tanks are offered for sale in the markets. This procedure cannot be commended from a sanitary standpoint, for the tanks are likely to become dirty and the fish liable to sicken and die slowly, so that the object of surveying only live, fresh, and wholesome fish is largely defeated. It is well known that fish decompose readily and should, therefore, be handled in a cleanly manner and used as fresh as possible. When refrigerated the temperature should be low. Frozen fish keep well.

"Fish poisoning" is doubtless sometimes due to a toxin produced by *Clostridium botulinum*, or a similar anaerobe. Poisoning from fish contaminated with *Salmonella* or one of the closely allied members of the colon-typhoid group is very seldom recorded. Allergy to fish is rather common.

**The Fish Tapeworm, the Broad Tapeworm of Man (*Diphyllobothrium latum*).** This is the only tapeworm of man which is acquired through the eating of raw or insufficiently cooked fish. It has a complex life history. The adult tapeworm, which may be up to 30 feet or more long, lives in the alimentary canal of man and a number of fish-eating carnivores and omnivores. The egg, when reaching fresh water, hatches, releasing a free-swimming larval stage known as coracidium. These, when eaten by certain of the small crustaceans of the genus *Diaptomus* (Cyclops), develop to the next larval stage known as the proceroid. The third larval stage, the plerocercoid, develops in the muscles of fish which have eaten the *Diaptomus* containing the proceroid. The plerocercoid of these small fish are capable of developing if eaten uncooked by man or some other definitive host. However, most human infections are acquired from eating a larger fish, a transfer host, which has acquired the plerocercoid stage in its muscles as a result of having eaten a smaller infected fish.

The disease is most highly endemic on both sides of the Baltic coast but is particularly common in Finland, where 10 to 15 per cent of the population is infected. It occurs, however, elsewhere in Europe particularly in the Danube basin and around the Swiss lakes. It has been imported into the United States in the Great Lakes region and into Canada as far north as Lake Winnipeg; apparently imported by the Finnish population which has moved into those areas. Recently Summers and Weinstein (1943) found evidence of a small center in Florida. Somewhat over 100 cases have been reported from the northern lake regions and are largely divided into two groups. The first group are the native Finns who continued their habit of eating raw fish. The second group are Jewish housewives. Macbeth has

studied the latter group in Winnipeg, Canada, and traced the infection to the preparation of gefüllte fish which they are accustomed to taste raw in the process of seasoning. Similarly there are reports of its occurrence in Jewish housewives in New York City from fish shipped from the Great Lakes region.

Fig. 23-1. Life cycle of *Diphylobothrium latum*, the fish tapeworm.

This tapeworm infection has long been associated with macrocytic anemia, and it is not impossible that it is at least a precipitating factor in the production of such anemias. Often the anemia reported is absolutely indistinguishable from the so-called pernicious anemia. Birkeland (1932) has suggested certain differences between the classical pernicious anemia and that associated with some of the fish tapeworm infections. He notes, however, that there are relatively few cases of this anemia compared to the population of infected Finns, and calls attention to the fact that it is rare or absent among the infected individuals in this country. It is possible that this worm may provide a precipitating factor in the production of the disease but it has never been demonstrated that it actually causes the anemia.

The most obvious control procedure is the thorough cooking of all fish eaten. However, freezing at temperatures around  $1^{\circ}$  to  $10^{\circ}$  C for at least 24 hours is sufficient to kill the plerocercoid stage. This procedure could perhaps be utilized

When fish are stored or shipped under refrigeration, by merely dropping the storage temperature. However, since fish are rarely eaten raw in this country this may prove to be a costly way to serve relatively few people. Inspection of fish for the plerocercoid stage is impractical on two grounds. It would require cutting the fish open and thus destroying their saleability and, furthermore, they harbor the plerocercoid stage of a number of other worms which are not infectious for man but which would be mistaken for, in fact are indistinguishable from, the plerocercoid stage of *D. latum*.

Since man is the most effective host for the adult stage, it may be that man constitutes the principal source of infection for the various aquatic organisms coming up with the fish which are eaten by man. Thus, the adequate disposal of fecal material is important. Although the eggs may survive passage through sewage and constitute a localized source of potential infection when emptied into fresh water, the direct deposition of feces into water from open privies is also an important source of infection. It would, however, be inadequate to consider that man is the only possible source of infection. While the worms in dogs frequently never pass eggs or only very few eggs, Vergeer (1930) has concluded that both dogs and the brown bear constitute important sources of infection for the aquatic intermediate hosts. The problem warrants further study but, unlike many other parasitic diseases, it seems probable that we cannot approach the question of control only in terms of fecal sanitation and must have recourse to the processing of the fish which is eaten by man. Cooking offers the only guarantee against infection.

**TREMATODES.** A number of the trematodes of man are acquired by eating raw fish. However, a number of them including the schistosomes are not acquired in this manner. Therefore, the group is not discussed at this place, but the reader is referred to the trematode diseases (page 574).

### SHELLFISH

Shellfish include mollusks, as oysters, clams, mussels; and crustaceans, as lobsters, crabs and shrimp. When we eat clams, oysters and soft crabs, we take the entire animal except the shell. This insures the consumption of unrecognized food substances which may be important supplementary factors in our diet. Oysters contain vitamins A, B and C; they are rich in B. Clams contain vitamin B but not in appreciable amounts. They also have less A, but more D than oysters. Oysters are excelled only by liver in the amount of iron and copper which they furnish in an average serving. The protein compares favorably with the protein of other meat products. Shellfish are rather poor sources of fat and carbohydrates. Sea foods are of special significance in that their iodine content is higher than that of land plants or animals. They are nutritious, savory and digestible, and are important additions to the diet.

The conditions which render such food injurious are much the same as those discussed in connection with fish. No disease of shellfish is known to affect man. Snails convey flukes, but not by ingestion. Shellfish may be perfectly good and wholesome when fresh, but may become contaminated and injurious on keeping, especially if not properly preserved. It is seldom that they are responsible for illness, albeit they have a bad reputation. This is due in large part to the fact that

allergy (atopy) to these foods is rather common. In such instances the trouble is not with the food but with the person who eats it.

Man has made shellfish a danger to himself by polluting the water in which they live. With the growing pollution of tidal and inshore waters, clean beds for growing and collecting oysters and other mollusks have become a real health problem. On being transferred to clean water, shellfish may in time purge themselves of typhoid and other injurious bacteria. In this group, oysters and clams are the most important vectors of intestinal infections because frequently eaten raw.

**Oysters.** An active oyster in the combined process of breathing and feeding "drinks" daily many gallons of water through its gills. The food particles sifted by the gill are caught on the inner surfaces, which are coated with a mucous layer and which, actuated by cilia, move like an endless belt and convey the food particles into the funnel-shaped mouth. From the mouth, food enters the sac-like stomach cavity and passes through the short gut, reaching the cloacal or gill effluent chamber, and is ejected some five hours after entering the shell. Bacteria reaching the tissue surfaces have a tendency to elimination through the feeding function. In the language of the fisherman, floating is usually spoken of as "drinking," "plumping" or "laying out." This gives the oyster a chance to purge its intestinal tract. Such oysters are cleaner and keep in better condition for shipment. There is a sanitary advantage in floating oysters provided the water be clean. The health hazard, however, is great because of the difficulty of finding satisfactory inshore water.

Oysters are most active during the warm summer months, drinking large quantities of water, and they therefore contain more bacteria then. When the temperature falls activity lessens; the shell closes at  $7.2^{\circ}\text{C}$ , when the oyster passes into an inactive condition, a sort of hibernation. The bacterial population of oysters is therefore seasonal.

**NUMBER OF BACTERIA.** Oysters are apt to reflect the bacteriology of the water in which they live. Bacteria are found both in the oyster and in the oyster liquor. Oysters from clean water contain few bacteria and no *E. coli*; oysters from polluted water usually contain many bacteria and numerous *E. coli*; although the reverse occurs. The number of *E. coli* is determined by a method of the American Public Health Association (1922).

The bacterial content of the water in which oysters are raised has a direct influence on the content of the shell liquor because oysters drink large quantities of water, from which they obtain their food. When tests of samples of oyster-shell stock or shucked oysters show a most probable number of 230 or more coliforms per 100 ml. of stock sampled at the growing area, unfavorable conditions or practices are indicated. Occasional estimates of 2,400 coliforms per 100 ml. may be tolerated but corrective measures should be taken immediately when this occurs in more than two consecutive samples.

**TYPHOID BACILLI.** Oysters from polluted waters may retain the typhoid bacillus for a long time. When placed in clean water the numbers rapidly decrease, so that the hazard from this source diminishes. The time of purification depends upon the temperature and purity of the water and its amount. Repeated changes of fresh water result in a rapid diminution, reaching about 99 per cent after three changes of water.

Krumwiede and others (1926) call especial attention to the prolonged persistence of minimal numbers of *S. typhosa* under different conditions. They state that apparently the only safe oyster is one which has been protected from contamination by fecal pathogens for at least some months prior to harvesting. They found *S. typhosa* to persist in shell oysters stored at refrigerator temperatures for 49 days, though the oyster died on the forty-first. On shells of stored oysters the bacilli apparently are dead after 14 to 40 days. A dead oyster serves as a culture medium and the number of *S. typhosa* will increase if the temperature is satisfactory.

Jordan (1925) found that the longevity of *S. typhosa* in the oyster juice of both shucked and shell oysters in storage varies with the temperature. In general, the temperature best suited for the preservation of the oyster tends to prolong the life of typhoid bacilli in the oyster. He found them to survive 22 days in shucked oysters and 60 days in shell oysters. In living shell oysters during dry storage at 45° F, typhoid bacilli survived for a longer period than the oysters. Kinyoun (1925) aroused oysters from hibernation, fed them with *S. typhosa*, and then stored them. *S. typhosa* was recovered 15 days after the oysters had been fed with the organism, when the feedings were discontinued.

Park states that *S. typhosa* persists in hibernating oysters much longer than in oysters that are actively drinking. Krumwiede and others (1926) isolated *S. typhosa* 14 days after contamination and return to natural waters of low temperature.

The transfer of oysters from a polluted water to a clean water may result in a marked and rapid drop in the number of bacteria, if the oyster drinks freely in the clean water. Krumwiede and others (1928) found that if oysters contaminated with *S. typhosa* are planted in natural waters during the warm months, *S. typhosa* cannot be isolated after 14 days. In sea water, *S. typhosa* may persist in small numbers for 19 to 24 days. Evidently this procedure cannot be relied upon to render oysters safe, especially during the colder months. The Health Department of New York City permits the transfer of oysters from doubtful to clean waters only during the closed season. The oysters must remain there at least 30 days. Such conditioning of oysters and wet storage should be allowed only when pure water of proper salinity is available.

*Oysters and Typhoid Fever.* Typhoid fever and other intestinal infections have been convincingly traced to infected oysters. They may be infected when dredged from sewage-polluted beds in which they live and grow. In practically every instance, however, that typhoid fever has been traced to oysters, infection has occurred through the process of floating or storage rather than from the oyster beds.

An epidemic of typhoid due to shellfish was reported by Pasquier in 1816. The oysters were floated in the moat of an old castle used for sewage disposal.

At Middletown, Connecticut, Professor Conn showed that the outbreak of typhoid fever at Wesleyan University during 1894 was due to raw oysters eaten at fraternity banquets. This is one of the pioneer classics in epidemiology. The evidence is convincing; the conditions were those of a planned laboratory experiment. Since then, many outbreaks have occurred (see page 198).

In Great Britain more than in other European countries, shellfish transmission of typhoid fever is regarded as quite frequent. In 1896, Newsholme, then health officer in Brighton, published careful studies showing that 30 per cent of the typhoid infections occurring in that city were due to oysters and other shellfish. For Belfast,

the investigations of Mair showed that the extensive increases of typhoid fever from 1897 to 1909 were due in a large measure to infection from cockles gathered along a shore not far from the main sewer outlet.

Fuller reviewed the literature on this subject which covered more than 20 separate outbreaks due to infected shellfish up to 1904.

**THE NEW YORK EPIDEMIC OF 1924-25.** The widespread epidemic of 1924-25 (Ramsey and others, 1928), which radiated from New York, exceeded in magnitude any heretofore recorded. As a rule typhoid outbreaks involve few people in a limited area, but this one involved at least 1,500 cases and caused over 100 deaths. It followed the shipment of infected oysters for a radius of much over 1,000 miles. It included New York, Washington and Chicago particularly; and there was an excess prevalence of typhoid fever probably due to infected oysters in Buffalo, New York; Cincinnati, Ohio; Grand Rapids, Michigan; Memphis, Tennessee; Pittsburgh, Pennsylvania; Providence, Rhode Island; Rochester, New York; Scranton, Pennsylvania; Yonkers, New York; and many other cities, extending even to San Francisco, California. The infected oysters were distributed between October 25 and December 20, and the disease prevailed three to four weeks later. This corresponds to the seasonal prevalence of oyster-borne typhoid, which occurs mostly in the fall and early winter. When oysters hibernate during cold weather they are less subject to contamination. The trouble was traced to oysters distributed by a producing company operating in the vicinity of West Sayville, New York, and it is probable that the oysters came from one bed or float and constituted a small proportion of the total.

**Prevention.** The safest rule would be to use oysters and shellfish only from clean water fit for drinking purposes. Not only should the oyster beds be clean, but special care must be taken to prevent contamination of the water in which oysters are floated because most oyster-borne outbreaks of disease have been traced to this source. Under these circumstances and with cleanly methods of handling, oysters are reasonably safe. If taken from doubtful waters, they should be purified by floating in clean sea water if available, otherwise chlorinated water.

Wells first called attention to the possibility of purifying polluted oysters in chlorinated sea water. The method is now used on a commercial scale. It is, however, impracticable to disinfect a live oyster with chlorine or any other germicide substance for the reason that if the chlorine water be strong the oyster closes up tight; in any case, the chlorine is soon used up. Chlorination, however, has a use, namely, to disinfect the water in which the oysters are floated. This is important because of the greater danger of inshore contamination. It gives a ready means of obtaining a safe water in which to condition oysters or for wet storage. By drinking and disgorging the purified water, the oysters tend to free themselves of bacteria. At least the danger of their picking up pathogens from the water is eliminated. The degree of purification following changing sea water approximates that observed with a similar treatment of chlorinated sea water. It is sometimes difficult to obtain clean sea water on shore without chlorination.

In view of the fact that oysters from sewage-polluted water may have a low score, the best index is the bacteriology of the water. This is not always practical. If the water be clean, the oysters will have a clean bill of health.

Oysters should be grown and dredged only from beds accredited on the basis

of a sanitary survey. This must be comprehensive and include a study of tides, currents and channels with reference to sewage pollution, as well as the bacteriology of the water and of the oysters at different points and different tidal times and seasons. The inshore oyster-houses or shucking plants, the water supply for drinking or wet storage, the fishing boats, personnel, toilet facilities, as well as refrigeration for shucked stock, must also be investigated.

Based upon the results of the survey, oyster beds should be licensed. Regulations should make it possible to trace shipments to their source. Prevention, therefore, needs official sanitary supervision of the industry.

Thorough cooking will kill typhoid bacilli and other nonspore-bearing intestinal bacteria sometimes transmitted by oysters.

Following the oyster-borne outbreak of typhoid fever of 1925, the U. S. Public Health Service undertook to make periodical surveys of the work of state agencies in charge of sanitation of shellfish areas. Based upon this work, lists of approved oyster shippers are published from time to time for the information of health officials in oyster-consuming states and cities.

**Other Shellfish. Clams.** There is epidemiological evidence tracing typhoid outbreaks to clams. That the infection may be so conveyed is clear, for clams are often collected from polluted beaches. Perhaps they are not frequently the cause of trouble because usually cooked before being eaten. The consumption of raw clams, however, is increasing. A few cases resembling mussel poisoning have also been reported.

**MUSSEL POISONING.** *Mytilus edulis*, the common mussel, is a source of poisoning in England and on the Continent, *M. californianus* on the Pacific Coast of the United States.

Three clinical types of mussel poisoning have been described: (1) erythematous, doubtless due to allergy; (2) enteric or intestinal, probably bacterial; and (3) paralytic, a toxemia.

Savage in 1918 summarized the cases reported in Great Britain, finding that from 1827 to 1909 there were 61 cases, eight of which were fatal, a case mortality of 13 per cent. A notable example of mussel poisoning occurred at Wilhelmshaven in 1885. A large number of dock laborers and their families were poisoned shortly after eating cooked mussels; three died. The mussels were examined by Brieger and Salkowski, who isolated several basic substances or "ptomaines," one of which, mytilotoxin, was poisonous to animals, causing similar symptoms.

A group of 102 cases with six deaths occurred in 1927 in San Francisco, California, as reported by Meyer and others (1928). In this outbreak the symptoms were peripheral paralysis varying from slight trembling and numbness about the lips to a complete loss of power in the muscles of the extremities and neck, and to death by respiratory failure. Symptoms in moderately severe cases came on in about 5 to 30 minutes, developing rapidly. Vomiting was inconstant and abdominal pains were not recorded. Muscular weakness increased so rapidly that within four to six hours the head could be raised only with great difficulty. The temperature was subnormal, pulse firm, slightly quickened. All those taken ill had eaten steamed, cooked or raw mussels of a Pacific Coast variety, *Mytilus californianus*, freshly gathered in different localities approximately 45 miles south and 50 miles north of the Golden Gate.

Subsequent to this outbreak, the studies of Meyer and his colleagues had contributed much to understanding this condition as it occurs on the Pacific Coast. Up to 1947, they had collected records of 409 cases of mussel and clam poisoning with 35 deaths. Most of the cases occurred along the central California coast. There were scattered outbreaks from Juneau, Alaska, to southern California and the Gulf of California, Mexico. There was a limitation to the seasonal distribution of these cases; they occurred between May 15 and October 26, the season of maximum risk was somewhat earlier in the southern than in the northern part of the coast. In 1936, the occurrence of cases of severe illness following consumption of mussels was observed in Digby County, Nova Scotia, on the Atlantic Coast (Gibbard and others, 1939). The poison found was similar to that which had been identified in California. It was recovered from two species of mussels, i.e., *Mytilus edulis* and *Modiola modiolus*. In a survey of commercially important shellfish areas of the region it was subsequently found that the poison could be recovered from shellfish only from the Bay of Fundy area in the late summer and early fall.

From the accumulated observations on the geographic and seasonal distribution of cases along the Pacific Coast, Meyer and his colleagues sought the causative factor in the food of the shellfish, i.e., the diatoms and the dinoflagellates. The poison was finally detected in and extracted from plankton (Sommer and others, 1937). The particular species of dinoflagellate finally identified as the source of the paralytic shellfish poison is *Gonyaulax catenella*. This dinoflagellate may multiply to such an extent that the water is a deep rust red color, so-called red water. It can be seen for miles in the daytime and is a beautiful luminescent spectacle at night. A method has been devised for detecting and quantitatively estimating the poison in shellfish. It consists in measuring amounts of alcohol soluble extracts of the livers of the shellfish by injecting mice peritoneally. The poison which chemically belongs to the class of alkaloids is one of the strongest known. It has been crystallized without losing its pharmacological activity (Dack, 1949).

*Prevention.* Mussels should be taken from clean water and handled with sanitary care to prevent bacterial contamination. The same principles that apply to oysters are applicable here. Cooking is prophylactic against this danger.

The prevention of the toxic form of mussel poisoning is based first of all upon the fact that the poison is seasonal. In California a quarantine is placed upon mussels and clams from June to September. The poison is thermostable. Cooking is not preventive, boiling does not destroy the poison. In the Wilhelmshaven episode, death occurred 15 minutes after eating boiled mussels. It has been found, however, that one-fourth ounce of bicarbonate of soda added during cooking for each quart of water used destroys 85 per cent of the poison in 20 to 30 minutes.

## EGGS

Perhaps no article of diet of animal origin is more commonly eaten in all countries and served in a greater variety of ways than eggs. Eggs are used in nearly every household in some form or other. It has been calculated that on an average they furnish 3 per cent of the total food, 5.9 per cent of the total protein, and 4.3 per cent of the total fat used per man per day.

When we speak of eggs we ordinarily mean hen's eggs, but the eggs of ducks

geese and guinea fowls are used to a greater or less extent; more rarely turkey's eggs and sometimes those of wild birds. Plover eggs are prized in England and Germany, while in this country the eggs of sea birds, such as gulls, terns, herons, and murre, have long been gathered for food. Other eggs besides those of birds are sometimes eaten. Turtle's eggs are highly prized in most countries where they are abundant. The eggs of the terrapin are usually served with the flesh in some of the ways of preparing it for the table. Fish eggs, especially those of the sturgeon, are preserved in salt under the name of caviar. Shad roe is also a familiar example of the use of fish eggs as food. The eggs of alligators, lizards, serpents, and some insects are eaten by races who lack the prejudices of western nations.

Large quantities of eggs are now broken out, mixed, frozen or dried. These products are largely employed by bakers and others who use eggs in quantities.

Hen's eggs vary considerably in size and appearance. The shell constitutes about 11 per cent, the yolk 32 per cent, and the white 57 per cent of the total weight of the egg. The eggshell consists mainly of carbonate of lime, and when freshly laid is covered by a mucous coating. The egg white consists of 86.2 per cent of water, 12.3 per cent nitrogenous matter, 0.2 per cent fat, and 0.06 per cent ash. The yolk consists of 49.5 per cent water, 15.7 per cent nitrogenous matter, 33.3 per cent fat, and 1.1 per cent ash. These are averages; different eggs vary somewhat in composition from each other. Hen's eggs average about 0.003 per cent of iron. It is noteworthy that eggs contain practically no carbohydrates and are poor in calcium. The chick gets its calcium by absorption from the shell.

**Nutritive Value.** The egg contains all the chemical complexes necessary for the formation of the chick during incubation. Eggs, therefore, furnish everything needed for the full development of the embryo. The egg is indeed a complete food, but not one which produces the optimum results when employed as the sole source of nutriment. There is an interesting contrast between eggs and milk. Aside from the calcium content of the white and yolk of the egg, which is much lower than that of milk, the contents of the egg resemble milk in a general way in nutritional value. The principal protein of egg yolk, like that of milk, contains phosphorus, but the fats of milk are phosphorus-free, whereas phosphorized fats (that is, lecithins) are abundant in egg fats. There is an abundance of lactose in milk, whereas the egg contains but a trace of sugar. The fats of eggs are fully comparable with butter fat as a source of vitamin A. The proteins of eggs are of high biologic value. The yolk is poor in vitamin B, but rich in antirachitic properties; it is even curative, but definitely less so than cod liver oil. Eggs vie with milk as a staple food for the production of a vigorous race. It has been shown that an egg a day for a child promotes growth and well-being.

**Classification.** In addition to fresh and refrigerated, eggs are classified in the trade as "rots," "spots," "checks," "ringers," "chickens," "dirty shells," "heated," or "incubated," etc. Eggs are assorted by inspection and candling. Candling consists in holding them before a bright light; the egg is translucent and the movable yolk may clearly be discerned, as well as the air space which is always at the larger end. A practiced eye quickly detects eggs that are not first quality. Rotten eggs are distinguished as "red rots" and "black rots," depending upon the kind of putrefaction. By "spots" are understood eggs that contain opaque spots under the light. These spots usually consist of local growths of mold that have penetrated a crack in the

shell, although they may be due to coccidia, embryos or foreign bodies. "Checked" eggs are those which have slight cracks or nicks in the shell. "Ringers" contain small embryos of about two days' growth, which are flat, disk-like and reddish in appearance. "Chickens" contain embryos of larger growth. Eggs with dirty shells are undesirable more from esthetic than other reasons. The dirt usually consists of hen excrement. A "heated" egg is a shrunken egg, that is, an egg that has been exposed to the summer temperature for several days. Some water is lost by evaporation through the porous shell, the air sac on the end has increased considerably in volume, and in many instances the embryo is partly developed; therefore, heated eggs are also known as incubated eggs. Many of the eggs gathered during the hot months of summer, especially in July and August, belong to this category. These eggs are much less desirable than the spring and fall layings. Eggs are also graded as to size, the very small eggs commanding a lower figure in the market. Further, eggs are classified as strong- or weak-bodied, depending upon how they "stand up" when broken out.

**Bacteria in Eggs.** Eggs as they come from the hen frequently contain bacteria, worms, gravel, blood clots and foreign bodies of various kinds. Practically all eggs contain bacteria, although numerous observers report occasionally that an egg is sterile. As a rule, these observations are based upon planting a small part of the egg. If the entire egg is planted a growth is almost invariably obtained. Thus, in the 18 freshly laid eggs examined every one of them contained bacteria in the yolk; two of them contained *E. coli*. Curiously enough, there are practically always more bacteria in the yolk than in the white; the white contains some bactericidal property, probably similar to that possessed by fresh blood. The bacteria doubtless gain entrance to the egg while in the oviduct. Pernot examined the eggs from over the size of a pea to the perfect egg and found bacteria at every stage. It is well known that the bacteria may also get into an egg through the shell, as it is porous and permeable. When the shell is moist and dirty the chances of growth and mold piercing it are increased. A recently laid egg is covered by a thin layer of protein material called the "bloom." It gives the egg a dull appearance. Although this layer is easily removed by handling, it serves to restrict the entrance of micro-organisms through the shell while it remains intact. Eggs laid in the summer time (July and August) contain many more bacteria than those laid in the spring, fall, and colder months. Summer eggs do not keep as well as winter and spring eggs. Sterile eggs keep better than fertile eggs.

Ordinary methods of cooking eggs do not destroy the bacteria contained therein. Rettger and others (1916) report on an investigation of the possibility of *Salmonella pullorum* in eggs infecting humans. They found that soft boiling, coddling, and frying eggs on one side did not destroy bacteria in the yolks. Other work has shown that boiling eggs until they are very hard and frying on both sides until the yolk is hard will destroy bacteria such as those causing dysentery.

**Eggs and Disease.** Of all standard foods, so far as known, eggs are less liable to convey disease or contain harmful properties than any other single food of animal origin. The literature is singularly free of instances of sickness attributed to eggs. (See salmonellosis, page 207.)

Eggs do not agree with some people, who have an "idiosyncrasy," so that a small quantity will bring on symptoms of allergy. This condition is an instance of

specific hypersensitiveness to egg protein. There are several cases on record in which this hypersensitiveness has been cured by the administration of infinitesimal amounts of egg white, gradually increasing the amount. The entire treatment should extend over a period of months. In this way tolerance may be established in man analogous to the desensitization which may be established by repeated injections of an alien protein into guinea pigs. The treatment is also applicable for other food for which there is a specific idiosyncrasy.

## PLANT FOODS

Plants are the ultimate source of practically all our dietary needs. Carbohydrates and proteins, as well as vitamins, are synthesized in the plant kingdom. In this sense, man lives a parasitic life on the vegetable world. Plants also carry important mineral elements. We do not always take the offerings of the vegetable kingdom directly. A cow eats a liberal plant ration daily during several years to provide the milk and meat for our use.

For purposes of nutrition, plant foods are classified as seeds, roots and tubers, leafy vegetables and vegetable oils; also fruits, berries and nuts. Each class has distinct dietetic qualities.

### THE NUTRITIVE VALUE OF PLANTS

**Seeds.** Seeds are storage organs and can be classed together so far as their food value is concerned. The bulk of seeds consists of starch. The proteins of most seeds are incomplete because they lack some of the amino acids necessary to rebuild human protein. Seeds are also poor in mineral elements, especially calcium, sodium and chlorine. McCollum examined wheat, corn, rice, oats, barley, rye, Kaffir corn, millet seed, flaxseed, pea, and both navy and soy beans. All, with the exception of millet seed, were below the optimum in their content of vitamin A. Seeds are also deficient in vitamin B and in antiscorbutic properties. When seeds alone are used as the sole source of nutriment, it is not possible to secure appreciable growth in young animals.

*Wheat* is the most important seed grain used as food by all western peoples. The chief protein of wheat (gliadin) is superior to that of any other grain. The prominent place of wheat in the diet of mankind is justified by the results of experiments on animals. Wheat, however, is poor in calcium, phosphorus, sodium, chlorine and iodine. The wheat germ contains most of the proteins which are of good quality, is exceptionally rich in vitamin B and contains some vitamin A. The oil of the germ contains vitamin E. In making white flour, the germ and bran are both removed.

*Whole wheat flour* contains about 95 per cent of the kernel, including the germ. *Graham flour* consists of the whole wheat kernel ground to a fine powder between the upper and nether millstones. *Patent flour* is a refined flour made by the roller mill process. *White flour* represents only about 73 per cent of the wheat kernel. Its popularity consists in the fact that it keeps better than whole wheat flour on account of the absence of fats. Furthermore, flour which contains the germ such as whole wheat or graham flour, tends to harbor weevils. Patent wheat flour contains an average of about 11 per cent protein and 72 per cent starch. It is conspicuously lacking in mineral components and deficient in all vitamins. It has become our most

important energy-yielding food. While patent flour is inferior in nutritive value to whole wheat flour, it is a valuable food, but it should be supplemented in the diet to make up for its deficiencies.

*Rice*, next to wheat, is the most important cereal grain in the diet of more than half of the human race. It is used especially in the wetter parts of the world. The practice of polishing rice had its origin in the desire to improve its keeping quality. The demand for white rice and the artificially established liking for white flour and white corn meal are illustrations of the failure of the instinct of man to serve as a safe guide in the selection of food. The esthetic sense is appealed to by products of low biologic values.

**OTHER SELDS.** The proteins of corn have a slightly lower value in nutrition than those of wheat. The oat kernel is comparable to wheat in its dietary properties in nearly all respects. The legume seeds, such as peas and beans, are richer in protein than any of the cereal grains, but nutrition experiments show their protein to be incomplete.

**Leaves.** Edible leaves can be classed together as foodstuffs of similar character. They resemble one another just as do the seeds in other nutritive properties. Leaves are especially rich in just those elements in which the seed is poorest, namely calcium, phosphorus, sodium and chlorine. They are also a source of vitamin A. Thin leaves are more complete foods than thick ones. The thin leaves are cellular structures. The thick leaves contain reserve food material and some, like the cabbage, have been modified to storage organs containing reserve food and comparable to that stored in the endosperm of the seed. The fleshy leaves therefore tend to have in some degree the dietary properties of the seed.

Chief among the leafy vegetables are cabbage, lettuce, spinach, collards, turnip tops, beet tops, Brussels sprouts, endives, dandelion greens, kale and water-cress. Asparagus and string beans have much the same properties as the leafy vegetables.

The leaf is the synthetic laboratory of the plant. It builds up proteins, starch, sugars and fats. The surfaces of the leaf are a mosaic of living cells. They contain all the chemical complexes which are necessary for the nutrition of the animal cells, and are qualitatively complete foods. In general, leaves are analogous to cellular organs of animals, such as liver, pancreas and kidneys, in dietary properties. Leaves are exceptionally rich in minerals, especially calcium and vitamins. They contain vitamins A, B and C, but C is injured when the leaf is cooked. The outer green leaves of head lettuce contain a greater concentration of vitamin A than the inner bleached part. This suggests a relation between chlorophyll and this food factor. The indigestible residue is smooth and nonirritating. The leafy vegetables are excellent supplementary foods.

White celery is succulent, structurally weak and chlorophyll-free. Pathologically it is edematous, rachitic and anemic.

**Tubers.** After the seeds, the tubers of certain plants constitute one of the most important classes of energy-yielding foods. The potato is by far the most important representative in this group in Europe and America, but several other kinds of tubers are widely used as human food in the Orient. The potato and other tubers are classed with the seeds from the standpoint of nutrition, because they consist mainly of reserve material. Potatoes contain vitamin C, and crop failure with famines are part of the history of scurvy.

**Fleshy Roots.** Fleshy roots, such as the sugar beet, sweet potato and carrot, are similar in a general way to the potato, respecting both dietary properties and biological functions. They have a cellular layer at the periphery, and the interior is loaded with reserve foodstuffs. Steenbock and Gross found that carrots and sweet potatoes, both of which contain yellow pigment, are far better sources of vitamin A than are any of the roots which do not have a yellow color, as rutabaga, dasheen, beet, parsnip, potato, mango and sugar beet. Feeding tests have shown that the properties of the beet resemble those of the seed and tuber rather than those of the leaf. The fleshy roots and the potato and the sweet potato have an inorganic content which resembles that of the seed in a general way.

**Fruits and Berries.** The chief uses of fruits in the diet depend upon their salt content, their laxative properties, and their antiscorbutic value. Fruits do not rank high as sources of energy to the body; that is, their caloric values are rather low in comparison with most of the common food products. Fruits are almost without exception devoid of fats and are poor in protein. They are fair sources of mineral salts. Some of them contain carbohydrate, such as the sugars in the orange and the banana. They all have a high percentage of water. The citrus fruits are rich in organic acids.

Most fruits contain vitamin C, especially the citrus fruits—oranges, lemons and grapefruit. The tomato ripened in the field is also rich in it, but those picked green and ripened by time contain very little. Berries contain the same organic acids as are found in the ordinary fruits, which they resemble in dietary properties.

Fruits and vegetables are manipulated and prepared for the market in different ways, some of which interfere with their vitamin content and nutrient value. They are picked green and air ripened; reddened and ripened with ethylene; dried, pasteurized, etc. Methods for removing the residues of arsenical sprays have health implications.

The addition of fruits and vegetables to the diet tends to establish the acid-base equilibrium. They favor elimination and should be used regularly.

**Nuts.** Nuts are the seeds of plants. They are useful but rich, that is, a concentrated food which limits their use in the diet. With the exception of the chestnut, they are rich in proteins and fats but poor in carbohydrates, and are an available source of vitamin B.

The proteins of nuts are similar to those of meat and fish. The protein of coconut contains all the essential amino acids. Since the protein of nuts is fairly high in lysin, it is a valuable supplement to the grain proteins.

Nuts, however, lack a satisfactory balanced mineral and vitamin content, being poor in calcium and vitamins A and C. The homely peanut is relatively rich in basic amino acids in which the cereal proteins are relatively poor. Nuts vary considerably in composition. Chestnuts are starchy; coconuts and walnuts are rich in fat; while almonds, Brazil nuts, butternuts and peanuts are rich in both proteins and fat. Nuts in general, being rich in protein and fat, are comparable with meats as food.

**Vegetable Oils.** Vegetable oils are readily digested and are good sources of energy. Olive oil, cottonseed oil, maize oil, soy bean oil, coconut oil and sesame oil lack vitamin A and are not equivalent to such animal fats as butter and the fat of liver or kidney.

For a further discussion of the nutritive value of plants see McCollum and Simmonds (1925).

### HOW PLANTS MAY INJURE HEALTH

**Poisonous Plants.** Many plants contain a poison, such, for example, as aconitine, strychnine, ricin, abrin, muscarine, and a long list of other substances normally present. According to Chesnut (1902), there are about 500 species of plants in North America which are said to be poisonous. Most of these are rare specimens, and never eaten by man; some are poisonous only during certain seasons of the year; other are poisonous only when introduced parenterally into the human body; still others, such as the poison ivy, are injurious externally only to susceptible individuals, while many of them are known to be poisonous only to domestic animals.

Chesnut estimates that in the United States there are only about 30 species of plants which have been associated with poisoning in man, and furthermore most of such cases must be considered as extremely rare accidents. Instances of such accidents have been recorded by Jordan (1917), who cites the mistaking of the American false hellebore (*Veratum viride*) for the marsh-marigold; the use of the fruit of the Kentucky coffee tree (*Gymnocladus dioica*) in mistake for that of the honey locust; the use of daffodil bulbs for food; the substitution of the mountain laurel (*Kalmia latifolia*) for wintergreen, and the mistaking of the water hemlock (*Cicuta maculata*) for other edible roots. Poisoning from the latter cause is probably more frequent than supposed; in one year, in New Jersey alone, 10 cases, two of which were fatal, occurred. The water hemlock is one of our commonest swamp and brookside plants and one of the most deadly. This is probably the plant by which Socrates met death at the hands of the Athenians. The manuals on poisonous plants cite many other instances of accidental poisoning, due to the substitution, usually by children and the ignorant, of poisonous plants for similar food plants. A good example of this is the eating of castor beans, which are poisonous on account of the ricin they contain. Three or four beans cause violent gastro-intestinal symptoms, five or six are fatal for a child, and 20 for an adult.

There is a great variation in the toxicity of plants, and tropical plants are more often poisonous than those of cooler climates, as is the case with fish, insects, snakes and other animals.

*Mineral substances* in plants rarely cause poisoning. Lead in grass has been shown to be the cause of symptoms of lead poisoning in cows, and plants manured with superphosphates which contain arsenic may absorb enough arsenic to cause sickness. Similarly, there is possibility of poisoning due to the use of insecticidal sprays, washes and powders on vegetables and fruits (see page 453).

*Acids* are of more common occurrence. Prussic acid occurs free in some plants as a glucoside in some others, especially in those of the rose and apple family. The bitter cassava (*Manihot utilissima*), from which ordinary tapioca is derived, contains prussic acid in considerable amount, and cannot be eaten in the fresh state. The prussic acid is dissipated by heat. Cases of poisoning due to this cause are not known.

Oxalic acid is common in many plants, and illustrative of its poisonous quality is the outbreak of so-called "ptomaine poisoning" reported in New York, which was

shown to be due to soup prepared from "Qchav" or "Szchav" leaves, more commonly known as sour grass, a species of sorrel. Two grains of oxalic acid were found in each ounce of the leaves, and four grains in each ounce of the stems of this plant. The soup which was taken contained about 10 grains of oxalic acid per pint. Robb (1919) reports a fatal case of oxalic acid poisoning due to eating dried rhubarb leaves. Marked exhaustion, hemoptysis, early cardiac failure, and greatly delayed coagulation time of the blood were the prominent symptoms observed in this case. The oxalic acid content (as oxalates) of the stalks of rhubarb varies from 1.5 per cent to 40 per cent, but there seems to be no figure available for the amount in the leaves. Many other foods contain oxalic acid, but in harmless amounts.

**OILS.** Some of the common vegetable *oils*, such as the oils of chamomile, cloves, cinnamon, sassafras, etc., may be poisonous in excessive amounts. Chesnut (1902) cites an instance of the death of a child following the ingestion of two nutmegs, while Jordan (1917) calls attention to an outbreak of sickness in Germany in 1911 due to the inclusion of maratti-oil (from the tropical plant *Hydrocarpus*) in a commercial substitute.

**CAROTINEMIA.** As reported by Hess and Myers (1919) a diet rich in carotin, which is the coloring matter contained in carrots, spinach, egg yolk and oranges, may produce a yellow discoloration of the skin, which resembles jaundice, except that the sclera are not involved. Carotin is also present in squash, and pigmentation of the skin has long been observed among vegetarians in Japan, where unusual amounts of this vegetable are used among farmers as a partial substitute for rice. There are no symptoms other than the pigmentation. The carotin and xanthophyll pigments derived from food are the sources of the coloring matters of milk fats and body fats, of egg yolk, of the corpus luteum, nerve cells, and other structures. Carotin (now carotene) is the precursor of vitamin A.

**Parasites.** Certain vegetables, such as lettuce, celery, water cress, radishes, and similar plants, eaten raw, may convey typhoid fever, cholera, dysentery (both amebic and bacillary), the eggs and larvae of animal parasites, and other agents of infections. This occurs from the use of night soil as fertilizer, or from infected water from a foul source. The extensive irrigation of crops of vegetables, generally eaten raw, with river water highly contaminated by raw sewage or the unchlorinated effluents of sewage treatment is a more recent source of danger. Exposure to the sun and desiccation of bacteria on the vegetables during marketing tend to mitigate the danger. All vegetables to be eaten raw should be washed thoroughly beforehand although this cannot be depended upon to remove all the bacteria.

#### POISONING FROM PLANTS

**Rhus Poisoning.** *Rhus* poisoning, also known as *Rhus dermatitis*, or *Dermatitis venenata*, is caused by an irritating resinous substance in the sap of numerous plants. The various plants which may provoke such irritation in susceptible subjects are at least 60 or 70 in number. The most common and best known of this group belong to the genus *Rhus*. *Rhus toxicodendron*, or poison ivy, is distinguished from other suspected creepers of a similar appearance by its possession of three leaflets instead of five. *Rhus diversiloba*, or poison oak, which grows especially in the western part of the United States, is a shrub or small tree. *Rhus venenata*, known as poison

sumac, poison dogwood, and poison elder, is a shrub or small tree, growing in swampy places in the United States and Canada as well as in Japan.

Of the six varieties of the rhus family that grow wild in Japan, *Rhus toxicodendron* and *Rhus vermicifera* are the most injurious. Among the plants which less frequently cause dermatitis are the nettle (*Urtica doica*), the primrose (*Primula obconica*), cowhage (*Macuna pruriens*), smartweed (*Polygonum punctatum*), balm of Gilead (*Podophyllum, Balsanum gileadense*), oleander (*Nerium odorum*), and rue (*Ruta*).

The part of these plants to be feared is the resinous sap. This sticky sap exudes from all parts of an injured plant, and when it comes in contact with the skin causes intense irritation resembling a burn. It frequently begins in the fingers, is acute in character, with swelling, often with vesicles and blebs, the exudate from which is nontoxic. The dermatitis occurs in sharply defined patches, elongated streaks, and other irregular shapes, corresponding with the original area of contact. It does not follow the nerve trunks. It seldom attacks the scalp or the inside of the hands. The original areas of contact are most affected and the parts of the skin to which the poison has been transferred from the original sites of contact are usually less severely affected. McNair (1916) reports that, together with the local lesions, there are a leukocytosis, and constitutional disturbances, such as fever, coated tongue, loss of appetite, constipation, and a trace of albumin in the urine. The attack may subside in from four to six days, depending on the amount of the irritant and the sensitiveness of the skin. Idiosyncrasy plays an important part. Some persons are exquisitely susceptible; others resistant. The resin is not toxic for the lower animals.

The toxic principle in rhus poisoning is not volatile, as was once supposed; in other words, contact is necessary, although not actual contact with the plant itself, for the sap may be carried indirectly by clothing, tools, insects, smoke, etc., to the skin of persons far from the actual neighborhood of the plant, thus explaining those mysterious "recurrent" cases of rhus poisoning. Sap thus carried loses its toxic properties by oxidation, the loss being more rapid at body temperature and moist atmosphere.

Japanese lacquer ware when new has caused a dermatitis in a large number of persons. The sap of the lacquer tree produces typical rhus poisoning. Susceptible individuals may be affected by passing under a lacquer tree, or by simply going by a lacquer-ware shop. This does not mean that the poison is volatile, for in such instances the sap is transferred in some mechanical way.

McNair has shown that smoke from the heated leaves of poison oak causes dermatitis if blown on the wrist. If, however, the smoke is filtered through glass wool, it is no longer irritating, showing that the smoke is only a mechanical carrier of the poison, thus confirming the oft-repeated observation that poisoning may result from exposure to smoke of camp fires, etc. The exact nature of the chemical substance is not known, but it is now clear that it is resinous in nature, and that it is absent from the pollen and plant hairs. The toxic substances in the several plants are identical or very closely related.

Prevention consists in avoiding the plants. In addition, those who are susceptible should exert care in handling articles of clothing, tools, playthings and pets which have been in contact with them. The poisonous plants may be eradicated by spraying with a strong solution of common salt in soapy water or with kerosene. Innumer-

able attempts have been made to immunize against rhus poisoning by ingestion of the leaves, oral administration of the tincture and by hypodermic injection of toxic extracts. None of these measures has proved successful as a preventive.

The dermatitis may sometimes be averted, even after handling these plants, by the free use of an alkaline soap and water, or alcohol, containing a little dissolved sodium hydroxide. The poison is soluble in alcohol and alkalis. Gasoline may also be used. An aqueous solution of sodium bicarbonate is less effective. The washing must be prompt and thorough or else it will only tend to spread the irritating poison.

**Ergotism.** Ergotism is a form of food poisoning brought on by the prolonged use of meal or bread made from grain contaminated with ergot, a parasitic fungus (*Claviceps purpurea*), which is a disease of rye and occasionally of other grains. The fungus grows in the grain as a hard, blackish mass called the sclerotium, the presence of which may be suspected by the color of the meal which is grayer than usual and often shows violet-colored specks. The chief source of the poisoning in man is from rye, in which case the fungus may entirely replace the grain.

The composition of *ergot* is complex and still not completely understood. Several active principles have been extracted. One of these, *ergotoxin*, has a powerful action on the tissues. Ergot also contains several bases, such as *tyramine* and *ergamin* (histamine), which are also found in putrefying meat and are derived from the amino acids, tyrosine, histidine, and leucine by the loss of the carboxyl group. It contains ergosterol, the precursor of vitamin D.

*Chronic poisoning* with ergot may take either of two forms, *gangrenous* or *convulsive*. The gangrene is evidently due to vasomotor constriction and contraction of the unstriated muscle, and usually involves the limbs, especially the fingers and toes, but occasionally the ears and nose. Sometimes the whole arm or leg becomes cold and anesthetic, dark in color, and then dry, hard and shrunken, and falls off with little or no pain and no hemorrhage. In the milder cases there is only skin necrosis. In the convulsive form, the first symptoms are depression, weakness and drowsiness, often headache and giddiness, painful cramps in the limbs and itching of the skin. The spasms are prefaced by muscular pains and cramps and may continue only a few hours or perhaps for days. In severe cases paroxysmal convulsions set in, often epileptiform. This form was often fatal in early times. As a general rule, the gangrenous type prevailed almost exclusively in the epidemics in western Europe, while in eastern Europe the convulsive form was usual.

Ergotism occurred in epidemics from the use of bread containing ergot after poor harvests and especially in wet seasons. The last large epidemic in the United States occurred in New York in 1825. The history of ergot was given by Kobert in 1889. The disease was formerly endemic in Europe, but of late years epidemics have become rare except in Russia. Some of the "plagues" of medieval Europe may have been due to ergot poisoning. Hirsch reported some 28 outbreaks in the nineteenth century.

**Lathyrism.** Lathyrism or vetch poisoning is a rather rare condition met with in some parts of Europe, notably Austria and Italy, in northern Africa, and in India. It is associated with wretched conditions of living. The vetch seed is ground in the form of meal and used as a partial substitute for wheat. The seed is popularly known as chick-pea. The vetch seeds are obtained chiefly from *Lathyrus sativus* and *Lathyrus cicera*. The eating of bread prepared from meal containing the seeds of the

lathyrus is followed by sudden and severe pains in the lumbar region, girdle sensation, spastic motor paralysis of the lower extremities, tremor and fever. The nature of the poison is not known, but it is probably of the nature of a toxalbumose, of which ricin and abrin, the poisons of the castor bean and the jequirity bean, respectively, are well-known examples.

**Favism.** Favism (*fava*, bean) is the name applied to a disease which has been reported in Italy. It is attributed to the use of beans as food, or even just smelling the blossoms of the bean plant. It is said to occur only where beans are cultivated on a large scale, and then usually only during the spring of the year. Of 1,211 cases which were studied by Fermi in Sardinia, 752 were ascribed to ingestion of the beans, and 459 to inhalation of the odor or pollen of the bean plants. The onset of symptoms occurs a day or so after ingestion or from two to six hours following inhalation. It is distinguished by acute, febrile hemolytic anemia with jaundice and hemoglobinuria, but there may also be abdominal pain, nausea, vomiting and diarrhea.

**Mushroom Poisoning.** The ill effects from eating mushrooms are usually due to mistaking the poisonous for the edible species, and in America this is usually done by children, immigrants or the ignorant.

The number of species of poisonous mushrooms which are capable of causing death is not very great, perhaps 20 or 30. *Amanita* and *volvaria* are the most poisonous genera, and are the ones usually involved in the fatal accidents.

Ford (1906) estimates that from 12 to 15 deaths occur annually in the United States from *amanita* poisoning. In September, 1911, in the vicinity of New York, following heavy rains, 22 deaths were reported.

*Amanita phalloides* and *Amanita muscaria* are exceedingly poisonous, dangerous and seductive species, responsible for most of the deaths from toadstool eating. *Amanita phalloides*, because of its white color, is mistaken for the common mushroom, *Agaricus campestris*. *Agaricus campestris* does not grow in the woods, neither has it white gills, nor white spores, nor a volva at the base of the stem. No dependence, however, should be placed upon color, size, shape or general appearance. It often requires a trained mycologist to distinguish one species from another.

The first historic instance of mushroom poisoning occurred in the family of the Greek poet, Euripides, who lost, in one day, wife, daughter and two sons. Among others whose lives have been sacrificed through ignorance may be mentioned Pope Clement VII, the Emperor Jovia, Emperor Charles VI, Berronill of Naples, the widow of Tsar Alexis, and the Princess of Conti. Poisonous fungi have figured prominently in many of the accidental and craftily malicious tragedies of history.

Poisonous mushrooms contain at least four classes of poison: (1) a "toxin" represented by amanitotoxin; (2) muscarin, an alkaloidal-like substance, resembling pilocarpine; (3) a hemolytic poison; and (4) a number of poisons more or less ill defined, such as the Pilztoxin of Harmsen. These poisons do not all occur in any one species, but are found singly and in various combinations in the different genera and species. Ford (1923) classifies mycetismus, or mushroom poisoning (1) gastro-intestinal, (2) choleric form, (3) nervous form, (4) hemolytic and (5) cerebral form.

*Amanita phalloides*, the "white or deadly amanita," is the cause of the greatest number of cases of mushroom poisoning, if we include in this group *A. verna*, *A.*

*bulbosa*, *A. alba*, *A. virescens*, *A. mappa*, and many other species known by various names in different localities. Fatal poisoning takes place when the fungi are eaten raw or cooked. Two or three deadly amanitas are sufficient to cause profound illness with fatal outcome in an adult. Plowright reports the death of a child of 12 years from eating a third of the pileus of a small raw plant.

In 1891, Kobert isolated from *Amanita phalloides* a substance having a powerful hemolytic action which he called *phallin*. For some time it was believed that phallin was the essential poison of *Amanita phalloides*, but Ford (1906) showed that there is another substance present which is much more toxic, and to which most of the symptoms can probably be traced. This is supported by the fact that boiling *Amanita phalloides* destroys its hemolytic power, but fails to neutralize its toxic action. This substance Ford has called "amanitotoxin" and states that it has no hemolytic action, but rather produces hemorrhage and causes necrosis and fatty degeneration of the parenchymatous organs. He also succeeded in producing an antihemolysin which completely neutralizes the blood-laking properties of phallin. Clark and others (1915) found that in cases of *Amanita phalloides* poisoning, the pathological lesions consist chiefly of central necrosis of the liver, epithelial necrosis of the kidney, acute enteritis and colitis, the kidneys being the seat of the most marked changes. These investigators conclude that the nervous and mental changes observed are probably uremic in character, and not due to some peculiar "neurotoxin."

The symptoms of poisoning by *Amanita phalloides* usually do not develop for from 6 to 15 hours after ingestion, the onset being marked by sudden, severe abdominal pain, intense thirst, nausea, retching, vomiting and profuse watery evacuations, sometimes containing blood and mucus. A state of collapse may soon develop. There is usually a rapid loss of strength and flesh, and the patient develops a peculiar yellow color. The pupils are usually contracted; the breath is quite fetid and the mucous membranes dry and glazed, and there may be bleeding from the gums. Visual disturbances leading to confusion, delirium and convulsions may develop, but convulsions are usually due to a mixed intoxication, which in turn is due to *Amanita muscaria* being mixed with *Amanita phalloides*. After three or four days in children, and usually six or eight in adults, the patients sink into a profound coma from which they do not often awake. Ford (1906) states that the case fatality rate of *Amanita phalloides* poisoning is from 60 to 100 per cent. The danger is much less in the case of *Amanita muscaria*.

Muscarine is the active poisonous principle of *Amanita muscaria* (*Agaricus muscarius*, "fly" amanita). Muscarine ( $(\text{CH}_3)_3\text{NOH} \cdot \text{CH}_2\text{OH}$ ) is a syrupy, alkaloidal-like substance obtained in crystallizable form as a hydrochloride. It was first isolated by Schmiedeberg and Koppe in 1869. Chemically it evidently is an ammonia substitution compound and is classed with the ammonia bases. It may be prepared synthetically by the oxidation of chlorine.

The physiological action of muscarine resembles pilocarpine very closely. It stimulates the myoneural junctions between the nerves and epithelial cells. Atropine is an almost perfect physiological antidote for muscarine, paralyzing the myoneural junctions, and is used with more or less success in mushroom poisoning.

The symptoms of muscarine poisoning come on quickly, often within 15 minutes after eating the mushroom (*Amanita muscaria*). They consist of salivation exces-

sive perspiration, a flow of tears, nausea, retching and vomiting, pain in the abdomen, and violent movement of the intestines, causing profuse watery evacuations. The pulse is sometimes quickened, sometimes very slow and irregular. The pupil is contracted, respiration often quickened, and dyspneic. Dizziness and confusion of ideas are often complained of, but mental symptoms are not so conspicuous as those from the peripheral organs. Mental symptoms, such as hallucinations, delirium and convulsions are attributed to the Pilztoxin of Harmsen. Eventually the respiration becomes slower, great muscular weakness supervenes, but consciousness remains more or less clear until the breathing ceases.

The peasants of the Caucasus prepare an intoxicating beverage from *A. muscaria* which produces wildly riotous drunkenness. Death from muscarine orgies is not uncommon in this part of Russia. Similar species in Northeastern Asia are also used as an intoxicant. The poison is excreted in the urine which is sometimes later consumed for its intoxicating effect. It is probable that a sort of tolerance to muscarine is developed among the habitual users of the muscaria decoction.

The alkaloid is soluble in water and poisoning may be prevented by soaking the mushrooms in water slightly acidulated with vinegar before they are cooked.

**Potato Poisoning.** Outbreaks of poisoning attributed to potatoes have occurred among troops. In 1895, Schmiedeberg reported outbreaks involving 357, 90, 125 and 101 men, respectively, and in 1899, Pfuhl recorded an outbreak involving 56 soldiers. The trouble was attributed to potatoes, sometimes new, sometimes old sprouting ones, and sometimes potato salad.

The onset of symptoms occurs usually only a few hours after eating the potatoes. Symptoms reported have been headache, abdominal pains, nausea, vomiting, diarrhea, prostration, dizziness, drowsiness and slight delirium. Fever has usually been absent. In some cases, dilatation of the pupils is reported. The symptoms only rarely become threatening and practically all the victims recover rapidly.

These cases were long regarded as solanin poisoning, but it is now plain that this does not account for outbreaks, some of which at least are bacterial in origin.

*Solanin* ( $C_{42}H_{75}O_{15}N_4$ ) is a glucosidal alkaloid closely resembling the saponins in reaction, and found in many species of *Solanum*, such as *S. nigrum* (black nightshade), *S. dulcamara* (bittersweet), and *S. tuberosum* (potato). The solanin content is highest in the potato peel, decreasing toward the center of the potato. It occurs chiefly in immature, sprouting or diseased potato parts which ordinarily are discarded before cooking.

Toxicologic tests on man have demonstrated that 0.2 gm. of isolated solanin may provoke untoward symptoms. Seldom would that amount occur in the quantity of potatoes which an adult might consume in the course of a day.

## FOOD ESTABLISHMENT SANITATION

WALTER TIEDEMAN, B.E.

The construction and operation of establishments in which foods are processed or in which they are prepared and served influence the safety and quality of the foods handled therein. Frequently, design and construction details which favor the protection of the health of workers and of the food consuming public and facilitate plant sanitation may be included not for those reasons but because they cut maintenance costs. The two go hand in hand. Even after foods are packaged, mishandling during shipping and storage may affect the sanitary quality as well as the nutritive value of such foods. For example, unfavorable conditions with respect to moisture and temperature may cause unwanted fermentation, and rat feces or urine may contaminate food. Manufacturers and processors of foods have become conscious of this to the extent of employing sanitarians to supervise their plant housekeeping. Good plant construction simplifies this function.

**Types of Food Establishments.** There are many types of establishments in this category; for instance, canneries, frozen food packing plants, bottling plants, breweries, flour mills, bakeries, plants producing edible fats and oils, milk and milk products plants, candy factories, syrup plants, sugar refineries, abattoirs, meat packing plants, food locker plants, cold storage and other food warehouses, as well as retail food markets and restaurants. The word "restaurants" is used here in the broad sense to include all establishments in which food or drinks are served to the general public. The special problems in the health field vary with type of establishment but common basic principles of control are quite generally applicable.

**Location.** Still speaking generally, the location of the plant is of fundamental importance from the standpoint of health as well as for economic reasons. A good potable water supply is the life blood of most food establishments and should be a primary consideration in the selection of the site. The chemical composition of the water also is important. Chlorination may be necessary and softening often is essential to maintaining clean equipment and a good product. Of equal importance are drainage of the site; sewage, waste and garbage disposal facilities; and assurance that gaseous wastes may be discharged into the air without health hazard or odor nuisance. The classification of natural waters into which wastes or effluents may be discharged has an important bearing upon the cost of waste treatment and the possibilities for the ultimate disposal of liquid wastes and, therefore, is a factor in selecting the site for a food plant. Interference from nearby industrial plants as through smoke, dust- or odor-laden air also should be considered. Other ordinary considerations in the selection of a site for any plant such as space for expansion,

shipping facilities, and suitability for the purpose may affect sanitation indirectly if not directly.

**Danger of Floods.** An item that may be easily overlooked in the selection of a site for a food processing or storage plant is the danger of flooding. Irreparable damage may be done to foods by flooding of a plant with polluted river water. The salvaging of foods from flooded plants has created serious problems for health officials. In one instance a large lot of chicle worth thousands of dollars which was drenched with sewage polluted river water was required to be held for months until freedom from coliform organisms was demonstrated and the chicle then was assumed to be free of pathogens and released for use.

**Water Supply.** Where a municipal water supply is not available at reasonable cost, development of an adequate supply of water satisfactory for various uses is of great importance. The fact must be recognized that our ordinary surface and ground water supplies are not just  $H_2O$  but a conglomeration of added chemicals, in small concentrations as a rule, but nevertheless capable of entering into reaction with foods, detergents or other substances. Filtration or chlorination or both may be necessary to make the water safe for human consumption. Generally it pays to soften and condition the boiler water supply to prevent encrustation. Softening of the water for cleaning or other purposes also may result in economies, improved food quality and improved operations. Iron removal may be necessary. Making the water immediately available in ample quantity at the various points where it may be needed throughout the plant is essential to efficient operation. Too frequently jobs such as washing containers are done ineffectively because of faulty design of pipe lines within the plant.

**Waste Disposal.** The disposal of liquid wastes may be or become a serious problem for plants discharging large volumes of such wastes. The advice of a competent consulting sanitary engineer should be sought in connection with special problems. The construction and operation of special plant waste treatment facilities usually is costly. The disposal of effluents from treatment plants also may become a problem. A southern New Jersey freezing plant with liquid waste amounting to 10,000,000 gallons on peak packing days reports that it is disposing of this waste economically by spraying it at a rate equivalent to 50 inches of precipitation per week in a forest. Similar nearby cultivated land would not absorb a small fraction of this waste.

**Sewage.** The discharges from the water closets and urinals should be handled in city sewers wherever possible. When sewage must be disposed of on the premises it should be handled separately from the food wastes and other drainage in order to minimize the quantity of waste that may contain human pathogens and to utilize for this purpose well known sewage disposal methods as by septic tank and cesspool or subsurface drainage which are not likely to be applicable to the bulk of the liquid waste.

**Solid Wastes.** Solid wastes from food plants vary tremendously in character and quantity. In small plants ordinary garbage disposal facilities may be utilized. The storage of garbage cans in specially designed cold rooms has been utilized to advantage to control fly breeding and prevent odors. Special wastes may be put to special uses. For instance, some sugar plants utilize the waste sugar cane after extracting the juice to operate the boilers and manufacture alcohol and ether from the waste

molasses, a mixture of which is used to operate sugar farm tractors and automobiles. The problem of disposal of solid wastes is one of the many that must be solved satisfactorily for smooth plant operation without nuisance.

**Height of Buildings.** In new structures the trend appears to be toward single story buildings with high ceilings and relatively few partitions. Such buildings generally lend themselves readily to the maintenance of good sanitation. However, multistory buildings often are necessary and there is no reason why such structures cannot be so built as to make it easy to maintain good sanitary conditions therein.

**Plant Layout.** The factors that ordinarily affect plant layout, such as the even flow of materials to prevent the crossing of lines of movement, generally favor sanitary maintenance. In estimating the required floor space for food processing machines it is especially important to allow sufficient room around each unit to permit the easy removal of every part for cleaning and servicing as well as to permit cleaning of the outer surfaces of the machine. For instance in well planned milk pasteurizing plants it is likely that not more than one quarter of the usable floor space will be covered by equipment. Required headroom depends somewhat on the type of operation and needed heads for gravity flow of the product through equipment. Frequently, workrooms in plants that are easy to operate and maintain have ceiling heights between 15 and 20 feet.

**Materials.** The materials used for constructing the building are important from the standpoint of sanitation as well as from the standpoints of appearance, fire resistance and durability. Well-mixed concrete with smoothly trowelled surfaces is satisfactory for most purposes. Concrete blocks and cinder blocks present rather rough wall surfaces that are unsatisfactory in places subject to splashing with food. The growth of bacteria and molds on walls may become a problem. Smooth glazed tile walls usually are satisfactory and are easily maintained. The use of hollow tile for inner partition walls in warehouses has presented a problem from the standpoint of rodent control. Many tiles have been found to be broken or nicked sufficiently to permit rats to enter and nest in the hollow spaces. In general surfaces should be smooth, hard and easily cleanable.

**Floors.** Hard, wear-resistant floor brick or tile can be used to advantage for floors frequently wet and which are subject to wear as from rolling cans or barrels or trucking products over them. The inclusion of a steel grating, such as subway grating, in the surface of a concrete floor also serves to provide a wear-resistant surface. Another possibility is to incorporate a fine flint aggregate into the surface layer of concrete in floors. Terrazzo floors are subject to cracking and to attack by weak acids in wastes.

**Floor Drains.** Where floor drains are needed they should be placed close enough, say not more than 20 feet on centers, to avoid great differences in elevation between high and low points. Slopes of one-fourth inch per foot are sufficient and with careful finishing of the surface this may be reduced three sixteenths of an inch. Floor drains should be trapped and connected in accordance with the Standard Plumbing Code.

**Lighting.** Whether light is provided in working areas by means of windows or by artificial means or both is not likely to have a direct bearing on sanitation or health of personnel, providing good light is available at all times. In northern climates it is important that the artificial lighting be adequate as it is likely to be used a large percentage of the working hours. Considerations of morale, first cost and

economy of operation may determine how much natural lighting to provide. The important consideration is to direct natural light with alternate artificial light so as to prevent glare and at the same time to provide all points where food handling or cleaning operations are carried on with adequate light for the purpose. It is almost certain that a surface which the worker cannot see easily during the cleaning process will not be well cleaned.

An arbitrary standard suggested for public eating and drinking establishments by the United States Public Health Service Code is 10 foot-candles of light as measured by light meter on all working surfaces and places where utensils are washed and four foot-candles at 30 inches off the floor in storage areas. The basic criterion is that persons charged with the important duties of preparing and handling food for human consumption or of cleaning and disinfecting the equipment or containers with which it comes in contact shall have sufficient fixed light to clearly see that this work is done well and that there are no visible contaminants in the food. Dependence should not be placed upon the routine use of electric lights on leads which have to be carried from one point to another as the workers may not find it convenient to use them.

**Ventilation.** Ventilation is as important, if not more so, in the food plant as in many other types of work rooms. Excessive humidity and the presence of foreign odors are likely to be damaging to the flavors and consistencies of foods. Dust also may be harmful. Ventilation by air inlet and vent flue will do for some operations. In specific locations or over cooking operations, hoods and exhaust fans are necessary. For a number of operations in food plants in which control of flavor, texture or moisture content is important air conditioning is essential.

**Toilet Facilities.** The provision of adequate toilet facilities for employees generally is required under labor laws. Much effort has been directed toward requiring vestibules and self closing doors between toilet rooms and rooms in which food is handled. The basis for this is that flies may carry pathogens from fecal discharges to foods and that without this protection foul odors are more likely to reach foods. This is more of an esthetic than a health problem. Vestibules frequently do not serve the purpose for which they were intended. It is good practice to locate toilet rooms next to locker rooms. It is important that handwashing facilities be provided where they are convenient for workers after using the toilets, as well as in locations where food or sterile containers are handled. It is desirable that basins be installed with running hot and cold water and that soap and single service towels be provided. Many sanitary codes require that such facilities be provided. The posting of signs stating that workers are required to wash their hands after visiting the toilet and before returning to work is required in some health jurisdictions. Attractive pictures of hand washing may be a more pleasant reminder. This is one of many details of the personal hygiene problem which can best be handled by education of food handlers in this important subject.

**Disease Carriers and Cases.** The body discharges of workers in food handling establishments constitute a source of pathogenic bacteria necessary for the spread of human diseases. Fortunately, most workers carry pathogens in such discharges only sporadically and many of the bacteria in the spray from coughs and sneezes and those transferred by soiled hands do not fall on fertile ground. In other words instead of gaining access to bland moist foods they may be transferred to foods that

are too dry to support bacterial life for long periods or otherwise unfavorable or they may enter foods which later are subjected to heat treatment sufficient to destroy such organisms. Chronic carriers of diseases, such as typhoid fever, when they work at food handling frequently cause record outbreaks. The public health program of following up cases of disease likely to result in carrier status, thus locating carriers who then can be prohibited from handling foods and kept under surveillance, has been fruitful in decreasing the number of recorded food-borne outbreaks of such diseases. Nevertheless, every practical safeguard should be taken to see that carriers do not work in food plants.

**Medical Examinations.** Attempts at controlling the spread of diseases through routine medical examinations of food handlers have been decidedly unfruitful. In fact they tend to give a false sense of security. Some diseases develop very rapidly. Physical examinations cannot be made frequently enough nor, in quantity, thoroughly enough to offer real protection. Perhaps the best that can be done is to encourage workers to report illnesses no matter how minor, to provide sick leave or temporary employment that does not involve food handling for such workers and also for those with suppurating wounds on exposed parts of the body.

**Food Handler Training.** Wherever workers in food plants handle foods to be served without further cooking, health officials are justified in requiring training in personal hygiene. Much has been done directly by health departments in establishing such training courses. Such departments are in a good position to know what should be taught and have personnel who know the subject but seldom can combine this with good educational methods. Furthermore they are not usually well enough staffed to continue offering such courses indefinitely. Team work between health departments and departments of education may lead to putting food handler training on a sound basis from the standpoints of quality and sustained effort.

**Rodent Control.** For food handling plants in general, the design of the building and the building materials should be such as to build rats out. Such things as false ceilings, boxed staircases, enclosed hollow wall spaces of nonrodent-proof materials and improperly boxed counterweights should be avoided. Access of rats should be barred to places where they can secure food or drink.

**Roaches.** Similarly, life in the food plant can be made unattractive to roaches by eliminating harborages, as by avoiding loose mouldings, sealing electric fixtures and conduits, and making it difficult for roaches to reach food and water.

**Flies.** The answer to the control of insects such as flies is not simply screening. Screens keep flies in as well as out and with the continuous moving of goods into and out of the building many gain access to the building notwithstanding effective screening. The incorporation here and there of well-placed panels of electric screening frequently is effective. Flytraps also may be used with good effect. The use on walls and ceilings of contact poisons such as DDT or chlordane may be satisfactory, at least until resistant strains of flies develop in rooms that may be treated at times when no food or containers or equipment with which food may come in contact are exposed. Caution must be observed to avoid the use of contact poisons in places where they may scale off or drop into foods, or food containers or equipment. The routine use of space sprays is not indicated. However, they may be used under controlled conditions. Some plants resort to directing the air currents from powerful fans against much used doorways to keep flies out. The provision of entrances only

through refrigerated vestibules generally is impracticable but may impose an effective barrier against flies. Electric screens and flytraps may be used economically and effectively.

**Infestations.** For special types of food plants frequent fumigation may be necessary to control such insects as weevils or beetles or their larvae. In some instances it may be advisable to install and use fumigation chambers through which all products entering or leaving the plant must pass. Fumigation is a special problem in flour mills where such insects as the confused flour beetle may cause considerable damage to the product.

**Fumigation.** The infestation of foods with insects or their larvae is repulsive to the consumer and the tendency on his part is to destroy foods so contaminated. However, there is no convincing evidence at the present time that specific diseases may be transmitted in this way. In instances where supplies of food have been limited, as with combat forces, attempts have been made to remove insects by sieving flour or to use the flour including the insects, larvae and eggs without apparent ill effects. The only satisfactory procedure commercially is to control such insects by fumigation at the manufacturing plant followed by packaging in well-sealed units.

**Fumigants.** Among the fumigants used in gaseous form are methyl bromide, ethylene dichloride mixed with carbon tetrachloride, chloropicrin and hydrocyanic acid. Methyl bromide is valued because it penetrates well, is noninflammable, non-explosive and does not injure equipment or most foods. It is effective but relatively slow in action so must be securely confined and cannot be used in loosely constructed buildings.

*Ethylene dichloride* ordinarily is mixed with 25 per cent of carbon tetrachloride to cut the fire hazard. The mixture evaporates to form a penetrating heavy gas which sinks to the bottom of confined spaces. Like other fumigants it must be used with caution but is slightly less toxic to man and insects than hydrocyanic acid gas and chloropicrin.

*Nitrotrichloromethane* or *chloropicrin* is toxic to insects in all stages. It tends to cling to fumigated objects requiring thorough airing after fumigation. Explosion or fire hazard is not a problem. It is quite irritating, especially to the eyes.

*Hydrocyanic acid gas* is most effective. It works rapidly and without damage to most foods. In the concentrations used it does not create a fire hazard. Great care must be exercised in its use because it is a deadly poison to humans.

**Provisions for Fumigation.** In designing a new plant the need for the control of infestations should be recognized depending upon the foods to be handled and provisions should be made for methodical control by fumigation or otherwise. Failure to build so as to make control simple and the application of spasmodic efforts to clean up when conditions become unbearable is not only unscientific but unbusiness-like.

**Air Conditioning.** The control of temperature or humidity or both during processing is important in some food plant operations. With modern air conditioning this can be done according to need. The removal of particulate matter or gases from the air circulated through the plant or used in processing may in some instances be a necessity. Savings in waste and added returns resulting from the production of consistently high class products generally will cover the cost.

**Instrumentation.** Instrumentation throughout the plant may not have a direct bearing on health but should help improve the keeping quality and nutritive value of the product which is an indirect benefit to health. Such instrumentation may include automatic temperature and pressure controls with chart records and automatic timing of processes. Such control is invaluable in food processing. From the standpoint of public health this is especially true of operations involving pasteurization or sterilization. It may be carried further to automatic sorting operations and color control.

**Control Laboratory.** The product control laboratory is an essential element in maintaining a uniformly sound, tasty, good looking and nutritious food product. This laboratory also should be utilized to check the sanitary quality of such foods. Surprising evidence has been obtained in a number of instances of the part played by bacteria of devious kinds in changing the initial product or by-products and in making it difficult to maintain good quality. Good laboratory work can do much toward resolving operational difficulties and at the same time make the product safe.

**Storage.** Adequate facilities must be provided for the storage of packaged products pending shipment. For unrefrigerated storage, systematic stacking of the product in such manner as to avoid the creation of rat harborages is necessary. Where floors are damp, metal frames may be required to keep the first layer of cartons off the floor. Some products, such as evaporated milk, require inversion at monthly intervals, but even these should be stacked carefully to avoid forming nesting places for rats or, if this is not done, the interval between inversions should be made less than 25 days which is the average gestation period for rats. For the storage of products in bulk or in cloth or paper sacks rodent control is especially important. In addition to many other skills the plant sanitarian should be trained to recognize rat runways and rat harborages. He can do much to facilitate rodent control in his periodic inspections of the plant, including storage rooms.

**Cold Storage.** Where cold storage of products is necessary, attention should be given to the construction of floors, walls and ceilings to provide adequate durable insulation. Duplicate refrigeration units are desirable with a standby power source, if possible. Either good circulation of air should be established to maintain a uniform temperature in various parts of the cold storage room or the temperature distribution should be studied and various foods should be so placed as to be in the most favorable temperature zone. The ripening or curing in cold storage of products such as Cheddar cheese has been shown to proceed much more rapidly at 60° F than at 40° F. Since pathogens, if present, tend to die off more rapidly with speedier ripening this is one instance favoring a higher storage temperature.

The control of cold storage plants either operated by a food plant or as a separate entity in the food marketing program is considered necessary in many states for the protection of consumers. Direct health hazards are believed to be unlikely. However, with gross mismanagement, which would be possible without control, problems could arise resulting in food poisoning or the culturing in food of chance pathogens. Present control consists largely of licensing operators, requiring the numbering and dating of individual lots of food, regulation of storage temperatures, the keeping of records, periodical reporting, and restrictions upon the length of time certain foods may be held in storage.

**Frozen Food Locker Plants.** Since the introduction of the process of quick-freezing foods for storage, there has been a rather extensive development of frozen food locker plants, especially in rural communities. There appears to be a tendency to start such plants on limited capital and in some instances to develop them by adding slaughtering and food processing operations beyond the limitations of the original plant or site resulting in insanitary conditions. Furthermore, the original insulation of the cold storage rooms and capacity of the refrigeration plant are likely to be inadequate. As the result of the study of this problem the Committee on Sanitary Engineering and Environment of the National Research Council made the following recommendations:

1. It appears to be most important that operators who proposed to build locker plants be required to have plans drawn up under the supervision of a competent engineer and to submit them to and secure the approval of the state health authority before any construction work is commenced.

2. To insure low heat infiltration and thus encourage the maintenance of required low temperatures, special attention should be given to the construction of the floors, walls and ceilings of cold rooms and of the conductances of materials used in building them.

3. Separate compressors of the same make should be provided for the chill room, and for the sharp-freeze and storage rooms. Each of these compressors should have sufficient capacity to carry the whole cooling load and should be so installed that it can readily be used for either service.

4. Standby electric service should be provided wherever possible.

5. Locker plant operators should consider future requirements for services such as operating slaughter houses, meat processing plants, food processing plants, kitchens and bakeries in conjunction with their locker plants.

6. Locker plant regulations should be sufficient to insure health and sanitation without standing in the way of individual initiative and progress.

**Equipment.** Too much of the equipment in the food field has been designed and built by well intentioned engineers with extensive experience in building for mechanical perfection but little if any knowledge of public health, sanitation or food quality control. In fact, frequently, little attention has been given to the effectiveness with which the equipment performs the function for which it is intended. Engineers in the public health field have been insisting more and more that primary consideration be given to performing public health functions and to construction that makes cleaning easy. Beyond this, maintenance of quality of the product becomes the next important item.

**3-A Standards.** Realizing that the setting of standards for milk plant equipment by each local health department would result in confusion and require expensive custom-made equipment and that health officials, suppliers and users of equipment had identical interests, the International Association of Milk and Food Sanitarians, the United States Public Health Service and a Dairy Industry Committee are co-operating in a program for setting standards known as 3-A or three agency standards for various pieces of milk plant equipment. This program is well under way and a number of standards have been established to the apparent satisfaction of all concerned.

**N.S.F. Standards.** More recently the National Sanitation Foundation has in-

augurated a program in which a joint committee comprised of representatives of all the leading public health associations in the United States, working with task committees of various industries in the food equipment field will establish what are known as N.S.F. standards for food equipment in those fields. It is the intention to permit the use of an identifying seal of approval on equipment that has been tested and found to meet the established standards. The State and Territorial Health Officers Association acted at their meeting in 1950 to encourage the creation of such standards by the National Sanitation Foundation. Work now is in progress for establishing standards for soda fountain and luncheonette equipment, for food service equipment, and for spray-type dishwashing machines.

**Official Control of Plants.** The regular inspection of milk pasteurizing plants by local health departments is an established procedure. The public health need for official control of retail food stores and of restaurants is recognized and many local health departments perform this function. The amount of work to be done is tremendous. Progressive business men realize that it is to their interest to maintain good sanitary standards. The most successful programs in this field are being carried on primarily by industry with the cooperation of health and other officials.

**Restaurants.** Popular demand for the inspection by health officials of public eating and drinking establishments stems from occasional observations by patrons of revolting conditions surrounding the preparation and serving of food, in addition to attacks of food poisoning they experience. Regardless of relative health importance, the public frequently insist upon official control. Enforcement procedures that have been tried include alphabetical grading, numerical scoring, awarding approval and the issuance of revocable permits or licenses. Any of these systems can be made to work but none are self-enforceable and all require constant effort on the part of operators and enforcement officials.

The same general principles of sanitation apply to restaurants as have been discussed for food plants generally. Primary considerations are safe water and food supplies. Only pasteurized milk and milk products, including cheese, should be served. Cases of undulant fever among persons who always drink pasteurized milk at home have been traced to the unwitting consumption of infected raw milk products at unsupervised wayside eating establishments. Pork should be thoroughly cooked. Other foods, such as oysters, should be secured from approved sources. Adequate refrigeration is essential especially for cooked meats, custard filled pastries, and similar foods in which toxin producing bacteria may grow. Such foods have been responsible for many reported outbreaks of food poisoning. The training of all food handlers in hygienic methods of performing their daily tasks generally is recognized as of equal importance. An Ordinance and Code Regulating Eating and Drinking Establishments has been recommended by the United States Public Health Service (1943). This contains explanations of the public health reasons for various requirements, suggested enforcement procedures and an inspection form. Those who do not favor alphabetical grading may use the alternate provision for enforcement by permit revocation.

**Washing and Sanitizing Dishes.** Serving drinks in soiled glasses and food in soiled dishes or supplying food encrusted silverware is disgusting if not a menace to health. The finding of wash water with a standard plate count of 3,000,000 per ml. in a single-tank dishwashing machine in a busy city restaurant pointed out the

possibilities. This does not represent average conditions but it occurred in a popular and supposedly well operated restaurant located on the main street of a large city. The potential hazard is apparent when it is taken into consideration that this wash water was maintained at a favorable incubating temperature, became a good medium for bacterial growth through constant additions, from soiled dishes, of residues of food including milk and gravy, became a haven for organisms from the mouths of hundreds of patrons, was not completely emptied between meals providing long incubation periods, and that the final rinse water was applied for perhaps 10 seconds at a temperature of about 140° F and did not strike all portions of the dishes due to the shielding effect of the wooden dish racks. A study of mechanical dishwashing by Mallmann and others (1947) served to point out the importance of maintaining adequate temperatures and pressures, fixing time intervals and securing good spray patterns in mechanical dishwashing. This was implemented by a report by the National Research Council (1950) giving users, especially the armed forces and hospitals, a basis for buying and installing machines that can be operated effectively.

**Single Service.** Expendable paper cups and paper or wooden forks and spoons are available in a number of forms. Bacteriological examinations of packaged cups have shown them to be quite free of bacteria in general and there is no evidence that pathogens may be found. With normal current methods of manufacture and handling their use does not present a public health problem. Where adequate facilities for washing and sanitizing utensils cannot be provided as, for example, at small concessions at fairs, the use of single service containers is essential. For many other uses paper is acceptable and economical. There have been instances of abuses such as the re-use of cups used for serving water. Generally, single service paper containers may be used with confidence as to safety and sanitation.

**Conclusion.** Food is used so generally, affects health so directly, and is subjected to so much handling and holding in storage in its passage from farm to consumer that the public has a vital interest in the sanitation of the plants and processes through which it passes. Fortunately, factors that favor maintaining good quality, which is something the consumer can judge for himself, also favor the protection of the public health and maintenance of good sanitary practices. Self-inspection by industry is an important adjunct. Effective official control at all stages of handling is impractical and must necessarily be limited to certain phases of food handling which are commonly acknowledged to be of more direct public health importance.

### 25

#### TEMPERATURE

##### HIGH TEMPERATURE

**Mechanisms of Heat Loss.** The ability of the body to maintain an almost constant internal temperature while exposed to a wide range of external temperatures is due to its remarkable power of physiological adjustment. The human body is constantly producing heat as a result of metabolic processes within the cells. In order to maintain heat balance, a compensable amount of heat must be lost continuously. Excessive heat loss to cold environments or failure to lose heat in hot environments is disastrous to life. Only by adjusting the heat loss and heat production in relation to environmental conditions can the body survive.

The principal route of heat loss from the body is through the skin; small amounts of heat are lost also through the excreta and the expired air. Heat may be lost from the surface of the body by three methods: (1) conduction-convection, (2) radiation, and (3) evaporation. The environmental factors which determine the rate of heat loss through the skin are: the temperature of the air, the temperature of surrounding objects, the relative humidity, and the air movement.

When the air temperature is lower than the skin temperature, heat is lost from the body by conduction. Heat loss by conduction \* involves the direct transfer of heat to the air in contact with the skin or clothing. When the air in contact with the body becomes heated, it becomes less dense and rises. It is replaced by cooler air which in turn becomes heated. This motion of the air which results from differences in density is known as convection.† The rate of heat loss by conduction-convection depends on the difference between the temperature of the body surface and that of the air in contact with the surface—the greater the difference, the greater the heat loss. The skin temperature is normally between 31° and 32° C. Any adjustment which raises the temperature of the skin will increase the heat loss if the air temperature remains constant. When the external temperature equals the surface temperature (skin or clothing), no heat can be lost by conduction; when it exceeds the skin temperature, heat is gained by the body. Movement of the air, by changing the layer of air in contact with the body surface, increases the conduction heat loss when the air temperature is below the temperature of the body surface, but air motion has

\* "Thermal conduction is defined as the process of heat transfer through a material medium in which kinetic energy is transmitted by the particles of the material from particle to particle without gross displacement of the particles." (ASHVE Guide, 1949.)

† In actual practice, the term convection also includes forced air motion as well as the natural circulation of the air.

no effect on conduction heat loss if the temperature of the surface and air are equal.

The second method by which heat may be lost (or gained) by the body is through radiation. Radiation involves the transmission of energy by means of so-called electromagnetic waves. When such radiant energy, especially in the longer wave lengths, is absorbed, heat is produced, and an increase in the temperature of the absorbing body results. This form of heat transfer is commonly called thermal or heat radiation. All objects, which are above absolute zero degrees temperature, are continuously emitting radiant energy. The sun is the chief natural source of radiation. Wave lengths above 700 millimicrons, i.e., in the infrared range, are the most important portion of the spectrum for the production of heat. In addition to the sun, radiant energy in the heating range is emitted in large measure by open fires, molten metal, stoves, and all hot objects. Heat radiation, since it is the same type of energy transfer as visible light, travels at the speed of light, in straight lines, and is independent of the presence of air. The amount of heat radiation which is emitted from any object depends on the temperature, size, and character of the surface of the emitting body. A dull black surface emits the maximum amount of heat radiation for any given temperature. In contrast, aluminum foil at the same temperature emits very little heat radiation. The amount of heat radiation which falls on any object or person depends on the amount of heat radiation emitted by the surrounding objects and on the relation in space of the receiving object to the emitting surfaces. Heat radiation which falls on a surface may be absorbed or reflected by the surface or it may penetrate the surface depending on the character of the surface. When radiant energy falls on the skin or clothing, little penetration or reflection occurs and most of the radiation is absorbed at the surface. A surface with a flat black finish absorbs the maximum amount of infrared radiation. On the other hand, highly polished metals, such as aluminum or even aluminum foil, reflect 90 to 95 per cent of the infrared radiation; some metals also reflect the visible rays.

Since the body is constantly emitting heat radiation and constantly absorbing the same from surrounding objects, the net result may be either a gain or a loss of heat. If the temperature of the body surface is greater than the temperature of the surrounding objects, the body will lose heat. For example, if a person is surrounded by cold outside walls, he will lose more heat by radiation to the walls than he will gain from the walls. If, on the other hand, he is surrounded by walls or objects which are at a higher temperature than the body surface temperature or if he is exposed directly to sunlight, he will gain heat by radiation. Men exposed to large surfaces of heat radiation may have a skin temperature of  $107^{\circ}\text{F}$  when the air temperature is only  $33^{\circ}\text{F}$ . The temperature of the air plays no role in heat transfer by radiation except that it may alter the temperature of the surfaces with which it comes into contact. Foreign materials or water in the air may absorb radiant heat.

The third method by which heat is lost from the body is by evaporation of water from the body surface or from the clothing since, whenever one gram of liquid water is changed to water vapor, it absorbs 0.59 calorie of heat. The rate of evaporation depends on a difference in vapor pressure at the body surface and that in the surrounding space. The vapor pressure at the surface of the body varies with the degree of wetting and with the temperature of the surface. The vapor pressure in the

surrounding space depends on the temperature and relative humidity \* of the air. The higher the temperature, the more water vapor a space can contain at saturation. Evaporation ceases when the relative humidity reaches 100 per cent. Air movement aids evaporation from the body only by replacing the humid layer of air at the body surface with drier air. When the air temperature equals the body surface temperature and the moisture in the air is completely saturated, air movement is of no value in increasing heat loss either by conduction or by evaporation. Under comfortable environmental conditions, when a person is at rest, about 25 per cent of the heat loss is due to evaporation of water which diffuses through the skin (insensible perspiration) and to evaporation of moisture from the respiratory mucosa through the expired air. When sweating occurs, the amount of heat loss by evaporation is greatly increased, and at high temperature, evaporation of sweat is responsible for practically all of the heat lost from the body.

**Physiological Adjustments to High Temperatures.** At normal environmental temperatures, a person who is not engaged in physical work can lose sufficient heat by radiation and conduction without any physiological adjustment, provided there is no major source of radiant heat in the surroundings. As the external temperature increases above normal, certain physiological adjustments take place to facilitate heat loss. The first adjustment is vasodilatation in the skin which increases the circulation and thus the temperature of the skin. Because of the higher skin temperature, the heat loss by radiation and conduction is increased. However, peripheral vasodilatation tends to produce a fall in blood pressure. Under normal conditions, this fall in blood pressure is compensated immediately by an increase in pulse rate, and by a redistribution of the blood. There is also some evidence that dilution of the blood may occur, which leads to an increase in the blood volume and pressure. If the external temperature is further increased so that sufficient heat cannot be lost by conduction and radiation, a second mechanism is brought into play to increase heat loss: the sweat glands become active, and evaporation becomes the important method of heat loss. The temperature at which sweating begins depends on the rate of work, type of clothing worn, and on other factors. Sweating usually starts at a temperature between 81° and 88° F when at rest, but at lower temperatures when working. As much as two liters of sweat per hour, or even more, may be produced. The sweat which runs off the body is of little value in removing heat from the body, since heat is lost only when sweat is evaporated. The rate of sweating varies with a number of factors; i.e., the temperature and humidity of the air, physical work, acclimatization, water intake, condition of the individual, etc. The concentration of sodium chloride in sweat varies with the individual idiosyncrasies, the rate of sweating, the internal and skin temperature, the type and duration of work, the intake of water and salt, and, especially, the degree of acclimatization. Concentrations of NaCl in sweat from 0.03 to 0.6 per cent have been reported by different observers. This great loss of water and salt from the body, if not adequately replaced, may lead to a marked dehydration of the body tissues and reduction in blood volume, even

\* "The relative humidity is the ratio of the actual partial pressure of the water vapor in a space to the saturation pressure of pure water at the same temperature or, in other words, it is the ratio between the amount of moisture actually present in the environment to the amount which would be present if complete saturation occurred at the same temperature." (ASHVE Guide, 1949.)

to the extent of 6 to 8 per cent of the body weight. Drinking of water alone does not restore the blood volume; salt must be taken at the same time. It has been shown that men do not voluntarily replace the water lost by sweating; the sensation of thirst is quite inadequate.

If the temperature and humidity are both high, the body can no longer lose sufficient heat. The body temperature rises, the pulse rate increases, and the blood pressure becomes unstable, usually with a fall in diastolic level. Under extreme conditions, the metabolism increases, thereby leading to a greater heat production. Dehydration accentuates the rise in rectal temperature and pulse rate.

**Acute Clinical Conditions Resulting from Exposure to High Temperature.** Three general clinical conditions, which are directly related to the physiological stresses which have just been described, may result from exposure to high temperatures. They are: heat exhaustion, heat cramps, and heat stroke.

The most common clinical condition resulting from exposure to heat is heat exhaustion (heat collapse or heat prostration). This condition is one of circulatory collapse resulting from a failure of the circulatory system to compensate for the peripheral vasodilatation and dehydration described above. The symptoms may be very mild, with only dizziness, fatigue, and headache, or complete collapse with unconsciousness may occur. The body temperature may be as low as 96° F or it may be normal or slightly elevated. The blood pressure is always low at the time of collapse but may be normal by the time the patient reaches the dispensary. The skin is moist and may be either hot or cold. The blood and urine are usually normal. The treatment is similar to that used in all cases of circulatory collapse and consists of administering intravenous saline and glucose and cardiac stimulants.

The second type of acute clinical condition which results from exposure to heat is heat cramps. This occurs in men who are doing heavy muscular work in high temperatures and who are sweating profusely. The chief symptoms are the painful spasmodic cramps of the skeletal muscles most actively used during the preceding work period. The onset is usually sudden and may not occur until after the end of the work shift. The body temperature may be normal or slightly increased, the pulse rate is increased; the blood pressure, normal; and the skin, hot and moist. The blood is usually so concentrated that it is difficult to secure a blood sample. Analysis of the blood shows a marked fall in sodium and chloride, an increase in phosphorus and calcium, no change in the potassium, and either no change or an increase in the sugar. Heat cramps are due to the fall in sodium chloride in the blood and body dehydration which results from the loss of sweat. In severe cases, saline should be given intravenously; in light cases, water and salt may be taken by mouth. The cramps are relieved at once by such treatment. Administration of intravenous glucose and of drugs is of no value in relieving the cramps.

The third clinical condition which may result from exposure to high environmental temperature is heat stroke or sun stroke. There is no evidence that sun stroke differs from heat stroke; the effects of the sun are entirely due to the radiant heat. Heat stroke is by far the most serious of the clinical heat conditions. The fatality rate is about 40 per cent if the rise in body temperature does not reach 110° F, and 80 per cent or more if it rises above this. Patients with heat stroke often collapse without exhibiting any marked prodromal symptoms. Coma followed by convulsions and active delirium usually occurs. The outstanding feature of heat stroke

is a marked rise in body temperature, usually between  $107^{\circ}$  to  $110^{\circ}$  F, although lower or higher temperatures may occur. The pulse is rapid, the blood pressure often is slightly elevated; the peripheral blood flow is normal; and the skin is usually hot and dry since cessation of sweating usually, although not always, precedes the attack. The blood shows no marked concentration, no fall in sodium and chloride, and no other outstanding changes at first, although later, acidosis and a high nonprotein-nitrogen usually occur. There appears to be no dehydration; in fact, some patients show edema of the tissues. The treatment consists in bringing the body temperature down as rapidly as possible by an ice water bath, an ice pack, or evaporative cooling. There appears to be no reason for the intravenous administration of saline or glucose. Patients suffering from heat stroke must be watched carefully for several days. It is reported that certain cases have shown permanent central nervous system symptoms resulting from the high body temperature.

The etiology of heat stroke is not clearly understood at present, although it is usually attributed to a breakdown in the sweat mechanism.

In addition to the three acute systemic conditions which may result from exposure to high temperature, mention must be made of the skin conditions which occur as a result of exposure to high environmental temperatures. Prickly heat or heat rash (*miliaria rubra*) is the most common, and is described as an acute inflammatory disorder of the sweat glands. A second type of skin condition, which is attributed to obstruction of the orifice of the sweat ducts, is called sudamen or *miliaria crystallina*. These skin conditions can be very irritating and annoying especially to persons who live in the tropics.

Exposure to excessive heat radiation or extremely hot air (and, of course, direct contact with hot objects) may cause burning of the skin. Breathing of hot air does not appear to produce damage to the deep lung tissue unless the temperature is sufficiently high to cause burning of the skin and upper respiratory mucosa. It is stated that a person cannot breathe air above  $240^{\circ}$  F ( $105^{\circ}$  C).

**Relation of High Temperature and Humidity to Physical Work.** Muscular work at high environmental temperatures accentuates all of the physiological reactions which result from exposure to heat. Exercise, even in normal temperatures, leads to an increase in heat production and in heart rate and, under some conditions, to a rise in body temperature. At high temperatures, the added heat production, combined with the inability of a body to lose heat, places a severe strain on the body. As a result, the ability to perform heavy physical work is greatly limited, and the effects of high temperature are greatly accentuated. When a person works at high temperature, the pulse rate and body temperature increase to a greater extent than when he is doing the same work at normal temperatures. Even a few minutes of exercise will produce a marked rise in pulse rate. The capacity of a man to work drops off markedly, and under extreme conditions little or no work is possible. The limiting factor under these circumstances does not appear to be a lack of adequate fuel supply to the muscles, a lack of oxygen, or a marked increase in the lactic acid in the blood. Although the body temperature may rise appreciably, the rise in temperature also does not appear to be the controlling factor. Some people believe that a fall in cardiac output, in spite of the rise in pulse rate, is the limiting factor for work in high temperatures.

The decrease in work with increasing temperatures and humidities is shown in Figure 25-1 which is taken from experiments of the American Society of Heating

From McConnell, W. J., and Yaglou, C. P., J. Am. Soc. Heat. & Ventil. Engin., 31:103, 1925.

Fig. 25-1. Average total work subjects were capable of producing in still and moving air experiments.

and Ventilating Engineers (McConnell and Yaglou, 1925). In these investigations the subjects lifted 40-pound weights at the rate of 75 times per five minutes and alternated with five-minute rest intervals until compelled to leave the test chamber. The subjects were capable of performing four times as much work in a temperature of 100° F with a relative humidity of 30 per cent as they could at the same temperature with 100 per cent humidity. When the relative humidity was 60 per cent, the subjects performed five times as much work at a temperature of 90° F as at 120° F. A number of studies in the heavy industries have shown that the output falls off when the temperature becomes very high. There are a few laboratory studies which indicate that muscular coordination may also be impaired at high temperature.

**Acclimatization.** When persons are continuously exposed to high temperature for several days, they gradually become acclimatized to the heat, and tolerate the high temperatures with much less physiological stress. The exact mechanisms re

sponsible for this acclimatization are not well understood at present. Some acclimatization occurs within a few days; further adaptive changes follow upon prolonged exposures of several months to the heat. Upon leaving the hot environment, the acclimatization gradually decreases, although some degree of adaptation remains as long as six weeks.

The importance of acclimatization was well shown during World War II when troops were sent to hot climates for training purposes. Those who were forced to perform heavy physical exercise for long periods immediately on arrival almost invariably developed heat exhaustion. On the other hand, when the work was light at first and then gradually increased in intensity or when the length of the work period was short at first and then gradually increased, the men gradually became acclimatized and avoided all clinical symptoms of heat exhaustion. Furthermore, the latter groups were able to perform heavy physical work for long hours within a few days, whereas the other group was unable to work at all. A general program for developing acclimatization should be followed by all individuals who go into hot climates or hot industries after residing in a cold environment. These persons should not attempt to do heavy physical work for long hours immediately upon exposure to heat but should gradually increase the intensity or duration of their work during the first week of exposure. Likewise, the duration of work periods might profitably be reduced during the first few days of a sudden hot spell in summer.

**Tolerance Limits to High Temperatures.** In the preceding paragraphs, the adjustment of the body to high temperatures and the clinical conditions which result when the thermal stresses become too severe, have been reviewed. It is now necessary to consider the upper limits of physiological adjustment and the maximum temperature conditions which a person might be expected to tolerate without a breakdown in the physiological mechanisms.

**LIMITS OF PHYSIOLOGICAL RESPONSE TO HEAT.** When a man is exposed to extreme heat, the physiological responses eventually reach a point beyond which further readjustment cannot occur, and breakdown ensues. These limits have been determined to some extent.

The upper limit of body temperature which the average person can survive is about 110° F. The limit of effective cardiac acceleration in high temperature when a person is sitting at rest appears to be about 140 beats per minute. While exercising at high temperature, subjects are usually at the borderline of collapse when their heart rate reaches about 180 beats per minute. The cardiac output under thermal stress is able to increase only 1.4 to 1.7 liters per minute, whether a person is at rest or at work. The upper limit of the rate of sweat secretion is about 1,800 grams per hour at rest and about 3,900 grams per hour when exercising. These rates of sweating cannot be maintained for any great length of time. According to Herrington (1949), this rate of sweating represents a water turnover per hour which is equivalent to more than half the normal blood volume.

**UPPER LIMITS OF ENVIRONMENTAL CONDITIONS.** The upper limits of environmental temperature and humidity which man can tolerate for any length of time vary with many factors. However, before discussing these factors and the limits which have been found, it is necessary to decide on the maximum physiological changes which should be accepted as tolerable for more or less continuous exposures. Usually, it is assumed that conditions causing a rise in body temperature over 101° F

and an increase in pulse rate to about 125 beats per minute represent the limits which should be allowed for repeated exposures. For shorter periods, rectal temperatures of 102° F and pulse rates up to about 160 or 170 beats per minute have been considered as limits of tolerance by some authorities.

The upper limits of environmental temperature which man can tolerate depend largely on his condition. Heavy physical work, lack of acclimatization, extensive dehydration, improper clothing, old age, lack of physical fitness, excessive adipose tissue, and a low ratio of body surface area per unit of metabolic tissue all lower his tolerance levels. Obviously, a young acclimatized soldier can tolerate higher temperatures than can an older, stout man accustomed to sedentary work. Unfortunately, most of the studies which have been made to determine the upper limits of environmental temperature which man can endure have been made on young men. Data on older persons and women are lacking. In addition to the condition of the man, the maximum tolerable temperature and humidity vary with the duration of the exposure. Man can tolerate air temperatures as high as 150° F for short periods, whereas, for long periods under some conditions, he cannot even tolerate 85° F. High day temperatures can be tolerated better if sleeping temperatures are low. Sources of heat radiation and air movement also influence the tolerance limits.

A number of investigations have been made to determine the maximum thermal levels which can be endured by man. Some authorities have set the limits in terms of dry bulb temperature and relative humidity, whereas others have specified the limits in wet bulb temperatures.\* The early experiments to determine the upper thermal limits which man can tolerate were performed by Haldane (1905). This distinguished physiologist found that the wet bulb temperature, regardless of the dry bulb temperature, accurately indicated the upper limit of temperature which men could endure without an abnormal rise in rectal temperature. The following wet bulb temperatures were the limits which he reported for the specific conditions studied by him: for men lightly clothed or stripped to the waist when at rest in still air, 88° F; for similar conditions but with a linear air movement of 170 feet per minute, 93° F; for men stripped to the waist and leisurely climbing at the rate of 13 feet per minute in still air, 78° F; and for similar conditions but with air moving at 135 feet per minute, 85° F.

In more recent years, The American Society of Heating and Ventilating Engineers has carried out a number of experiments to determine the upper limits of temperature man can tolerate. Also investigations along this line have been performed in various university laboratories and by the Armed Forces. The results of these studies have been summarized by Yaglou and others (1950) in a report of the Committee on Atmospheric Comfort of the American Public Health Association. These data are reproduced in Tables 25-1 and 25-2 and Figure 25-2. According to this committee: "Young healthy persons, working under the conditions defined in Table 1, are capable of maintaining heat balance after having been ac-

\* The dry bulb temperature is the temperature recorded by the ordinary thermometer and is affected only by the air temperature. The wet bulb temperature is the reading of the thermometer when the bulb is covered with a wet wick and when a strong current of air is passed over the wick. The amount of heat lost by the bulb under these conditions, and thus the reading of the thermometer, is affected by both temperature and humidity. The wet bulb temperature is always below the dry bulb temperature except when the relative humidity is 100 per cent, at which point both temperatures are equal.

Prevention of Effects of High Temperature. PERSONAL MEASURES. The harmful results of exposure to high temperatures may be avoided by certain preventive measures. The most important personal procedure is to replace the water and salt which are lost from the body through the sweat. The best method is to drink abundant quantities of water containing about 0.1 per cent sodium chloride. If a salt solution is not available, salt tablets may be taken with the water. Some persons develop nausea from salt tablets, especially if the tablets do not dissolve rapidly. Under these conditions, enteric coated or impregnated tablets should be used. Men

working in high temperatures and losing between 5 and 8 liters of sweat per day require at least 15 grams of salt per day. The normal salt intake in food is about 10 grams. It is recommended that an additional 2 to 5 grams of sodium chloride be taken each day. In order to supply 5 grams of salt, 5 liters of 0.1 per cent

From Am. J. Pub. Health, 40:134, 1950. Data from Am. Soc. Heat. & Ventil. Engin.

Fig. 25-2. Thermal standards in industry. Safe exposures in relation to environmental temperature.

NaCl are required or 8 ten-grain tablets with at least 5 liters of water. If men are doing very heavy work or if the temperature is very high, a greater quantity of salt and water will be required. There is no advantage in adding sugar or potassium to the salt tablets nor in taking vitamins.

Another method of reducing the incidence of heat cases is to decrease the amount of physical work and the duration of exposure to hot environments. Alternating periods of work and rest may be desirable, especially if the exposure to heat follows suddenly upon prolonged exposure to cool temperatures. A period of systematic acclimatization, such as discussed under the section on acclimatization, might prove valuable. The severity of heat cases can be prevented by cessation of work and removal from the hot environment as soon as the first signs of heat effects, such as headache, dizziness, nausea, and exhaustion appear. In some instances, it

may be desirable to employ men who are less susceptible to the effects of heat. Procedures for selecting such persons have been worked out by some investigators.

The type of clothing is also important. A few of the principles of clothing design for hot exposures are given in Table 25-3. As little clothing as possible should be worn in hot environments except when exposure to heat radiation exists. White and light colored clothing are desirable since these colors reflect the shorter infrared rays. However, they do not reflect the longer rays; therefore, they are only partly effective against heat radiation. Clothing should be made of material which is thin and light weight and which requires little water for saturation, dries rapidly, and contains little air. Air-ventilated suits are now available for use in hot industries where the worker remains in one location. A complete discussion of the science of clothing in relation to heat regulation has been published recently (Newburgh, 1949). In order to avoid sudden chilling, clothing which has become soaked with perspiration should be changed before a person goes into cooler environments. For personal protection against radiant heat, metal shields, metal lined helmets, and metal treated clothing are most effective. Aluminum foil and aluminum are the best reflectors of radiant heat, and are resistant to ignition. The foil can be pasted onto cloth. Men clad in aluminum suits and protective goggles can withstand a tremendous amount of radiant heat from fires, furnaces, bombs, etc.

When the temperature of the air or the relative humidity are low, heat loss from the body can be increased by the use of local fans. However, air movement, as stated above, is of no value if the temperature and humidity are high.

**MECHANICAL MEASURES FOR REDUCING HEAT EXPOSURES.** There are a number of mechanical procedures for preventing exposure to excessively high temperatures. If heat is being produced by an industrial process, it may be possible to prevent exposure of workers by insulating the process, by isolating it so that only those workers necessary for that process are exposed, by operating the equipment from a distance, and by exhausting the hot air or steam as it is produced. If the building acquires heat only during the day, it can be cooled during the night by exhausting the heated air and replacing it with the cooler night air. This principle is used in private dwellings where large exhaust fans, placed in the attic, are operated at night. On the other hand, if hot air from outside of a building is the source of the heat, the air temperature of the interior can be lowered by insulation of the building with insulating materials or air spaces and by flooding or spraying the roof with water. The latter procedure leads to evaporative cooling of the roof. The interior of buildings may be cooled by circulation of cold water through radiators or pipes in the rooms, and by air-conditioning units which supply cool, dry air. The cooled air may be distributed throughout the entire space or, in industries, it may be directed locally at the worker. The temperature of the air striking the workers should be not less than 80° F, and, for continuous exposure, the velocity should not exceed 200 feet per minute. Short exposures to much higher velocities of air movement are beneficial only in the presence of radiant heat. By providing flexible air ducts, the location of blasts can be regulated so as to avoid chilling of the head, shoulders, and back. Dehumidification of the air which allows greater evaporation of sweat is at times more desirable than cooling of the air.

If the heat exposure is from radiation sources rather than from hot air, other measures are applicable. Radiant energy from the sun reaches the interior of a build-

Table 25-3. Theoretical considerations in the principles of clothing design for the tropics

Conditions	Color	Texture	Thickness	Water Vapor Permeability	Weight	Extent	Openings	Fit	Water Repellency	Underclothes
Solar radiation	Light	Close	Moderate	Moderate to high	Medium	Well covered	Not important	Loose	Nil	Moderately desirable
Radiation from hot objects	Immaterial	Close	Moderate	Moderate to high	Medium	Well covered towards source	Depends upon humidity. Away from source	Loose	Nil	Depends upon humidity

ing partly by direct transmission through the glass windows. By the proper orientation of the building in relation to the sun, it is possible to obtain a minimum of solar radiant energy inside the building in summer and a maximum in winter. The transmission of infrared radiation through glass may be avoided by use of heat absorbing glass and by window shades. Outside shades made of aluminum are the most effective. Radiant energy from the sun is absorbed by the building materials (walls and roof) and is then transmitted to the interior by reradiation and conduction. The amount of radiation absorbed depends partly on the color of the surfaces. Dark colored surfaces absorb most of the heat rays. Light colored surfaces do not absorb as much since they reflect the shorter infrared rays (but not the longer rays) which are present in the sun. A much higher percentage reflection is obtained by some of the metals than by other building materials. Aluminum metal, paint, and foil are all excellent materials to prevent the absorption of radiant heat. Furthermore, even when aluminum is heated by conduction, it re-emits very little radiation. The roof or other exterior surfaces may be covered with aluminum metal or paint or the inside of the roof may be lined with aluminum foil. Aluminum materials can be used most effectively to reflect radiant heat not only from the sun but also from hot furnaces and other sources in industries.

### EFFECTS OF LOW TEMPERATURES

**Physiological Reactions to Cold Environments.** When the human body is exposed to a cold environment, two types of physiological adjustments are brought into play in order to maintain the body temperature. In the first place, the heat production is augmented by voluntary movements and by the onset of shivering. It is possible to increase the metabolic rate five to seven times for short periods by shivering, but this increased rate cannot be maintained indefinitely. Shivering is abolished by very low body temperatures, a fall in blood sugar, anoxia, anesthesia, alcoholism, and physical exhaustion. There is evidence also that low temperatures affect the metabolic rate indirectly through the adrenal cortex or thyroid gland. In the second place, the body maintains its temperature when exposed to cold by decreasing the heat loss from the skin. This conservation of heat is accomplished through constriction of the blood vessels in the skin and a reduction in plasma volume. These two mechanisms reduce the blood flow through the skin and thus lower the temperature so that less heat is lost by conduction and radiation. Reduction of surface area by changes in posture, such as "hunching up the body," also assists in reducing heat loss.

Although acclimatization to heat is a well-known physiological process, the problem of physiological acclimatization to cold is subject to controversy.

**Acute Conditions Resulting from Excessive General Body Chilling.** Because of the adaptive mechanisms described above, the body temperature does not usually fall more than 2° to 3° F. If, however, the exposure to the cold air is intense and prolonged or if the body is unable to compensate sufficiently, the body temperature may continue to fall. The pulse rate and blood pressure decrease after an initial rise, the original feeling of cold and pain gives way to numbness and loss of sensations, and muscular weakness and a desire for sleep ensue. When the body temperature reaches 80° F, coma sets in. However, individuals treated with cryotherapy have

survived body temperatures of 80° to 85° F for a week or more without apparent damage to their tissues. Death usually occurs when the body temperature falls to 77° or 70° F. According to Herrington (1949): "on more severe exposure heart failure is apparently the cause of death and is attributed to direct cold injury of the heart and its functional exhaustion due to great increases in blood viscosity." Other authorities have suggested that perhaps solidification of tissue lipoids or failure of respiration may be factors in the cause of death.

If the body is immersed in cold water, rather than cold air, the body temperature falls much more rapidly. If the water temperature is below 60° F, or even below 68° F, heat production cannot keep pace with heat loss, and the body temperature falls until death ensues at internal temperatures of about 77° F.

**Tolerance Limits to Cold.** A number of factors, such as age, amount of adipose tissue, degree of physical fitness, physical exercise, and clothing, affect the ability of man to adjust to cold environmental temperatures and, thus, his chance of survival. The lowest outdoor temperatures in which man can survive depend, of course, on the duration of the exposure. Few data are available on this subject at the present time. However, Yaglou (1950) has estimated the endurable limits as follows: "at +10° F air temperature endurance of inactive persons is reduced to less than 6 hours; at -10° F to about 4 hours, at -40° F to 1½ hours, and at -70° F to 25 minutes. With physical work these limits may be extended." Attempts also have been made to specify the lower limits of ambient air temperature for prolonged thermal comfort. The figures predicted as the lowest temperatures for comfort in dry cold air are shown in Table 25-4.

Table 25-4. Predicted lowest ambient temperature for prolonged thermal comfort

\* From Belding, H. S., in *Physiology of Heat Regulation and the Science of Clothing*, edited by L. H. Newburgh, Philadelphia, W. B. Saunders Co., 1949, p. 352.

In cold water, the human body cannot survive for even as long periods as in cold air. When the water temperature is 60° F, men can survive only two to five hours. At 40° F water temperature, the rectal temperature rapidly falls 11° or 12° F, and death may occur within one hour. It has been estimated that a man

could probably survive eight hours in water if the temperature was not less than 62° F, whereas, even when nude, he could survive for eight hours in air at 46° F.

**Conditions Resulting from Excessive Local Chilling.** Of greater importance than general body chilling, are the local changes which occur in the extremities (hands and feet) upon exposure to cold. The extremities cool rapidly because of the large surface area relative to the mass of tissue and because of the small quantity of blood circulating through them. Some confusion exists in the terminology which is applied to the various conditions resulting from local cooling of the skin; but, in general, three reactions can be differentiated: (1) acute transient inflammatory reactions, (2) trenchfoot, immersion foot, etc., and (3) frostbite or freezing of the skin.

**ACUTE TRANSIENT INFLAMMATORY REACTIONS.** When the skin of the extremities is exposed to cold, vasoconstriction occurs in the small superficial blood vessels and later in the large arteries. This reaction is followed by an intermittent reactive vasodilatation of the smallest vessels, due, according to Lewis (1941) to the liberation of a histamine-like substance in the tissue acting through an axon reflex. The dilatation leads to a local redness of the skin. A sensation of pain, independent of the cold sensation, arises as the skin temperature falls to 59° F, but at 50° F pain is replaced by numbness and loss of all sensation. Swelling of the skin also occurs; the volume of the affected tissue, such as the finger, may be increased as much as 15 per cent. This acute inflammatory reaction in the extremities subsides within a few hours after removal from the exposure.

**TRENCHFOOT, IMMERSION FOOT, ETC.** Prolonged exposure to cold and wetness may lead to extensive damage to the extremities. The initial reactions are similar to the acute transient reactions with spasm of the terminal arterioles and venules. Later marked dilatation of the capillaries, stagnation of the blood and edema occur. Tissue degeneration may follow. When removed from the exposure, the feet are cold, swollen, waxy white with some cyanotic areas, numb, and anesthetic to pain. Shortly afterwards, the affected parts become red, hyperemic, hot, and swollen. At this stage the skin presents a livid appearance. Later, blebs with extravasations and often gangrene appear. During World War II, many cases of immersion foot occurred among men who were forced to sit for days in crowded lifeboats. The exposure to the cold and wetness, accompanied by the inactivity, led to this condition. During World War I, a similar condition, called trenchfoot, occurred in men who stood for long periods in wet trenches.

**FROSTBITE.** The term frostbite usually is applied to tissue damage which results from exposure to intense cold, whether the damage results from the profound vascular changes (described above under acute transient reactions and trenchfoot), or from actual freezing of the tissues. However, Lewis (1941) suggests that the term be limited to conditions in which actual freezing occurs. The freezing point of the skin is between 0° and -2° C; but the skin rarely freezes until its temperature falls to -5° or -10° C, or even much lower, because of supercooling of the skin. Lewis (1941) claims that supercooling is possible to a greater degree in unwashed skin and is probably related to the relative dryness of the horny layer. Frostbite occurs commonly when the air is dry and well below the freezing temperature. The skin, when frozen, appears pale, dull, opaque, and yellowish. A prickly and itching

sensation develops; vasodilatation leads to local redness, swelling occurs, and usually a wheal is formed over the frozen area. If the freezing period lasts only a few seconds, the wheal disappears after several hours. If freezing continues for a longer period, an extensive exudative inflammation with blister formation results. Prolonged deeper freezing, lasting for some minutes at, for example,  $-15^{\circ}$  or  $-20^{\circ}$  C, leads to necrosis of the tissue and gangrene.

**RECOVERY FROM LOCAL CHILLING.** Rewarming of the tissue in the case of trenchfoot or frostbite is followed by massive edema and hyperemia. The capillaries become packed with red blood cells and stasis occurs. There is no agreement as to whether the accumulation of red cells is a result of loss of fluid or of some special clumping property of the cells. The complex vascular changes during the cooling and rewarming periods and the mechanism of the stasis and necrosis are not well understood. Various methods of treatment have been suggested, but no one procedure has been generally accepted. Three types of conditions after recovery from trenchfoot have been described: excess vasospasm, pain with numbness, and mild chronic inflammation.

**CONTRIBUTING FACTORS.** Damage to the extremities upon exposure to cold is much more likely to occur when there is pressure on the extremities which interferes with the circulation. Tight gloves, shoes, or other clothing heighten the effects of the cold. Immobility of the part also facilitates the effects of cold, wet surroundings.

**Other Effects of Cold.** There are a number of other items which should be mentioned briefly in discussing the effects of cold, one of which is the allergic reaction. Some persons exhibit typical allergic manifestations upon exposure to cold; local reactions involving urticarial wheals and swelling are reported to occur as well as systemic manifestations.

Another subject which should be mentioned is the possible danger of breathing extremely cold air. Experiments on animals have indicated that cold air, even as low as  $-40^{\circ}$  C, when inhaled, is warmed so rapidly in passing through the upper respiratory tract that damage to the lungs is unlikely to occur. Continuous exposure, however, may lead to sublaryngeal tracheitis with obstructive edema.

In addition to the effects of cold on the body tissues, it should be noted that exposure to cold alters the ability to work chiefly because it interferes with the dexterity of the fingers. Lastly, exposure to cold, because it leads to shivering and muscular movement, causes the early onset of fatigue.

**Prevention of the Effects of Cold.** Excessive cooling of the body may be prevented under most circumstances by the proper clothing, by exercise, and by environmental heating. A splendid review of the science of clothing has been published recently (Newburgh, 1949). In brief, it can be said that the clothing should be thick, multilayered, light in weight, and windproof. Warmth depends far more on the amount of air held in the interstices of the cloth than on the kind of fiber. Therefore, thick clothing composed of fibers which are not easily compressed, and which allow air to be trapped but which prevent convection currents, is the best type for cold exposures. The clothing should allow some ventilation next to the skin and be permeable to water vapor. The design of clothing for cold climates presents some difficulties. If the clothing is warm enough for a man when he is resting, it will be too warm for him when exercising. Furthermore, sweat which is produced during

the exercise may be precipitated in the cold outer layers of the clothing. Upon cessation of exercise, rapid evaporation of the moisture in the clothes may lead to chilling. Clothes should be made so that they can be closed tightly around the arms, legs, and neck when the man is resting; but opened when he is exercising. Clothing should be loose fitting; any clothing which restricts the movement of any part of the body or interferes with the circulation of the blood is undesirable. It is most important that foot and hand covering fit very loosely. Electrically heated clothing may be used in some circumstances.

The insulating value of clothing is expressed in a unit called the "clo." It is defined as follows: "The clo is a unit of insulation and is the amount of insulation necessary to maintain comfort and a mean skin temperature of 92° F in a room at 70° F with air movement not over 10 feet per minute, humidity not over 50 per cent, with a metabolism of 50 Calories per square meter per hour. On the assumption that 76 per cent of the heat is lost through the clothing a clo may be defined in physical terms as the amount of insulation that will allow the passage of 1 Calorie per square meter per hour with a temperature gradient of 0.18° C between two surfaces.

$$1 \text{ clo} = \frac{0.18^{\circ} \text{ C}}{\text{cal./sq.m./hr.}}$$

"The ordinary business clothing of men has an insulation value of about 1 clo. The best clothing has in practice a value of about 4 clo per inch of thickness. The theoretical value for absolutely still air has been estimated at 7 clo per inch at 18° C" (Newburgh, 1949).

According to Yaglou and others (1950): "The warmest practical clothing made has an insulation value of about 4.5 Clo, the warmest mittens 1.5 Clo, and the warmest footwear 2.5 Clo. These will not protect the wearer indefinitely in temperatures below the freezing point without physical activity."

The harmful effects of cold may be prevented also by a reduction in the duration of exposure and by alternating periods of exposure and rewarming. Persons with circulatory disturbances of the extremities should not be employed in positions requiring exposure to low temperatures.

## RELATION OF TEMPERATURE AND HUMIDITY TO SUSCEPTIBILITY TO RESPIRATORY INFECTIONS

**Acute Respiratory Infections.** There is no proof at the present time that exposure to high temperature or to low temperature per se increases a person's susceptibility to acute infectious diseases of the respiratory tract, but there is some evidence that a fall in outdoor temperature and chilling, especially following exposure to high temperature, may predispose to acute respiratory infections. A number of statistical studies have been made on the relation of changes in the outdoor temperature to the death rates from respiratory infections. Reed (1924) determined the correlations between death rates and climatic factors. He found that deviations of the mean temperature below normal were associated with high death rates for respiratory diseases at all seasons, but especially in the winter. At this season the correlation coefficients ranged from  $-.4$  to  $-.6$ . Since the correlations were calcu-

lated between temperature deviations of one week and the death rates of the following week, the temperature deviation appears to be associated with the onset of the illness rather than with the termination. Other studies have shown similar results. A negative correlation also has been demonstrated between the incidence of minor respiratory infections and changes in outdoor temperatures.

The relation of climatic factors to the geographic distribution of pneumonia and influenza in the United States also has been studied by the use of correlation coefficients. Herrington and Moriyama (1939) reported that the geographical distribution of bronchopneumonia in persons over one year of age and lobar pneumonia were associated with a low outdoor temperature and a stable climate. Influenza did not appear to be related to climatic factors. The seasonal curve of respiratory diseases also suggests a climatic effect, since the highest rates occur in the cold winter months in both the Northern and Southern Hemispheres. However, it should be noted that none of these climatic studies gives any definite proof that the temperature has a direct effect on resistance of persons to infectious agents. It is possible that the greater incidence of respiratory infections, associated with the low outdoor temperatures, is due to closer contacts with other persons in cold weather when there is a tendency to remain indoors, or to some other indirect effects of climate.

In addition to the climatic studies, some industrial studies support the idea that there is a change in host susceptibility with exposure to changes in temperature and chilling. Morbidity and mortality studies have shown that iron and steel workers and foundry workers have high pneumonia rates. These men are exposed to high temperatures and to sudden changes in temperature. Some of the results of one such study are presented in Table 25-5.

Table 25-5. Frequency of pneumonia according to nature of exposure in a steel plant, 1924-1928

Industrial Exposure	Annual No. of Cases of Pneumonia per 1,000 Men
Heat with wide changes in temperature .....	12.6
Inclement weather .....	13.6
No such exposures .....	3.9

From Brundage, D. K., and others, U. S. Pub. Health Serv. Bull. #202, 1932.

Similarly, men who are exposed to all sorts of outdoor weather conditions, such as in shipyard, quarry and cement works, have high pneumonia rates.

The effects of exposure to cold and to changes in temperature on susceptibility to respiratory infections has been studied on animals. These experiments have yielded contradictory results. Chilling of animals, especially guinea pigs, seems to lower their resistance to spontaneous infections, but not to experimentally induced infections.

The rather common idea that the dry atmosphere of overheated houses in winter is a factor in susceptibility to upper respiratory infections is not supported by experimental or statistical data. Although a low relative humidity may cause drying of the upper respiratory mucosa, there is no evidence at the present time that a low humidity is harmful to health. Variations in relative humidity, however, may affect

the length of time that droplets from the mouth and nose remain suspended in the air and thus indirectly may affect the transmission of respiratory infections. (See Chapter 2.)

**Tuberculosis.** There is no sound evidence at the present time to show that temperature, humidity or, in fact, any of the other factors which make up the climate, influence the susceptibility of either animals or men to tuberculosis or alter the course of the infection. Baetjer and Lange (1928) exposed one group of guinea pigs, inoculated with tubercle bacilli, to a temperature of 80° F and a relative humidity of 80 per cent and another group, similarly inoculated, to a temperature of 69° F and a relative humidity of 45 per cent. The mortality and the extent of tuberculous infection were identical in the two groups. According to other investigators, the development and progress of tuberculosis in guinea pigs is unaffected by artificially induced hyperpyrexia. Repeated exposure to intense cold, likewise, had no effect on tuberculosis in guinea pigs.

The treatment of tuberculous patients with diathermy or inhalation of hot moist air was reported to be without any marked beneficial effects. Human patients with tuberculosis appear to respond to good treatment equally well in all climates. Moriama and Herrington (1939) found that the correlations of tuberculosis mortality with climatic factors were not statistically significant.

## VENTILATION AND AIR CONDITIONING

**Changing Concepts of Ventilation.** During the nineteenth century it was assumed that the discomfort which occurred in close and crowded rooms was due to the chemical composition of the air which the occupants breathed. The undesirable chemical constituents were believed to be either an excess of carbon dioxide from the expired air or a hypothetical toxic substance in the expired air. Some persons thought the effects might be due to a reduction in the oxygen content of the air. On the basis of these ideas, it was considered necessary to supply fresh outdoor air to all schoolrooms and other indoor spaces when large numbers of persons were gathered together. The ventilating engineers believed that an air supply of 30 cubic feet of air per person per minute would be necessary to remove the supposedly toxic substance and maintain a low concentration of carbon dioxide. Hence, in 1895, this ventilation standard was adopted by the American Society of Heating and Ventilating Engineers. At about this same time, physiologists were studying the effects of close and crowded conditions on man. These scientists proved that there was no toxic substance in expired air and that the discomfort and faintness which occurred under such circumstances were not the result of the chemical changes in the air but were due to a failure of the body to lose sufficient heat. Furthermore, it was found that the air leakage in all ordinary buildings was sufficient to prevent any appreciable deficiency of oxygen or accumulation of carbon dioxide. Thus, the physical properties of the air which control heat loss from the body became more important factors in ventilation than the chemical composition of the air, and the early standards of ventilation, based on air supply per person, were no longer tenable.

What, then, are the current standards of ventilation? The desirable objective of ventilation and air conditioning is to maintain indoor conditions which are optimum

for health and comfort and which will prevent the spread of diseases. It is, however, impossible to set standards of ventilation which will prevent the spread of diseases. The relation of atmospheric conditions to the transmission of infectious agents from one person to another is discussed in Chapter 2. A review of the data presented in that discussion makes it evident that ventilation standards cannot be formulated on the basis of biological contamination of the air. Ventilation standards also cannot be set in terms of the chemical composition in the air, except where foreign chemical substances are present. As noted above, the normal constituents of the air do not vary appreciably under any usual circumstances. Only when dusts, gases, and other materials harmful to health are introduced into the air by industrial or other processes, are ventilation standards set in terms of the chemical composition of the air (see Section 6). Since the early physiological experiments showed that the physical properties of the air which control heat loss from the body were responsible for the discomfort, the physical factors have become the basis for modern ventilation standards. The physical factors of the environment which control heat loss from the body are, as discussed elsewhere in this chapter: the temperature, humidity, and movement of the air, and the temperature of the surrounding walls and objects. Although these factors are now accepted as the basis of ventilation and air-conditioning standards, it is not possible to specify the conditions which are optimum for health. Very little is known regarding the effects of temperature, humidity, and air movement on health. However, ventilation requirements can be based on the thermal conditions which place the minimum physiological stress on the body and which produce a sensation of comfort. Comfort is a composite sensation derived partly from a feeling of warmth which is related to the skin temperature, partly from a sense of freshness which depends on the lack of congestion in the upper respiratory mucous membrane, and partly from nerve impulses produced by light fluctuating air currents acting on the skin. A sensation of discomfort arises from too low or too high skin temperatures, from congestion of the respiratory mucosa and from a variety of complex physiological changes in heart rate, body temperature, metabolism, sweating, etc. It is believed that environmental conditions which are comfortable and which do not cause physiological stress favor good health.

**Recommended Thermal Standards.** **AIR TEMPERATURE.** For men who are doing sedentary work, the optimum dry bulb temperature of the air for winter in the cooler areas of the United States varies from 68° to 72° F. Women are more comfortable at about 75° F since they wear lighter clothing and may have a lower heat conductance from the interior to the skin. Older persons and sick individuals are more comfortable at higher temperatures, probably because of poorer circulatory adjustments. Under ordinary resting conditions the majority of persons are comfortable when the skin temperature is between 91° and 93° F, even though the air temperature varies from 55° to 82° F. Skin temperature is not a good measure of comfort when a person is sweating, is doing physical work, or is subjected to sudden changes in temperature.

During physical work, the air temperature must be lower because of the added heat production. However, temperatures below 60° F are not recommended, in general, since when the person ceases work rapid chilling may occur at the lower temperatures. There should not be a difference of more than 2° F in air temperature

between the floor level and head level since larger gradients of the temperature may be uncomfortable.

In summer, when people are acclimatized to hotter environments, temperatures from 75° to 80° F, or even up to 85° F for some persons, are more comfortable. There has been considerable discussion, but very few scientific data, to determine the maximum temperature gradient which a person can tolerate with reasonable comfort when passing from a hot outdoor temperature to a cool air-conditioned interior in summer. Everyone who traveled on trains in the early days of air conditioning, when only the diners were cooled, can remember the discomfort experienced at a temperature of 70° F after having been exposed to temperatures of 85° or 90° F. The ventilating engineers believe that gradients of 10°, 15°, or even 20° F between outdoor and indoor temperatures are satisfactory provided the indoor temperatures are 75° F. The physiologists, on the other hand, believe that 15° and 20° F gradients are undesirable. However, it must be admitted that evidence of any damage to health from such temperature changes in summer has not been published as yet.

**HUMIDITY.** The relative humidity of the environment plays only a small role in comfort except at very low and very high temperatures. At normal temperatures, the skin temperature exceeds the air temperature; hence the vapor pressure at the skin is greater than the vapor pressure in the surroundings, even when the latter is completely saturated. Because of this relationship, changes in humidity are not very important. At higher air temperatures, between about 84° and 93° F, when sweating has begun, the heat loss by evaporation is also fairly constant in spite of variations in relative humidity from 15 to 75 per cent. A rise in humidity tends to decrease evaporation, but the body compensates by increasing the secretion of sweat and by increasing the percentage of skin surface wetted. The increase in sweating balances the decreased evaporation resulting from the rise in humidity and maintains a constant heat loss. On the other hand, when the entire body surface is wetted with sweat, the relative humidity becomes the controlling factor in heat loss. Under these conditions, the humidity should be as low as possible. At low temperatures, the humidity is again important. It is well known that a cold damp climate feels colder than a dry climate with far lower temperatures. It seems probable that, in a wet climate, the moisture is absorbed by the clothing which, in turn, increases the heat conduction of the clothing. Therefore, in cold air it is desirable to have a low humidity. Variations in humidity affect the water content of the upper respiratory tract. In very dry atmospheres, the mucosa of the upper respiratory tract may become very dry. This may be unpleasant to some people. Although the amount of water lost through the expired air is greater at a low humidity, there is no appreciable effect on the total water content of the body. In high humidities, above 80 per cent, the water vapor can be perceived and produces an unpleasant sensation.

**AIR MOVEMENT.** The optimum velocity of air movement varies from 10 to 80 feet per minute depending on the temperature. It is usually stated that air velocities of 25 to 30 feet per minute are desirable for sedentary persons in winter and that velocities of 40 to 50 feet per minute are optimum in summer. Stronger air currents and those affecting only local areas of the body are uncomfortable. If the temperature of the air current is 2° F below the room temperature, air currents of 50 feet per minute may be uncomfortable. At high air temperatures, the air movement should be increased in order to produce greater heat loss, especially when individuals

are doing physical work. However, continuous strong air currents may prove uncomfortable. Some authorities (Yaglou and others, 1950) believe that in hot environments the velocity should not be over 200 feet per minute and the temperature of the air striking the worker should be not less than 80° F. When the temperature and humidity are both high, air movement is of no value in increasing heat loss.

TEMPERATURE OF SURROUNDINGS. The temperature of the surrounding walls and objects must be taken into account in setting ventilation standards. If there are large sources of radiation, such as direct sunlight, open fires, stoves, furnaces, molten metal, etc., the air temperature must be lowered to compensate for the heat gained by the human body from radiation. On the other hand, if there are large cold areas such as cold outside walls, the heat loss by radiation is increased, and the air temperature must be raised. It is stated (ASHVE Guide, 1945) that each degree reduction in the average temperature of the surface of three walls surrounding a room requires a rise of 0.3° F in the dry bulb temperature of the air to maintain the thermal equilibrium. The relationship between varying wall and air temperatures which produce the same degree of heat loss is shown in Table 25-6 and Figure

Table 25-6. The air temperature necessary to compensate for cold walls

Temperature of air and walls in control room	Air temperature (° F) required in cold-wall room, to give warmth equal to that of control room, when three walls were at a temperature of:			
	50° F	55° F	60° F	65° F
80	89.6	87.0	85.1	83.5
70	75.9	74.0	72.5	71.2
60	62.3	61.0	60.0	—

Adapted from Houghton, F. C., and McDermott, P., *Heat, Pip. & Air Cond.*, 53:57, 1933.

25-3. Winslow and others (1938) state that individuals are more comfortable in high temperatures with cooler air and hot walls than with the air and walls at the same temperature, even though the skin and body temperature are the same in both cases. At cold temperatures, persons are more comfortable when the air and walls are the same temperature than when the walls are hot and the air cold with the same overall cooling effect.

Many attempts have been made to express the thermal state of the environment in terms of a single unit, which will combine two or more of the factors of temperature, humidity, air movement, and radiation. The American Society of Heating and Ventilating Engineers' unit—the effective temperature index (°E.T.)—is the only one of these units which has attained sufficient practical use to justify description here. This index was determined by exposing subjects in a test chamber to air at a given temperature with 100 per cent relative humidity. The subjects then moved into an adjoining chamber where a lower humidity and a higher temperature prevailed. If this combination of temperature and humidity produced the same sensation of warmth as the first chamber, this latter combination was designated an effective temperature equal to the dry bulb temperature of the saturated chamber. Any

combination of temperature and humidity giving the same sensation of warmth or cold as a given dry bulb temperature with 100 per cent relative humidity was called an effective temperature equal to this dry bulb reading. The original effective temperature charts were determined for practically still air and for persons who were

Fig. 25-3. Relationship between temperature and mean radiant temperature\* for combined convection and radiant heat losses of 250, 300 or 350 BTU per person.

\* Mean radiant temperature = mean surface temperature of the surrounding walls and objects. This is not actually the arithmetical average of the temperature of the surface but the temperature corresponding to the average rate of heat emission per square foot of surface or the temperature at which a black surface would radiate an intensity equal to the mean observed

not engaged in physical work. Other charts were subsequently prepared taking air movement and physical work into account. Two of the effective temperature scales are reproduced in Figures 25-4 and 25-5. Figure 25-5 is the basic scale applicable to persons at rest and stripped to the waist; Figure 25-4 is the normal scale applicable to persons at rest but dressed in customary indoor winter clothes. The American Society of Heating and Ventilating Engineers Guide (1949) reported that the optimum effective temperature for men and women at rest and normally clothed in winter is 66° E.T. with a range from 63° to 71°; and in summer, 71° E.T. with a range from 66° to 75°. Yaglou (ASHVE Guide, 1949) believes that men at rest and stripped to the waist are most comfortable at 72.5° E.T., with a range of 66° to 82°. It has been found that the effective temperature scale overestimates the

importance of humidity at low temperatures and does not make sufficient allowance for humidity at high temperatures.

The real difficulty in attempting to combine the four factors which control the thermal conditions of the environment lies in the multiple adjustments made by the human body when exposed to changes in temperature. As yet, no one has devised an instrument or any formula which makes adequate allowance for these factors and which can be applied to practical working conditions. Public health authorities working in the field of ventilation recommend that the four factors: temperature, humidity, air movement, and radiant heat be measured separately and that the standards of ventilation be expressed in terms of these four factors.

**Recommended Air Supply.** At the beginning of this discussion, it was pointed out that the original ventilation standards were set in terms of air supply per person per minute. It was also noted that the basis for this standard at the time of its adoption was not correct. With the currently accepted standards of ventilation based on the cooling power of the air, it is obviously not possible to specify a fixed amount of air which should be supplied since this varies with the temperature in the room, the outdoor temperature and the other factors discussed above. However, it is necessary to consider the air supply in relation to the removal of odors, tobacco smoke, and possibly infectious agents. The latter subject is discussed in Chapter 2. Odors and tobacco smoke are often disagreeable and in crowded places should be removed.

Table 25-7. Minimum outdoor air requirements, to remove objectionable body odors under laboratory conditions

Heating season with or without recirculation. Air not conditioned

Type of Occupants	Air Space Per Person Cu. Ft.	Outdoors Air Supply CFM per Person
Sedentary adults of average socio-economic status . . . .	100	25
	200	16
	300	12
	500	7
Laborers . . . . .	200	23
Grade school children of average socio-economic status.	100	29
	200	21
	300	17
	500	11
Grade school children of lower socio-economic status . .	200	38
Children attending private grade schools . . . . .	100	22

From Heating, Ventilating, Air Conditioning Guide, 1951, Chap. 6, p. 119.

The amount of air supply necessary to remove body odors varies from 10 to 30 cubic feet per person per minute, depending on the condition of the persons in the room and the degree of crowding as shown in Table 25-7. The Committee on Atmospheric Comfort of the American Public Health Association (Yaglou and others, 1950) recommended not less than 15 cubic feet per minute per person for

From Am. Soc. Heat & Ventil. Engin. Guide, 27:227, 1949.

Fig. 25-4. Thermometric chart showing normal scale of effective temperature. Applicable to inhabitants of the United States under following conditions: *clothing*, customary indoor clothing; *activity*, sedentary or light muscular work; *heating methods*, convection type, i.e., warm air, direct steam or hot water radiators, plenum systems.

Fig. 25-5. Thermostatic chart for human beings at rest and stripped to the waist.

persons doing light work and not less than 20 cubic feet per minute per person for persons engaged in heavy work. This air supply probably will be effective in removing tobacco smoke.

On the basis of this discussion, it is evident that under normal conditions, ventilation, either natural or mechanical, is essential chiefly to maintain a normal cooling power of the air and only secondarily to remove body odors and tobacco smoke. In industries or other places where foreign materials harmful to health are present in the air, the ventilation for the removal of these chemical substances becomes of great importance.

## RADIATION

### ELECTROMAGNETIC RADIATION

**Nature and Source of Electromagnetic Radiation.** Radiant energy is emitted as a result of internal changes in the atoms. This energy is believed to be given off as discrete packets or quanta of energy. In other words, this radiation may be considered as a stream of particles (or photons as they are called) each carrying a quantum of energy. The quantity of energy in each quantum is related to the frequency (per second) of the radiation and thus to the wave length—the higher the energy value of the quantum, the shorter the wave length. In a vacuum, all electromagnetic radiation has the same velocity, namely,  $3 \times 10^{10}$  cm. per second. Electromagnetic radiation may be classified into seven groups according to the wave lengths. Cosmic, x, and gamma rays have very short wave lengths and very high energy values; ultraviolet radiation, visible light, and infrared radiation have increasingly longer wave lengths and progressively lower energy values; and Hertzian, or radio waves, have very long wave lengths and even lower energy values. The

Table 26-1. Wave lengths of various radiations

	ANGSTRÖMS *
Cosmic rays .....	0.0005
Gamma rays .....	below 1.40
X-rays .....	below 150
Ultraviolet .....	below 4000
Limit of sun's U.V. at earth's surface .....	2920
Visible spectrum .....	4000-7000
Violet .....	4000-4240
Blue .....	4240-4912
Green .....	4912-5750
Maximum visibility .....	5560
Yellow .....	5750-5850

Red .....	6470-7000
Infrared .....	greater than 7000
Hertzian waves .....	beyond $2.20 \times 10^6$

\* To change from Angström units to millimicrons, divide by 10.

Chiefly from Hodgman, C. D., Editor, Handbook of Chemistry and Physics, 32nd edition, Cleveland, Chemical Rubber Pub. Co., 1950-51, p. 2247.

wave length distribution of these various radiations, all of which represent the same type of energy, is shown in Table 26-1. In addition to the distribution of radiant energy according to the frequency or wave length, it should be noted that, at any given wave length, the total intensity of the radiation emitted by the sun or any object also may vary.

The sun, which is the natural source of radiant energy, emits radiations continuously over a very wide range of the spectrum. However, in the passage of sunlight through the atmosphere to the earth, this spectrum is altered because the atmosphere absorbs and scatters many of the sun's rays. The ozone in the upper atmosphere absorbs the shorter ultraviolet wave lengths; the water vapor absorbs some of the infrared wave lengths; and the smoke, dust particles, gas molecules, and water droplets scatter the rays, especially those of shorter wave lengths. The solar spectrum at the earth has a range in wave lengths from 290 millimicrons in the ultraviolet range to over 2,000 millimicrons in the infrared range with a maximum intensity at about 480 millimicrons.

In addition to the sun, every gas, liquid, or solid object at a temperature above absolute zero degrees gives off radiant energy. Solid objects emit almost continuous spectra. At low temperatures only radiation of the longer wave lengths in the infrared range is emitted but as the temperature of the object is increased, more and more of the shorter wave lengths are added. This fact is demonstrated most easily by heating a piece of metal. When steel reaches a temperature of about  $1,700^{\circ}\text{F}$ , it gives off radiation at the red end of the visible spectrum and appears dull red. As the temperature is further increased, the shorter rays also are emitted, until at about  $2,100^{\circ}\text{F}$ , the metal appears white, due to the emission of wave lengths throughout the entire visible range. Gases, when heated, emit radiant energy only at certain wave lengths, which are characteristic of their chemical structure. The wave lengths emitted by gases may be either in the ultraviolet, visible, or infrared range of the spectrum. The mercury vapor discharge tube which is used widely for the production of ultraviolet radiation gives off a number of lines in the ultraviolet range of the spectrum. Ultraviolet radiation is emitted also from carbon arcs, electric welding arcs, and other sources when they are heated to extremely high temperatures. The sources of x-rays and gamma rays will be described later in this chapter under the section dealing with atomic particles and allied radiations.

The effects of radiant energy on the body fall into four distinct types: the heating effects of infrared radiation described in Chapter 25; the effects on the eye of visible radiation; the effects of ultraviolet radiation; and the ionizing effects of x and gamma rays described later in this chapter in connection with the atomic radiations.

## ILLUMINATION

**Sources of Visible Light.** Radiant energy in the visible range is emitted by the sun and by certain substances when heated to a sufficiently high temperature. The wave lengths of radiant energy which stimulate the retina and produce a sensation of light range from about 390 millimicrons to 770 millimicrons (see Table 26-1). Wave lengths somewhat shorter than 390 millimicrons may be perceived, but the sensitivity of the retina to these shorter wave lengths is slight. The intensity of the sunlight just outside the earth's atmosphere is greatest at about 480 millimicrons, i.e., at the shorter end of the visible spectrum. The visible light which reaches the earth from the sun varies in intensity with the time of the day, the season of the year, and the degree of atmospheric pollution.

In addition to the sun, which is the natural source of visible radiation, radiant energy for lighting purposes may be produced by heating solids such as tungsten filaments, or by electrical discharge through a gas such as mercury or neon. In the

ordinary incandescent electric light bulbs, the tungsten filament is heated to the temperature at which visible radiation is emitted. However, these bulbs are very inefficient because the greater part of their radiant energy falls in the infrared range. Furthermore, since the intensity of the radiation in the visible portion of the spectrum increases with an increase in wave length, the color of the light is predominantly yellow. In fluorescent bulbs, mercury vapor is heated, but, since the wave lengths given off by this substance are chiefly in the ultraviolet range, the bulbs must be lined with phosphors which absorb the short wave lengths and re-emit them in the visible range. The wave lengths which are re-emitted depend on the chemical nature of the phosphor. It is now possible to obtain fluorescent bulbs which have their maximum intensity of radiation at various wave lengths or bulbs which emit rays at all visible wave lengths so that the light is somewhat similar to daylight in its spectral distribution. Fluorescent bulbs emit the greater part of their radiant energy in the visible range and very little in the infrared range; hence, they are cool and efficient. A very small amount of ultraviolet radiation is emitted from fluorescent bulbs, but the phosphors and the glass itself absorb almost all of this radiation.

**Units for Expressing the Amount of Light.** The amount of visible radiation (light) which is emitted by a luminous object, such as an electric light bulb, is measured in terms of candle power based on a standard international candle, the equivalent of which is maintained at the Bureau of Standards in Washington. The amount of illumination which falls on a surface from a light source is expressed in terms of foot-candles. One foot-candle of illumination is the intensity of illumination at any point on a surface one foot away from a light source of one candle power. The illumination falling on a surface varies inversely as the square of the distance from the light source. The total amount of light which falls on one square foot of surface, all points of which are one foot from a light source of one standard candle, is called one lumen, i.e., the lumen is the term used to measure light flux. The brightness of the light source or of an object which is reflecting light is usually expressed in terms of foot-lamberts or candles per square inch. One foot-lambert is equivalent to one lumen emitted per square foot of the light source. One candle per square inch is the candle power emitted per square inch of light source. Detailed definitions of these and other units used in illumination are as follows: \*

### INTENSITY

**candle.** The international candle is the unit of luminous intensity and is an arbitrary standard maintained by certain governments. The amount of light emitted by a light source can be determined in terms of this unit. An ordinary candle about an inch in diameter provides roughly one candle power in a horizontal direction.

### LUMINOUS FLUX

**lumen.** The unit of light (or luminous) flux emitted in a unit solid-angle (steradian) from a uniform point source of one international candle. Such a source emits 4 lumens because, as a simple matter of geometry, there are 4 unit solid angles or steradians surrounding a point. A lumen is the total light flux on a surface of unit area all points of which are at a unit distance from a uniform point source of one international candle. If the foregoing unit is one foot it is obvious that a foot-candle is equivalent to one lumen per square foot.

\* Chiefly from Luckiesh and Moss, *The Science of Seeing*, New York, D. Van Nostrand Company, Inc., 1937, pages 318-319.

## LUMINOUS EFFICIENCY

**lumens per watt.** A term expressing the luminous efficiency of an electric light source.

## ILLUMINATION

**foot-candle.** The foot-candle is the unit of illumination. The level of illumination upon a surface varies (1) inversely as the square of distance from the light source of small size relative to the distance; (2) directly with the candle power of the source in the direction toward the surface; and (3) with the cosine of the angle of incidence of the light upon the surface. The illumination (foot-candles) and the diffuse reflection factor of a surface determine the brightness of a diffusely reflecting surface. A foot-candle is approximately the illumination on a small area of vertical surface one foot from an ordinary candle. One foot-candle equals one lumen incident per square foot.

**lux.** A lux is one lumen incident per square meter.

## BRIGHTNESS

**lambert.** Brightness of perfectly diffusing surface emitting or reflecting one lumen per square centimeter.

**foot-lambert.** Brightness of perfectly diffusing surface emitting or reflecting one lumen per square foot.

**candle power per square inch.** Brightness of perfectly diffusing surface emitting or reflecting light equivalent to one candle per square inch.

A lambert = 1 lumen emitted per sq. cm.  
 = 1000 millilamberts (ml)  
 = 929 foot-lamberts (fl)  
 = 2.054 candles per sq. in.  
 = 0.3183 candles per sq. cm.

A millilambert = 0.929 foot-lambert or 0.929 lumens emitted per sq. ft.  
 = 0.00205 candle per sq. in.  
 = 0.001 lambert

A candle per square inch = 452 foot-lamberts  
 = 0.487 lambert  
 = 487 millilamberts

A candle per square cm. = 3.1416 lamberts  
 A foot-lambert = 1 lumen emitted per sq. ft.  
 = 0.00221 candle per sq. in.  
 = 1.076 millilamberts

**General Principles of Good Illumination.** INTENSITY OF ILLUMINATION. Sufficient illumination is essential for acuteness of vision (visual acuity), for maximum speed of seeing, for prevention of eye fatigue and eye strain, and, thus, for efficient work and prevention of accidents. Definite proof that poor illumination will lead to permanent eye injury is lacking, but some evidence indicates that a higher incidence of refractive errors, especially myopia, exists among persons who perform close eye work at very low levels of illumination than among persons who work under good illumination. Some authorities believe that the extremely low levels of illumination in coal mines may be a factor in the production of miners' nystagmus, a condition which is prevalent in Great Britain but not in the United States. In addition to the physiological and clinical considerations, it is believed that the character of the illumination affects psychological reactions.

Standards of illumination usually are set in terms of the amount of illumination which falls on the work area. However, since vision depends on the light reaching the eye, the important consideration is not the amount of illumination on the desk or work bench but the amount of light which is reflected to the eye. For example, if there are 50 foot-candles of illumination falling on a white object which reflects about 80 per cent of the visible light, then 40 foot-candles of illumination will be

reflected toward the eye. If the same amount of light falls on a dark object which reflects 20 per cent of the light, only 10 foot-candles of illumination will be reflected to the eye. Hence it is necessary to specify different standards of illumination for different circumstances depending on the amount of light which is reflected from each work area.

Authorities have differed on the amount of illumination which is essential for vision. In general, it can be said that visual acuity and speed of vision increase markedly with an increase in illumination up to about 10 foot-candles, and then increase more slowly up to about 20 foot-candles, as shown in Figure 26-1. The

Fig. 26-1. The relationship between relative visual acuity and intensity of illumination and speed of seeing at various levels of illumination. Note: If the reflection-factor of the background against which a black object is viewed is 80 per cent, the lower scale is applicable, for a reflection-factor of 8 per cent the upper scale is used.

rate of improvement with higher levels of illumination appears to be low. These data are based on visual tasks where the background had a reflection factor of 80 per cent and where there was optimum contrast in color (black letters on a white background). Hence, 15-20 foot-candles can be accepted as a basic minimum level of illumination for satisfactory vision under optimum conditions. When the reflection factor is reduced, as in work on dark colors, or when the contrast in color between the object and its background is reduced, higher levels of illumination are necessary for good visual acuity and speed of vision, as shown in the upper scale

in the graph. Higher levels are required also for continuous eye work and for fine work, i.e., when the size of the object is very small. Individuals with poor vision or eye defects require more illumination than those with normal eyesight. Hence, although 15-20 foot-candles of illumination are considered the basic minimum, many tasks require more illumination. It is generally recommended that, when the contrast in color and brightness between the object and the immediate background is good and when the object being viewed is the size of normal print, the lighting for continuous eye work should supply a minimum of 30 foot-candles on the object. Where poor contrasts exist or the size of the object is small, the minimum illumination requirement should be set at 50 foot-candles. Even higher levels are necessary under certain conditions, such as in printing and typesetting, or when working on black objects. The American Standards Association (1952) has published *Standard Practice for Industrial Lighting*; The Illuminating Engineering Society (1950), *Recommended Practice of Daylighting*; and the American Medical Association, Council on Physical Medicine (1950), *Basic Requirements in School Lighting* by Tinker.

**BRIGHTNESS AND GLARE.** The amount of light reaching the eye from a light source or by reflection from an object is commonly designated as the "brightness" of the source or object and is usually expressed in foot-lamberts. Although the eye can adapt itself to very high levels of brightness, such as daylight out of doors, it cannot tolerate great contrasts in brightness between the central field of vision and the surrounding area. Such contrasts interfere with vision and may produce an uncomfortable sensation. In viewing an object against its surroundings, the visual acuity is greatest when the surrounding area has the same brightness as the central field of vision. The brightness of the central field of vision should never be less than that of the surroundings. On the other hand, the brightness contrast between the central field of vision, subtending an angle of one minute at the eye, and the immediate surroundings, assuming the latter to be an area which subtends an angle of 60 degrees, should not exceed a ratio of 10:1. Brightness ratios smaller than 5:1, even 3:1, are more desirable for continuous work. Contrasts in brightness within an angle of 30 degrees are especially uncomfortable. Greater contrasts in brightness can be tolerated between the central and peripheral fields of vision, but even here the contrasts in brightness should not be great. For example, the brightness of the ceiling should not be more than 10 times as bright as that of the task area. In order to avoid contrasts in brightness, good general illumination, rather than only local lighting on the work, must be provided throughout the entire area.

Brightness contrasts are produced also when bright light sources are in the field of view. If the eye is adapted to a high level of illumination and the contrast is not great, a bright light in the field of vision does not produce discomfort, e.g., when viewing an automobile headlight during daylight; if the eye is not adapted to bright light or if the contrast in brightness between the light and the surroundings is great, as an automobile headlight at night, an uncomfortable glare sensation is produced. The degree of the glare sensation depends on the distance of the eye from the light source, the brightness of the light source in relation to that of its surroundings, and the position of the light source in the field of vision in relation to that of the object on which the eye is focused. Excessive reflection from shiny surfaces, so-called reflected glare, produces an uncomfortable sensation and may completely obliterate the outline of an object. These localized bright spots, whether they be due to unpro-

ected light sources or to reflected glare, markedly reduce critical vision. Hence, bare light bulbs should never be permitted in the field of vision.

**DIFFERENCES IN ILLUMINATION WHEN PASSING FROM ONE AREA TO ANOTHER.** Great differences in illumination between one work space and another or between a work area and a hallway are dangerous if people are required to move from one space to the other. When passing from a brightly lighted area to one with a low level of illumination, the visual acuity is markedly decreased until dark adaptation has occurred. Although some adaptation occurs fairly rapidly it requires almost one-half hour for complete readjustment of vision to dim light. During the readjustment period the ability of the eye to see clearly is so reduced that the danger of accidents is increased. It is because of this physiological fact that relatively high levels of illumination are recommended for stairs, hallways, storage rooms, etc. Adaptation requires only a few minutes when passing from a dimly lighted space to one at a high level of illumination.

**COLOR OF LIGHT AND SURROUNDINGS, SURFACE FINISH.** A contrast in color between the object and its immediate background is important; the more definite the color contrast, the greater the visual acuity and speed of vision. The value of color contrast is due partly to the dissimilarity in color and partly to differences in the amount of light reflected by the different colors. Recognition of an object becomes most difficult when a black object is viewed against a black background. Here differences in texture and shadows are necessary for vision. Higher levels of illumination are required where the color contrast is reduced.

The color quality of the light from the common illuminants has little or no effect on visual discrimination and, hence, is not very important, except where a particular color is essential for the work, as long as sufficient light reaches the eye. When artificial light is used to supplement daylight, it is desirable to have the artificial light as nearly like daylight as possible.

The color and finish of the walls, ceiling, furniture, and machinery are of great importance in illumination because the amount of light reflected is determined chiefly by the color. Table 26-2 shows the variation in the reflection of visible light by different colors and materials. In areas where good visual functioning is required, it is recommended that the colors of the surroundings be selected so that the following percentage of reflection is obtained: from ceilings, 75 to 85 per cent; from walls, 50 to 60 per cent; from school desks, 35 to 50 per cent; from office desks, 30 to 35 per cent; from machines 20 to 30 per cent; and from floors, 15 to 30 per cent. In order to obtain good diffusion of light and to avoid glare spots, a flat finish is recommended. All polished specular surfaces should be eliminated. The light should be uniformly distributed and harsh shadows should be avoided.

Multiple or contrasting colors often are used for accident prevention, e.g., to indicate moving parts of machines, edges of steps, steam lines and other dangerous objects.

**Recommendations of Types of Artificial and Natural Lighting. ARTIFICIAL ILLUMINATION.** It is evident from the discussion given above that a basic amount of general illumination, about 15 to 20 foot-candles, must be supplied to all areas of a room in order to prevent great contrasts in brightness. Certain situations will require higher levels of illumination. Additional light may be provided in some cases, by raising the general level of illumination throughout the area or, in other cases, by supplying local lighting units. Local or supplemental lighting, in addition

o general lighting, is necessary when high levels of illumination are required, when illumination is needed in specific areas not accessible to general lighting, where the light must come from a particular angle, where hand readjustments are needed, where shadows are required, for the prevention of reflected glare, and for other circumstances. Supplementary lighting sources should be arranged so that persons in the vicinity are not exposed to excessively bright spots of light. Local lighting without general illumination is undesirable for the reasons discussed above.

Four types of lighting fixtures for general illumination are available: (1) totally indirect units, in which all of the light is reflected to the ceiling; (2) totally direct units, in which practically all of the light is reflected downward; (3) semi-indirect units, in which part of the light falls on the ceiling and upper side walls and part is directed downward; and (4) totally enclosed units, in which the light is radiated in all directions.

Totally indirect units are most desirable, where such units can be used, since they give an even diffuse illumination throughout an area and produce no shadows, no direct excessive brightness, and no reflected glare. However, they can be used only when the ceiling is at a normal height and is painted white for good reflection. Furthermore, very high levels of illumination cannot be obtained with totally indirect units without excessive brightness of the ceiling. Indirect units are uneconomical to operate and deteriorate rapidly due to the accumulation of dirt in the reflectors. Direct lighting units are more economical than other types and are less likely to deteriorate due to dirt. However, they give great contrasts in illumination, cast harsh shadows, frequently give excess brightness in the field of view, and produce dark ceilings with little general diffuse light. They are used chiefly for local lighting and in shops where the ceilings are too high and dark for other types of units. When adequately equipped with diffusers, they may be used in other areas. Semi-indirect and totally enclosed units are the most practical types for general illumination under usual conditions. Care must be taken that direct, semi-indirect, and enclosed units are properly designed and placed so as to avoid excess brightness in the field of view. Large units having a lower candle power per square inch, such as long tubular fluorescent lights, give less concentrated lighting than round tungsten filament bulbs which have a higher brightness per unit area (see Table 26-3). However, large units with moderate brightness also may cause discomfort

if placed directly in the field of view. Exposed bulbs should never be allowed within the field of view. When fluorescent bulbs are used on alternating current, two bulbs must be used together, arranged to prevent the cycle flicker or stroboscopic effect.

Since all lighting units become less efficient with time, chiefly due to the accumulation of dirt, the illumination on the work table may be reduced 25 per cent or even 50 per cent in a short period. Allowance for depreciation should be made in the initial installation especially in areas where dusts, smoke, and fumes exist. All types of units require continuous maintenance.

NATURAL ILLUMINATION. Daylighting, if properly arranged, may be a very effective source of good illumination in a room. However, much more difficulty is encountered in designing for daylighting than for artificial lighting. The amount of daylight reaching a room varies with the location and orientation of the building with the presence of surrounding buildings, and with the time of day, the season

the weather, and the degree of atmospheric pollution. Furthermore, whereas artificial lighting can be evenly spaced throughout a room and directed as desired, daylight is available only from certain areas, and its distribution is more difficult to control. Because of these variable factors, only a few general recommendations for providing daylight illumination can be given.

Windows facing south give maximum heat for cold climates but considerable glare; those facing north are advised for warm climates. The glass area should be at least 20 per cent of the floor area of the room. The tops of the windows should be as near the ceiling as possible, since the higher the windows, the more effectively does the light reach the opposite side of the room. An increase in the height of a window produces a much greater increase in illumination than a proportional increase in the width. The width of the room should not be more than approximately twice the distance from the floor to the top of the window when windows are only on one side of the room because of the rapid decrease in illumination across the room. Too often the illumination near a window is excessively bright while the illumination in another part of the room is below the minimum required for good vision. Windows on two sides of the room are desirable, but where windows are only on one side of a room the glass area should extend the full length of the room, if possible. It is recommended that windows should not be in the field of view for normal working conditions. The size and position of monitors and skylights also must be related to the size of the building. Since direct sunlight often produces excessive brightness, it is necessary to provide some means of sunlight control, such as venetian blinds, shades, louvres, outside projectors, glass block, etc. For maximum reflection and diffusion, the interior of rooms should be painted in light colors. Where feasible, the outside walls of neighboring buildings situated opposite the windows can be painted a light color in order to increase the light reflected to the room. Supplementary artificial lighting is necessary for use when daylight is reduced.

A complete discussion of recommended practices for daylighting in schools, factories, offices, and homes has been published by the Committee on Daylighting of the Illuminating Engineering Society (1950).

### ULTRAVIOLET RADIATION \*

**Ultraviolet Radiation from the Sun.** The spectral range of ultraviolet radiation begins at wave lengths of about 390 millimicrons and continues down toward the shorter wave lengths. Wave lengths between 390 and 310 millimicrons are referred to as near ultraviolet, whereas those which are below 310 millimicrons in length are considered as far ultraviolet. At the surface of the earth, the ultraviolet radiation from the sun extends only to wave lengths of about 290 millimicrons. The amount of ultraviolet radiation which reaches the earth from the sun varies with the season, time of day, latitude, altitude, and composition of the earth's atmosphere. The intensity of ultraviolet radiation from the sun is greater at noon than at any other time of the day and is greater in summer than in winter. These variations are due to the changes in the position of the earth in relation to the sun and to the resulting

\* A comprehensive survey of the subject has been published: *Radiation Biology*, Vol. 2, *Ultraviolet and Related Radiations*, Hollaender, A., Editor, New York, McGraw-Hill Book Co., Inc., 1955.

differences in the thickness of the air mass through which the sun's rays must pass to reach the earth. The visible rays of the sun penetrate the air mass readily, but the ultraviolet radiation is greatly absorbed by the ozone in the upper atmosphere. Hence, as the thickness of the air mass varies, the amount of ultraviolet radiation reaching the earth will vary to a greater extent than the visible light. At noon, when the sun is directly overhead (i.e., at zenith), the thickness of the air mass is at a minimum; when the sun is at  $60^\circ$  (i.e., four hours from the zenith), the thickness of the air mass is twice as great as at the zenith, so that much less ultraviolet radiation reaches the earth at this time than at noon. For this reason, individuals are not likely to receive a sunburn in the late afternoon even though the visible rays of the sun appear as bright as at noon. Similarly, seasonal changes in ultraviolet radiation result from the differences in the thickness of the ozone layer through which the sun's rays must pass at different seasons. According to Luckiesh and others (1944): "The total amount of erythema or anti-rachitic ultraviolet energy received in the six-month period from October to March, inclusive, is only about 10 per cent greater than that received in the single month of June or July. Furthermore, the total erythema or anti-rachitic energy recorded for December is only 1 per cent of that for the whole year." The amount of ultraviolet radiation is greater at high altitudes than at sea level because the impurities in the earth's atmosphere absorb a part of the sunlight. The rays of the sun, especially the shorter visible and ultraviolet wave lengths, are scattered and reflected to the earth by the constituents of the atmosphere as "sky radiation." On a clear day in a temperate climate, "sky radiation" may contribute as much as 50 per cent of the total ultraviolet radiation which reaches the earth. Because of the indirect reflection from the clouds and sky, the amount of ultraviolet radiation at the earth may be greater on days when the sky is covered by high thin cirrus clouds than on cloudless days. For this reason individuals often receive a greater sunburn on a cloudy day than on a clear day. Since snow reflects about 75 per cent of the ultraviolet radiation, persons skiing often get severe sunburns even on the underside of the nose which has no direct exposure to the sunlight.

**General Effects of Ultraviolet Radiation.** Before discussing the specific effects of ultraviolet radiation on the tissues of the body, it is well to consider the general effects of this type of radiation on cells. Ultraviolet radiation does not penetrate the body tissues more than a few millimeters but is absorbed entirely at the surface of the body. Therefore, it can exert a direct effect only on the superficial organs of the body, namely, the skin and the eyes; all other effects must be the result of changes in these tissues. When ultraviolet radiation is absorbed by the cells, the radiant energy initiates a photochemical reaction. According to Blum (1945), the type of chemical reaction which follows "is determined by the kind of molecule present in the environing system as well as by the activated molecule itself." The type of photochemical reaction produced is characteristic of the specific wave lengths of the ultraviolet radiation which are absorbed. For the most part ultraviolet radiation causes injury to the cells as a result of its destructive action on proteins or nucleic acid. The degenerative changes in the cell may affect both the nucleus and the cytoplasm.

Visible radiation, like ultraviolet radiation, produces a photochemical change in the rods and cones of the retina which absorb this radiation. In contrast, infrared

radiation, when absorbed, does not produce a chemical reaction but only increases the kinetic energy of the molecules, and, hence, the temperature of the tissue.

**Effect of Ultraviolet Radiation on the Skin.** ERYTHEMA AND SUNBURN. The penetration of the skin by ultraviolet, visible, and near infrared radiation is shown in Table 26-4. From this table it is evident that none of the ultraviolet radiation penetrates to the subcutaneous tissue. The wave lengths in the extreme ultraviolet are absorbed in the outer layer of the skin, the corneum, which is about 0.03 mm. in thickness. Of the near ultraviolet, about 50 per cent is absorbed in the epidermal layer (the corneum plus the Malpighian layer) which is only 0.05 mm. thick, and the remainder is absorbed in the corium which extends only to a depth of 2 mm. The greater part of the ultraviolet radiation does not penetrate deeply enough to reach the blood vessels of the skin. When the skin is exposed directly to ultraviolet radiation, injury occurs to the epidermal cells, chiefly those in the Malpighian layer. A dilator substance, which resembles histamine but does not appear to be histamine, is either produced in the corneum or is liberated in the breakdown of the cells. This dilator substance diffuses into the papillary layer and causes dilatation of the minute blood vessels, which, in turn, is responsible for the local reddening or erythema of the skin. The erythema does not begin until after a latent period of at least one-half hour, or usually longer, and is limited to the area actually exposed to the ultraviolet radiation. With severe doses, an increase in capillary permeability, edema, and swelling of the tissue may occur. These reactions reach a maximum on the second day. At the same time an erythematous flare may extend beyond the exposed areas. Blistering and desquamation of the skin may follow later, and, in very severe cases, ulceration of the dermis may result. The most interesting reaction in the skin following exposure to ultraviolet radiation is the formation of melanin, the pigment which is responsible for sun tan. Following exposure to ultraviolet radiation, the melanin which is normally present in the Malpighian layer migrates into the corneum. Later more melanin is formed. The wave lengths in the ultraviolet which are most effective in producing the erythema and sun tan are about 297 millimicrons. Subsequently, a darkening of the sun tan pigment may be caused by longer wave lengths, about 300 to 420 millimicrons. The final reaction to the ultraviolet burn is a thickening of all layers of the epidermis. This reaction is apparently a protective mechanism to prevent further injury to the skin by ultraviolet radiation. The tanning of the skin possibly exerts some protection also, but the immunity conferred by this mechanism is believed to be quite secondary to that brought about by the thickening of the skin. The extent of the reaction to ultraviolet radiation depends on the duration and intensity of the exposure and on individual susceptibility. Negroes are much less susceptible to ultraviolet radiation than are white-skinned persons, possibly due to a more uniform distribution of pigment throughout the epidermis or to a greater thickness of the corneum.

**CANCER OF THE SKIN IN RELATION TO ULTRAVIOLET RADIATION.** Considerable evidence, both experimental and epidemiological, exists to indicate that repeated exposure to ultraviolet radiation may cause cancer of the skin. Cancer of the skin can be induced in mice and rats upon exposure to ultraviolet radiation. Skin cancer in man occurs most frequently in those parts of the skin which are exposed to the sunlight. The Negro skin, which is less susceptible to the effects of ultraviolet radiation than white skin, is also less susceptible to skin cancer. It is reported that men in

General Remarks	Extreme Ultraviolet	Far Ultraviolet				Near Ultraviolet		Visible Violet Green Red		Near Infrared		Far Infrared	
	All absorbed by corneum. No radiation reaching germinativum.		Greatest absorption in stratum corneum. Some radiation reaches corium (papillae).				Relatively large absorption in stratum Malpighii.				Minimum absorption in stratum corneum. Most radiation absorbed in corium.		Strongly increasing absorption in upper layers, decreasing in lower layers.
													Practically no penetration.
													Practically no penetration.

the Navy and those who are engaged in occupations, such as forestry and agriculture, which involve exposure to the sun, have excessively high rates of skin cancer. A recent survey by the Public Health Service indicated that cancer of the skin and lip is more prevalent in the southern than in the northern part of the United States. Blum (1945) considers that this distribution may be related to a difference in the degree of exposure to ultraviolet radiation. Although none of these facts alone prove that ultraviolet radiation causes cancer of the skin, all together they are suggestive of an etiological relationship.

**RELATION OF ULTRAVIOLET RADIATION TO VITAMIN D.** The role of ultraviolet light in the production of Vitamin D, and thus on the prevention of rickets, is well known. Vitamin D is formed by the action of ultraviolet radiation on 7-dehydrocholesterol or on some very closely allied steroid compound. It is believed that this photochemical reaction occurs in the corneum. Wave lengths shorter than 320 millimicrons (chiefly about 280) are most effective in producing this reaction.

**EFFECTS OF ULTRAVIOLET, INTENSE VISIBLE, AND INFRARED RADIATION ON THE EYE.** Ultraviolet radiation is absorbed chiefly by the outer surface of the eye, the cornea and conjunctiva, which absorb all wave lengths below 295 and, to some extent, wave lengths up to 320 millimicrons. The lens completely absorbs the wave lengths between 295 and 315 millimicrons and partially absorbs those between 315 and 380 millimicrons. The degree of absorption by the lens varies with age, being greater in older persons than in younger persons. Wave lengths between 390 and about 1,400 millimicrons reach the retina, and in young persons wave lengths as short as 315 millimicrons may penetrate to the retina. Wave lengths between 390 and 760 millimicrons produce vision; the longer wave lengths cause only heat effects. No wave lengths longer than 1,400 millimicrons penetrate to the retina since these are entirely absorbed by the anterior portions of the eye.

Since the shorter wave lengths are absorbed by the conjunctiva and cornea, the chief effect of exposure of the eye to ultraviolet radiation is a conjunctivitis accompanied by photophobia. A great number of cases of conjunctivitis, commonly known as flash burns, occurred in the shipyards during World War II as a result of exposure to the ultraviolet radiation produced in electric arc welding. The inflammation of the conjunctiva appears several hours after the exposure and reaches its height in about 6 to 12 hours depending on the dose. The symptoms consist in pain and a feeling as though a foreign body were in the eye. Necrosis of the cells and edema of the conjunctiva, cornea, and eyelids occur. If the exposure is very severe, opacities and ulcers of the cornea may result. The condition usually clears completely in several days. Wave lengths of about 305 millimicrons appear to be responsible for this reaction. Eclipse blindness may result from gazing directly at the sun. This condition is apparently due to heat coagulation of the retina by the infrared radiation in the sun, although intense visible radiation may contribute to this. Recovery usually occurs, although the scotoma may be permanent. Snow blindness, which results from excessive exposure to the rays of the sun plus those which are reflected by the snow, consists of an inflammation of the conjunctiva and cornea with photophobia, chiefly due to the ultraviolet radiation, and retinal scotoma, the latter probably due to the effect of the infrared and intense visible rays on the retina. The possible role of ultraviolet and infrared radiation in the production of cataract is not clear. Clark (1935, 1936) has shown that the lens protein *in vitro* is denatured by ultraviolet radiation and that, in the presence of

calcium, opacity develops if the material is subsequently heated to 40° C. Blum (1945) states that wave lengths shorter than 320 millimicrons, if sufficiently intense, can injure the lens epithelium. There is no proof, however, that these reactions cause cataract in man. Glass blower's cataract, which has been reported in England, has been attributed to prolonged exposure to intense infrared radiation.

In order to protect the eyes against ultraviolet, infrared, or excessive visible radiation, glasses which filter out the harmful wave lengths should be worn. The United States Bureau of Standards has established specifications for glasses which will protect against excessive sunlight and certain types of radiation exposures in industries. This agency also has numbered the various shades of filter lenses which correspond to specific spectral transmittances (Stair, 1948). Lenses which reduce the intensity of visible radiation should be used only where exposure to excessive sunlight or glare occurs. The use of tinted lenses inside of homes and offices is not recommended since the level of illumination indoors is low. The use of dark glasses at night for reducing the glare from automobile headlights also is considered inadvisable since the visibility of all other objects is reduced. In selecting glasses for industrial exposures, it should be noted that glasses which reduce visible light may not remove either the ultraviolet or infrared radiation produced in the industrial process. Glasses for protection against radiant energy in industry should be selected in accordance with the specifications of the Bureau of Standards.

**Other Effects of Ultraviolet Radiation.** Since ultraviolet radiation is entirely absorbed by the skin and eyes, any effect on the internal tissues of the body must be due entirely to indirect effects resulting from changes in the skin. Therefore, it is not surprising to find that contradictory and uncertain results have been reported to follow exposure to ultraviolet radiation. Ultraviolet radiation has little if any effect on metabolism. The effect on the blood cells is variable and depends on the type and extent of the exposure. In general, it is claimed that exposure to ultraviolet radiation leads to a slight increase in the red cells, white cells, and platelets.

In spite of the popular opinion that ultraviolet irradiation of the skin and the resulting suntan are beneficial to health and increase resistance to infectious diseases, there are no data to support this view. Animal experiments in which rats, mice, and rabbits were irradiated with ultraviolet radiation before or after or both before and after infection with pneumococci, *B. leprosepticum*, and other organisms have been negative. Studies on the effects of ultraviolet radiation on pulmonary tuberculosis in animals have yielded chiefly negative, although somewhat contradictory, results (Rich, 1944). Studies on man have shown no beneficial effects of irradiation with ultraviolet rays on susceptibility to acute respiratory infections. In one study (Doull and others, 1931) it was found that biweekly irradiation of adult did not reduce the incidence or severity of common colds in this group as compared with a non-irradiated control group. During World War II, when many persons in England worked under artificial lighting due to "blackout conditions," an experiment was performed to determine the effects of ultraviolet light treatment on the health of clerical and industrial workers and miners. Persons treated with ultraviolet radiation did not differ from those not so treated in respect to the incidence of sickness or to the duration of colds (Colebrook, 1946). On the other hand, the use of ultraviolet radiation in the treatment of some skin conditions has been favorably reported. Ultraviolet radiation, especially that between 250 and 280 millimicrons, exerts a marked bactericidal effect. The value of ultraviolet radiation

in preventing the transmission of infectious agents through air and water is discussed elsewhere in this book.

In view of the fact that ultraviolet radiation does not appear to be beneficial to health except in the prevention of rickets and in view of the fact that it may exert a harmful effect on the skin and eyes, the indiscriminate use of ultraviolet lamps in homes and industries should be discouraged. Treatment with ultraviolet radiation for the prevention and cure of rickets should be under the direction of a physician. Because ordinary window glass absorbs all of the antirachitic ultraviolet radiation, it has been suggested that ultraviolet transmitting glass be installed in schools and homes. However, under these circumstances, only children sitting in the direct sunlight coming through such glass will receive any appreciable amount of ultraviolet radiation. Other children in the room who sit outside of the range of direct sunlight would get as much ultraviolet exposure from two minutes outdoors in the sun at noon as they would receive after 20 hours in this room (Clark, 1933). Thus, the installation of ultraviolet transmitting glass is not recommended for schools or private dwellings. Under some circumstances, this glass may be used advantageously in hospitals, sanatoria, and the like.

## ATOMIC PARTICLES AND IONIZING RADIATIONS

**Source and Nature of Atomic Particles and Ionizing Radiations.** When atoms disintegrate spontaneously or are subject to fission or are bombarded with high energy particles, the atoms may emit one or more types of discrete particles and/or some radiant energy. These particles and radiations are usually classified all together as ionizing radiations. In order to understand the effects of these radiations, it is necessary to review the structure of the atom and the nature of these particles and radiations.

**STRUCTURE OF THE ATOM.** According to the classical theory, the atom consists of a tiny, heavy nucleus surrounded by a vacuum in which electrons move like planets about the sun. These electrons, known as planetary or orbital electrons, whirl around the nucleus in orbits which are located at the outer portion of the space. The distance between the nucleus and the orbit of the nearest encircling electron is a gap which is greater in proportion to the size of the nucleus and electrons than the space between the sun and the orbit of the earth. The nuclei of all atoms (except hydrogen) are composed of protons and neutrons. The protons have a mass of about  $1.66 \times 10^{-24}$  gm. and carry a unit positive electrical charge. The neutrons also have a similar mass but are electrically neutral particles. The electrons have a mass which is only 1/1850th of the proton mass and they have a unit negative electrical charge. The number of negatively charged electrons circling around the nucleus is equal to the number of positively charged protons, hence, the atom as a whole has no electrical charge. The atomic weight of the atom is the sum of the mass of the protons plus the mass of the neutrons. The atomic number is equal to the number of protons. The number of protons, i.e., the atomic number, and not the atomic weight determines the chemical properties of an element. The simplest atom, that of hydrogen, has one planetary electron and a nucleus with one proton, but no neutron. Heavy hydrogen has, in addition, one neutron in the nucleus. Helium atoms have two protons and two neutrons in the nucleus and two electrons circling in the outer orbit. All other atoms have structures similar to the

helium atom except that the number of protons, neutrons and electrons are greater.

**RADIOACTIVE ISOTOPES.** The isotopes of elements are chemically the same as the element and their nuclei contain the same number of protons but they differ from one another in the number of neutrons. For example, uranium 235 has 92 protons, 92 electrons and 143 neutrons; uranium 238 has the same number of protons and electrons but 146 neutrons.

Most elements present in nature exist in two or more stable isotopic forms, although some unstable isotopes, such as radium, occur naturally. In recent years unstable isotopes of all known elements have been produced. If the ratio of neutrons to protons in the nucleus of an atom lies within a certain limited range, the atom will be stable. If the ratio falls outside of this range, the atom will be unstable. The unstable nucleus undergoes spontaneous changes in an effort to attain stability, i.e., it emits atomic particles and in some cases gamma rays. These unstable atoms are called radioactive isotopes, or radioisotopes, and the spontaneous changes which take place in the unstable atomic nucleus are known as radioactive decay. Each radioisotope decays at a characteristic rate which is expressed in terms of its half-life, or the time required for the activity of a given quantity of a radioactive material to decay to half its initial value. The half-life has a definite value irrespective of the amount of active material originally present. Some radioactive isotopes have a half-life of many years, whereas others have a half-life of seconds. The half-life of a radioisotope is very important from a health viewpoint. Isotopes which decay rapidly into stable atoms produce ionizing radiations for only a short time and present relatively no problem in waste disposal. Those with long half-lives remain active for years and when taken into the body continue to produce damage until they are excreted. These slowly decaying isotopes present a serious public health problem in waste disposal since, if indiscriminately discharged, they could contaminate the water, soil or air for generations.

**ATOMIC PARTICLES AND RADIATIONS.** The nuclear particles which may be emitted from an atom include alpha particles, negative beta particles, positive beta particles or positrons, neutrons, protons, mesotrons, neutrinos and some other less well known types. The last few types are not well understood at the present time and will not be included in this discussion. In addition, electrons from the orbit may be emitted from the atom by internal conversion of gamma rays. The alpha particles are composed of two protons and two neutrons and thus are the same as the nucleus of a helium atom. Alpha particles are produced by the spontaneous disintegration of certain radioactive substances, e.g., radium, and are artificially produced by the bombardment of certain elements by neutrons. Alpha particles produce intense ionization but penetrate only 5 to 10 cm. of air or 0.1 mm. of tissue. Alpha particles which are produced adjacent to the body surface are entirely absorbed in the cornified epithelium of the skin. Hence, sources outside of the body constitute no great danger to health. If, however, alpha emitters, such as radium, are ingested or inhaled, great damage may be done to the tissues which are in close contact with these radioactive materials.

Beta particles are either high speed electrons or positrons which are ejected from the nucleus of an unstable atom. The beta particles are not considered as present in the nucleus but as created in the nucleus at the instant of disintegration. Often gamma rays are emitted simultaneously with the beta particles. The gamma rays may dislodge and eject planetary electrons which then act like beta particles.

Negative beta particles are emitted from natural radioactive elements, as from the disintegration products of radium, and from many unstable radioactive materials which are produced artificially. Beta particles produce ionization, but their effect is only about  $1/100$ th as severe for a given depth of penetration as that caused by alpha particles. Beta particles vary in their degree of penetration of air from about 1 cm. up to 15 meters. They penetrate only about 1 to 3 cm. of tissue. Thus, when beta rays are emitted close to the skin, the germinal epithelium and the upper layers of the derma will be harmed but the deeper tissues will not be affected. When beta emitters are ingested or inhaled, they constitute a serious internal hazard. Positive beta particles (positrons) are emitted in the decay of some artificially radioactive elements. These positive beta particles are similar to negative beta particles except that they carry a positive charge. Each positive beta particle combines with an electron and yields two gamma rays. Thus, the effects of exposure to positive beta particles are similar to the effects of exposure to negative beta particles plus gamma rays.

Neutrons are elementary atomic particles which form part of the nuclei of all atoms except hydrogen. Neutrons which travel at fast speed (fast neutrons) and those which travel at slow speed (slow neutrons) are produced as a result of atomic fission in a chain reacting pile. Fast neutrons can be liberated also by bombardment of beryllium with high energy particles. Fast neutrons can easily penetrate some substances like lead but are stopped by water. If the neutron collides with a hydrogen nucleus, this nucleus, or proton, is ejected. Slow neutrons react with some of the atomic nuclei of the substances through which they are passing. New elements or isotopes are formed with the liberation of gamma rays or protons. Neutrons in themselves do not produce ionization but they cause severe ionization indirectly through the formation of protons and gamma rays.

The proton is identical with the nucleus of the hydrogen atom. Protons are never emitted spontaneously by radioactive materials but are produced by the action of neutrons on light elements. They produce extensive ionization in a manner similar to alpha particles.

In addition to the particles which may be ejected from an atom, two types of radiant energy, the neutrino and the photon of electromagnetic radiation may be emitted by the atomic nucleus. The neutrino is a radiation which has never been detected and hence will not be considered here. The electromagnetic radiations which are emitted from the nucleus of the atom are the gamma rays and, under some circumstances, x-rays. These rays have exceedingly short wave lengths as shown in Table 26-1. Gamma rays are emitted from the atomic nucleus in the spontaneous decay of natural and artificially produced radioactive substances. They are usually produced in association with the emission of an alpha particle or a beta particle. Gamma rays are formed also in the fission of an atomic nucleus and whenever a positron and an electron combine. Gamma rays of themselves do not produce ionization but they cause the ejection of high speed electrons from the orbit of atoms near which they pass. These electrons in turn produce ionization. Gamma rays penetrate the air and tissues readily and thus produce harmful effects on the deep tissues of the body as well as on the skin. However, the ionizing power of gamma rays, for a given depth of tissue, is only about  $1/10,000$ th as great as that of alpha rays. X-rays are similar in their action to that of gamma rays. Since these radiations are generally of longer wave length than the gamma rays and have a

lower energy value, their ionizing power is less. X-rays are formed when a stream of fast electrons, moving in a vacuum, strikes a metal target. Unlike gamma rays, x-rays are not formed in the nucleus of the atom but by a shift in the position of electrons between the orbits; the energy lost is given off as x-radiation.

Atomic particles and gamma rays are produced also in the explosion of atomic bombs. It is stated (Glasstone and others, 1950) that "the explosion of an atomic bomb is accompanied by the emission of nuclear radiations consisting of gamma rays, neutrons, beta particles and a small proportion of alpha particles. The neutrons and some of the gamma rays are emitted in the actual fission process, that is to say, simultaneously with the explosion, while the remainder of the gamma radiation and the beta particles are liberated as the fission products decay. The alpha particles result from the normal radioactive decay of the plutonium 239 or uranium 235 which has not undergone fission." Radioactivity also may be induced in various elements normally present in the earth or in the sea by the neutrons which are liberated during the explosion if the explosion occurs underground or underwater or close to the earth. These induced radioactive isotopes usually decay by emission of beta particles accompanied by gamma radiation.

**UNITS AND TERMINOLOGY.** The units which are used to express the energy of atomic particles and ionizing radiations are somewhat complex. In fact, the measurement of these radiations in terms of their biological effectiveness presents a number of problems. The standard unit for determining the quantity of energy liberated in x- or gamma rays is the "roentgen" which is defined in terms of the ionization produced in a known mass or volume of unrestricted air. The roentgen is not applicable to measurement of the energy of atomic particles nor does it measure the biological effectiveness of ionizing radiations. As a result of these difficulties, two new units have been introduced: the roentgen equivalent physical (rep) and the roentgen equivalent man (rem) (see Radiological Terminology, below).

Various instruments for measuring the number of atomic particles and for measuring the intensity of x- and gamma rays are now available commercially.

Following is a list of definitions of terms which are currently used in the field of atomic energy.

#### RADIOLOGICAL TERMINOLOGY \*

**Ionizing radiation** is electromagnetic radiation (consisting of photons) or particulate radiation (consisting of electrons, neutrons, protons, etc.) usually of high energy but in any case capable of ionizing air, directly or indirectly.

**X-rays** (sometimes "x-radiation") are electromagnetic ionizing radiation. In radiology x-rays are often classified according to the voltage at which they are produced. The following classification according to voltage range is generally understood:

**Low-voltage x-rays:** Voltage range up to 140 kv.

**High-voltage x-rays:** Voltage range 140 to 250 kv.

**Supervoltage x-rays:** Voltage range 250 kv. to 3 Mv.

**Multimillion-volt x-rays:** Voltage higher than 3 Mv.

In this connection it is convenient to distinguish between the voltage at which the x-rays are produced and the energy of the x-ray photon. Kv or Mv refers to the former, and kev or Mev refers to the photon energy. When the radiation is monochromatic, kev or Mev is generally used.

**Roentgen rays** are x-rays usually produced by bombarding a (metallic) target with high-speed electrons in a suitable device. Gamma rays are x-rays originating in the nuclei of atoms.

\* Quoted directly from "Permissible Dose From External Sources of Ionizing Radiation," Handbook 59, National Bureau of Standards, September 1954.

In general "x-rays" and "roentgen rays" are used interchangeably in radiology. The distinction indicated here is made simply for convenience, since it does away with the cumbersome repetition of the expression "x-rays and gamma rays."

**Quality of x-rays.** The term "quality" refers in a general way to the penetrating power of an x-ray beam. *Soft x-rays* are x-rays of low penetrating power; *hard x-rays* are x-rays of high penetrating power.

**Half-value layer (HVL).** Quality is often expressed in terms of the half-value layer, which is the thickness of a specified material (usually aluminum, copper, or lead) required to decrease the dosage rate of a beam of x-rays at the point of interest to one half of its initial value.

**Beta rays (beta particles)** are particulate ionizing radiation consisting of electrons or positrons traveling at high speed.

**Alpha rays (alpha particles)** are particulate ionizing radiation consisting of helium nuclei traveling at high speed.

**Neutrons** (or neutron rays) are particulate ionizing radiation consisting of neutrons that either possess enough kinetic energy to set in motion, by impact, nuclei of atoms with sufficient velocity to ionize matter; or enter into nuclear reactions that result in the emission of ionizing radiation. The former variety is usually called *fast neutrons* and the latter *thermal neutrons*, with gradations of *epithermal* and *slow neutrons* in between.

**Heavy-particle radiation** is particulate ionizing radiation consisting of atomic nuclei of any mass traveling at high speed (protons, deuterons, helium nuclei, etc.). Alpha rays constitute a special kind of heavy-particle radiation.

**Specific ionization.** When a high-speed charged particle traverses matter, ions are produced along its path. The number of ion pairs per unit length of path is taken to represent the specific ionization of the particle at a given point in its trajectory or "track." In general, ionizing particles with different charges and of different energies may be present in the region of interest, and wide differences in specific ionization may occur. Because the biological effectiveness of an absorbed dose of radiation (see below) depends on the specific ionization, ideally one should know the specific-ionization spectrum of the dose in the locus of interest. This is not feasible at the present time and therefore in practice estimated average values are used.

The number of ion pairs per unit length of track is generally determined in air. In radiobiology, however, one is interested in the transfer of energy to tissues, which includes the energy required to produce ions and the energy imparted to other atoms and molecules that are not ionized but become "excited." It is, therefore, more appropriate to speak of "linear energy transfer per unit length" (LET, according to R. E. Zirkle) than specific ionization. Since in practice values of LET are generally derived from the specific ionization in air, the distinction between the two is essentially a formal one in the present state of the art.

**Dose.** In radiology a *dose* of ionizing radiation is a quantity of radiation. In this connection the term "quantity" represents the magnitude of the dose and may be expressed in various units. Since the adoption of the roentgen, it has been customary to express the magnitude of a dose of x-rays in roentgens. In recent years there has been an increasing tendency to regard a dose of radiation as the amount of energy absorbed by tissue at the site of interest per unit mass. Also, in physics "quantity of radiation" has always had a very special meaning. To avoid confusion the International Commission on Radiological Units at its Copenhagen meeting in July 1953 recommended that a distinction be made between dose in a general sense and "absorbed dose." A new unit, the "rad," was recommended for the latter.

**Dosage rate.** Dosage rate, or dose rate, is the time rate at which a dose is administered, that is, dose per unit time. When the dose is administered intermittently one may speak of an *average dosage rate*. In the case of generators emitting radiation in pulses, the *instantaneous dosage rate* (during the pulse) may be very high while the average dosage rate may be low. Dosage rates are expressed in roentgens or rads per minute or multiples or submultiples of these units, e.g., milliroentgens per hour (mr/hr).

**Intensity of radiation** is the energy flowing through unit area perpendicular to the beam per unit time. It is expressed in ergs per square centimeter per second or in watts per square centimeter.

**Quantity of radiation** is the time integral of intensity. It is the total energy that has passed through unit area perpendicular to the beam and is expressed in ergs per square centimeter or watt-seconds per square centimeter.

**Absorbed dose** of any ionizing radiation is the amount of energy imparted to matter by ionizing particles per unit mass of irradiated material at the place of interest. It shall be expressed in "rads."

The rad is the unit of absorbed dose and is 100 ergs/gm. One millirad (1 mrad) is one thousandth of one rad.

The roentgen is the quantity of x- or gamma radiation such that the associated corpuscular emission per 0.001293 gm. of air produces, in air, ions carrying 1 electrostatic unit of quantity of electricity of either sign. *One milliroentgen (1 mr)* is one thousandth of one roentgen.

**The rep.** Heretofore the rep (roentgen-equivalent-physical) has been used extensively for the specification of permissible doses of ionizing radiations other than x-rays or gamma rays. Several definitions of the rep have appeared in the literature but in the sense most widely accepted it is a unit of *absorbed dose* with a magnitude of ergs gm. The difference in magnitude between the rep (93 ergs gm.) and the rad (100 ergs gm.) is negligible in the estimation of permissible doses. Therefore, the adoption of the rad to replace the rep does not necessitate a change in the numerical values of permissible doses stated in reps heretofore.

**The rem.** The rem is the quantity of any ionizing radiation such that the energy imparted to a biological system (cell, tissue, organ, or organism) per gram of living matter by the ionizing particles present in the region of interest has the same biological effectiveness as an absorbed dose of 1 rad of x-radiation with average specific ionization of 100 ion pairs per micron of water in the same region.

**Effects of Atomic Radiations on the Body.\*** GENERAL EFFECTS OF IONIZING RADIATIONS. The effects of atomic particles, x-rays, and gamma rays on the tissues are believed to be fundamentally the same in all cases and are due to the process of ionization. When an electrically charged particle, such as an alpha or beta particle, passes through matter, it will occasionally approach close enough to an atom or molecule to exert an electrical force which is sufficient to remove an electron from the atom or molecule. The residue of the atom or molecule, after the removal of the electron, is a positively charged ion; the separate electron and the ion so formed constitute what is known as an ion pair. The electron which is lost from an atom may be an electron which binds the atoms together to form a molecule or it may be an electron from an orbit at another level. The ejected electron may cause the ejection of electrons from other atoms, but eventually it becomes attached to another atom, which then becomes negative.

Although the x-rays, gamma rays, and neutrons are not charged particles and cannot directly produce ionization, when absorbed they cause the ejection of high speed charged particles which in turn produce ionization.

The ultimate effect of ionization is damage to or death of the cells. According to Glasstone and others (1950), "It is the decomposition of certain molecules in living organisms resulting from the breaking of chemical bonds, which alters the characteristics of vital parts of the cells and causes physiological damage." Characteristic changes appear in the nucleus and to a lesser extent in the cytoplasm. Cell division is retarded and abnormal cell division may occur as a result of damage to the chromosomes. Cells at the beginning stage of mitosis appear to be most sensitive to radiation.

The extent of damage to the cells is related not only to the total energy absorbed over a period of time but varies with the intensity of the energy at any one time and with the frequency of the exposures. With low grade exposures repeated at intervals, the repair processes in the tissues may be able to compensate in part for the damage produced. Hence, greater total doses can be tolerated if they are fractionated than if they are administered at one exposure. However, the effects of repeated small doses of ionizing radiation must be cumulative since experiments on animals showed that exposure of the whole body to repeated, small amounts of radiation shortened the life span of these animals.

\* A comprehensive survey of the subject has been published: *Radiation Biology*, Vol. I, High Energy Radiation (in two parts), Hollaender, A., Editor, New York, McGraw Hill Book Co., Inc., 1954.

The type and severity of damage produced in the body as a result of exposure to ionizing radiations depends on the extent of the tissue exposed and on the particular tissue which absorbs the radiations. The tissues of the body appear to differ greatly in their susceptibility to the effects of penetrating radiation. Based on experience with x-rays, they can be listed in the following order of decreasing sensitivity: (1) lymphoid tissues, including bone marrow, blood lymphocytes, lymph nodes, and Peyer's patches; (2) polymorphonuclear leukocytes; (3) epithelial cells, including gonads and ovaries, salivary glands, skin, and mucous membrane; (4) endothelial cells, including blood vessels and peritoneum; (5) connective tissue cells; (6) muscle cells; (7) nerve cells. The lens of the eye and developing teeth also are very susceptible. The cellular changes which are responsible for the clinical symptoms resulting from ionizing radiation are not clearly understood at the present time, although various theories have been advanced to explain the effects produced.

The locus of damage resulting from ionizing radiation depends on the type of particle or radiation and on whether the radiation is applied externally or arises from radioactive material present in the body. Alpha particles are important only when the alpha emitter has been taken into the body through the respiratory or digestive tract or planted in the tissues. Beta particles can exert an effect by external application on the skin, and they can exert an effect internally on other tissues after absorption of the radioactive materials. A radioactive material when absorbed may have a peculiar affinity for certain tissues of the body and thus exert its effect locally on that particular tissue. X-rays always originate externally but owing to their penetrating power they affect the internal organs as well as the skin. Gamma radiation may originate externally or internally since many radioactive materials liberate gamma rays.

**CLINICAL AND PATHOLOGICAL EFFECTS OF IONIZING RADIATION.** *Acute Systemic Effects.* With massive doses of penetrating radiation to the whole body, such as with x- and gamma rays, death may occur in a few hours or days. In less severe cases, loss of appetite, nausea and vomiting occur within an hour or two. The symptoms then subside for a period which lasts one day to two weeks depending on the dose. After this so-called latent period, the original manifestations of illness reappear accompanied by the following symptoms: diarrhea, fever, bleeding and ulceration of the mucous membranes, fall in blood pressure, increased susceptibility to secondary infections, epilation, amenorrhea, increased capillary fragility and a marked decrease in all cellular elements of the blood, especially the lymphocytes and granulocytes. The relation of these clinical symptoms to the dose and interval of time following the exposure are shown in Table 26-5. The pathological changes include hemorrhages throughout the tissues and degenerative changes, chiefly in lymphoid tissue, bone marrow, testes, mucous membranes of the gastro-intestinal tract, and reticulo-endothelial tissue.

*Chronic Systemic Effects.* Multiple exposures to low-grade doses of ionizing radiations may, if continued over a sufficient length of time, produce serious damage. For whole body irradiation Evans (1951) lists the following possible dangers: (1) leukopenia, (2) anemia, (3) sterility, (4) fetal injury, (5) glandular dysfunction, (6) bone necrosis, (7) leukemia, and (8) tumor induction. Dermatitis and epidermoid carcinoma also occur. Other effects which may result from cumulative small exposures are: (1) reduction of life span, (2) injury to the ovaries, (3) increase in mutation frequency, and (4) production of cataracts by neutrons.

Table 26-5. Summary of clinical symptoms of radiation sickness

TIME AFTER EXPOSURE	LETHAL DOSE (600 r)	MEDIAN LETHAL DOSE (400 r)	MODERATE DOSE (300-100 r)
	Nausea and vomiting after 1-2 hours	Nausea and vomiting after 1-2 hours	
First week	No definite symptoms		
	Diarrhea Vomiting Inflammation of mouth and throat	No definite symptoms	No definite symptoms
Second week	Fever Rapid emaciation Death (Mortality probably 100%)	Beginning epilation	
		Loss of appetite and general malaise	
Third week		Fever	Epilation
		Severe inflammation of mouth and throat	Loss of appetite and general malaise
			Sore throat
Fourth week		Pallor Petechiae, diarrhea, and nosebleeds	Pallor Petechiae
			Diarrhea
		Rapid emaciation Death (Mortality probably 50%)	Moderate emaciation  (Recovery likely unless complicated by poor previous health or superimposed injuries or infections)

From Glasstone, S., Editor, *The Effects of Atomic Weapons*, U. S. Gov't Printing Office, 1950, page 147

*Skin Effects.* Beta particles and low energy (soft) x-rays are responsible for most of the damage to the skin since these radiations are absorbed at the surface of the body. High energy x-rays (i.e., hard x-rays) and gamma rays, penetrate the tissues more readily and hence have less effect on the skin. The skin reactions appear after a latent period of a week or two. The reaction includes erythema, edema, pruritis, blisters, sloughing of the epidermis and ulceration. Healing is usually slow. Delayed effects include hyperkeratoses, atrophy of the skin, sweat glands and sebaceous glands and eventually epidermoid carcinoma.

*Genetic Effects.* Since experiments have shown that irradiation of *Drosophila* and mice lead to an increase in mutations, considerable concern has been felt

regarding the possible genetic effects which may result from atomic weapons and the many potential sources of ionizing radiation in use today. No statement concerning the probability of genetic damage from radiation exposure in man can be made on the basis of the experiments on *Drosophila* and mice, and few data on man are available. However, certain general principles as reported by the Office of The Surgeon General (1948) should be considered. The majority of both natural and radiation mutations are recessive; therefore, the probability that they will manifest themselves in a future generation is relatively small. In about 95 per cent of mutations, the offspring die during gestation or soon thereafter. Of the remaining 5 per cent, 95 per cent are deleterious, and of these, 96 per cent pertain to other than sex chromosomes. In the studies which have been made to determine if the atomic bombings in Japan produced genetic effects little of a deleterious nature has been found to date.

**Cancer.** Ionizing radiations appear to be more or less universally carcinogenic. Experiments have shown that ionizing radiations can induce leukemia, malignant lymphoma, and tumors of the ovaries, lungs, mammary glands, skin and other organs in animals. Abundant evidence also exists to prove that ionizing radiations may produce malignant tumors in human tissues which absorb the radiation. Many of the early radiologists developed cutaneous carcinomas before the dangers of such radiations were recognized. A number of cases of leukemia also have been reported in radiologists and radiation workers. Osteogenic sarcomas have resulted from absorption of radioactive materials by luminous dial painters. During World War I, a number of girls painted dials with material containing radium salts and mesothorium. It is believed that these girls absorbed the radioactive materials chiefly through the mouth since they frequently pointed the paint brushes with their lips. They were also exposed to the dust of this material. Whether the agent responsible for the osteogenic sarcomas was radium or mesothorium is not known. A high rate of lung cancer has been reported among the workers in the Schneeberg and Joachimsthal mines in central Europe. These mines contain radioactive materials. Although the lung cancers have been attributed to the inhalation of radon or possibly radioactive dust, the exact agent responsible for the lung cancers has not been definitely determined.

A considerable latent period occurs between the irradiation and the development of the cancer. Cancers may be induced by a single intense exposure or by repeated exposures.

**Maximal Permissible Exposure to Atomic Particles and Ionizing Radiations.\*** No radiation level higher than the natural environmental conditions in which man has evolved can be regarded to be absolutely safe. Hence exposure to radiation should be kept at the lowest practicable level in all cases. In setting maximum permissible doses, the radiation authorities have selected levels which, in the light of present knowledge, are not expected to cause appreciable bodily injury to persons during their lifetime. The maximal permissible doses for external sources of ionizing radiations which have been tentatively adopted and published by the National Bureau of Standards (Handbook 59, Sept. 1954) are as follows:

\* Quoted chiefly from National Bureau of Standards, Handbook 59, September 1954, and Handbook 52, March 1953.

## LONG-TERM EXPOSURE

**Rule I. Ionizing Radiation of Any Type or Types.** For adults under 45 years of age whose entire body, or major portion thereof, is exposed to ionizing radiation from external sources for an indefinite period of years, the maximum permissible total weekly doses shall be 300 mrems in the blood-forming organs, the gonads, and the lenses of the eyes; 600 mrems in the skin; and the respective values of the weekly doses in millirems in all other organs and tissues of the body according to the basic permissible dose distribution. For persons 45 years of age or older similarly exposed, the corresponding maximum permissible total weekly doses shall be double the above stated values, provided that the portion of the weekly dose in the lenses of the eyes contributed by radiation of high specific ionization does not exceed 300 mrems.

**Rule II. X-rays (Roentgen Rays, Gamma Rays) with Photon Energy Less Than 3 Mev.** For adults under 45 years of age whose entire body, or major portion thereof, is exposed solely to X-rays with photon energies less than 3 Mev from external sources for an indefinite period of years; the maximum permissible total weekly dose shall be 300 mr measured in air at the point of highest weekly dose in the region occupied by the person, provided that the actual total weekly dose in the gonads does not exceed 300 mrad. For persons 45 years of age or older similarly exposed, the corresponding maximum permissible total weekly doses shall be double the above stated values, provided that the actual total weekly dose in the lenses of the eyes does not exceed 600 mrad.

**Rule III. Radiation of Very Low Penetrating Power (Half-value Layer Less Than 1 mm. of Soft Tissue).** For adults of any age whose entire body, or major portion thereof, is exposed to ionizing radiation of very low penetrating power from external sources for an indefinite period of years; the maximum permissible total weekly dose in the skin shall be 1,500 mrems, provided that the total weekly dose in the lenses of the eyes does not exceed 300 mrems.

**Rule IV-A. Local Exposure to the Hands and Forearms to Any Ionizing Radiation.** For adults of any age whose hands and forearms are exposed to ionizing radiation from external sources for an indefinite period of years; the maximum permissible total weekly dose shall be 1,500 mrems in the skin, provided the respective weekly doses in millirems in all other tissues of the hands and forearms are not in excess of those that would result from exposure to ordinary X-rays at a weekly dose of 1,500 mr in the skin.

**Rule IV-AX. Local Exposure of the Hands and Forearms to X-rays (Roentgen Rays, Gamma Rays) of Any Photon Energy.** For adults of any age whose hands and forearms are exposed solely to X-rays from external sources for an indefinite period of years, the maximum permissible total weekly dose shall be 1,500 mr in the skin.

**Rule IV-B. Local Exposure of the Feet and Ankles to Any Ionizing Radiation.** For adults of any age whose feet and ankles are exposed to ionizing radiation from external sources for an indefinite period of years; the maximum permissible total weekly dose shall be 1,500 mrems in the skin, provided the respective weekly dose in millirems in all other tissues of the feet and ankles are not in excess of those that would result from exposure to ordinary X-rays at a weekly dose of 1,500 mr in the skin.

**Rule IV-BX. Local Exposure of the Feet and Ankles to X-rays (Roentgen Rays, Gamma Rays) of Any Photon Energy.** For adults of any age whose feet and ankles are exposed solely to X-rays from external sources for an indefinite period of years, the maximum permissible total weekly dose shall be 1,500 mr in the skin.

**Rule IV-C. Local Exposure of the Head and Neck to Any Ionizing Radiation.** For adults whose heads and necks are exposed to ionizing radiation from external sources for an indefinite period of years; the maximum permissible total weekly doses shall be 1,500 mrems in the skin and 300 mrems in the lenses of the eyes, provided the respective weekly doses in millirems in all other tissues of the head and neck are not in excess of those that would result from exposure to ordinary X-rays at a weekly dose of 1,500 mr in the skin. For persons 45 years or older the weekly dose in the lenses of the eyes may be 600 mrems, provided the portion contributed by radiation of high specific ionization does not exceed 300 mrems.

**Rule IV-CX. Local Exposure of the Head and Neck to X-rays (Roentgen Rays, Gamma Rays) of Any Photon Energy.** For adults whose heads and necks are exposed solely to X-rays from external sources for an indefinite period of years; the maximum permissible total weekly doses shall be 1,500 mr in the skin and (1) 450 mr in the lenses of the eyes of persons under 45 years of age, (2) 600 mr in the lenses of the eyes of persons 45 years of age or older.

### OCCASIONAL EXPOSURE

**Rule V-A. Accidental or Emergency Exposure to X-rays (Roentgen Rays, Gamma Rays) with Photon Energy Less Than 3 Mev.** Accidental or emergency exposure of the whole body of adults or parts thereof to X-rays with photon energy less than 3 Mev, from external sources, *occurring only once in the lifetime of the person*, under the conditions and in the respective dosages stated below, shall be assumed to have no effect on the radiation tolerance status of that person.

(a) Exposure of the whole body—any adult. Total dose, measured in air: up to 25 r.

(b) Local exposure—any adult. Dose measured in air and additional to whole-body dose: (1) hands and forearms, up to 100 r; (2) feet and ankles, up to 100 r.

**Rule V-B. Planned Emergency Exposure.** Emergency work involving high-level exposure to X-rays with photon energies less than 3 Mev shall be carried out on the basis that the person will not receive doses higher than one-half the respective doses stipulated in Rule V-A. If the doses actually received in the performance of such work do not exceed the respective maximum doses stipulated in Rule V-A, the exposure may be considered to be in the category covered by Rule V-A. Women of reproductive age shall not be subjected to planned emergency exposure.

**Rule V-C. Accidental or Emergency Exposure to Other Types of Ionizing Radiation.** Rules V-A and V-B are applicable to accidental or emergency exposure to ionizing radiation of any type and energy when the tissue doses resulting therefrom in the different organs and tissues of the body (expressed in rems) do not exceed numerically the respective tissue doses in rads resulting from exposure to X-rays with photon energy less than 3 Mev, under the conditions stipulated in Rule V-A; provided, however, that the portions of the respective tissue doses in rems contributed by radiation of high specific ionization do not exceed 50 percent of the total tissue doses.

**Rule VI. Exposure to X-rays for Medical Reasons.** Exposure of any part of the body to X-rays resulting from ordinary medical diagnostic procedures shall be assumed to have no effect on the radiation tolerance status of the person concerned, provided that no contributory accidental or emergency exposure of the order of magnitude specified in Rules V has occurred within the previous 3 months.

According to Morgan (1955), the present basic permissible rate of 0.3 rem per week cannot be tolerated safely over a large fraction of a life span since the critical organs might accumulate an absorbed dose of 1,200 rem, the skin 2,400 rem and the appendages of the body 4,200 rem. Such doses likely would produce harmful effects.

The permissible concentrations for radioactive materials when taken into the body have been tentatively set for radium and a number of radioisotopes. Estimates made in a few fatal cases indicated that the storage of 1.2 micrograms of radium may prove fatal. Hence, the National Committee on Radiation Protection has set 0.1 micrograms of stored radium-226 as the maximum permissible amount of radium in the body. The allowable concentrations of radioisotopes in the body varies with the specific material. The National Bureau of Standards has published (Handbook 52, 1953) a table giving the maximum permissible amounts of the more common isotopes when fixed in the body and the permissible concentrations of these materials in air and water which one may take regularly into the body.

In connection with these standards it should be noted that air and water are naturally radioactive to a certain degree. Radon normally exists in the air in concentrations of about  $10^{-10}$  microcurie per cubic centimeter, although wide variations occur. Due to the presence of natural radioisotopes much of the drinking water has an activity ranging between  $10^{-6}$  and  $10^{-5}$  microcurie per cubic centimeter. In fact, many of the mineral springs in the United States have natural concentrations ranging between  $10^{-6}$  and  $10^{-4}$  microcurie per cubic centimeter of water.

**Types of Exposures to Atomic Particles and Ionizing Radiations.** In the early days, exposure to ionizing radiations occurred only in the use of x-rays and radium in medicine and in a limited number of research activities. Today, radioactive chemical substances and/or equipment which produce ionizing radiations are used extensively in all branches of medicine, in innumerable research projects of many types, and in many industrial processes. Furthermore, the general public may be exposed to atomic radiations through contamination of the air and water by radioactive waste products. Plumbers and other workmen also may come in contact with radioactive waste materials in the repair of buildings where radioactive isotopes have been carelessly discarded. Some of the most serious radiation exposures occur to persons operating x-ray and fluoroscopic equipment in hospitals, doctors' offices and industries. In some instances, salesmen and the public have been exposed to harmful radiations from fluoroscopic shoe fitting machines. Finally, exposure to these radiations may occur in military operations if atomic weapons are employed.

**Prevention of Damage Due to Ionizing Radiation. PROTECTION AGAINST EXTERNAL SOURCES.** Protection against external sources of radiation can be effected by the use of shielding equipment, by increasing the distance between the source and the personnel, and by decreasing the exposure time. Sources of x-rays, gamma rays, neutrons and beta particles should be surrounded by materials which will absorb the radiations. The material used and the thickness required to absorb the radiation varies with the type of radiation. For example, lead will protect against x- and gamma rays, concrete is satisfactory for gamma rays and neutrons, water absorbs neutrons, glass or plastic materials are effective against beta particles. All direct contact with radioactive materials should be avoided. The distance between the source of the radiations and the personnel should be as great as possible. Doubling the distance will reduce the dosage rate to one quarter in the case of point sources of exposure but not in cases where the sources of exposure are more extensive. Equipment and processes which produce harmful radiation should be operated by remote control when possible. All equipment should be designed so that stray radiation does not occur, and all equipment must be kept in good working condition. When some degree of exposure is absolutely necessary, the duration of the exposure should be reduced so that the total radiation exposure does not exceed the permissible limits.

Persons exposed to external radiation should wear monitoring devices which may be either a film badge or a pencil type ionizing chamber. These devices should be read at the end of each exposure period to determine the approximate degree of external radiation.

**PROTECTION AGAINST INTERNAL ABSORPTION.** Radioactive materials may enter the body through the respiratory tract, digestive tract, damaged skin and, under some circumstances, the intact skin. In order to prevent contamination of the air with radioactive materials, all processes which generate dusts or gases should be totally enclosed or supplied with exhaust systems. Proper cleaning and good house-

keeping are of great importance. Protective clothing should be worn and should be decontaminated or discarded at the end of each exposure period. Great care should be taken that the hands, the lips, and other areas of the skin do not become contaminated and that harmful materials are not introduced into the body through food or tobacco. These protective measures are described more fully in Section 6, since the same preventive methods apply to radioactive materials as are necessary for toxic chemical substances. However, the radioactive materials present additional problems since the more dangerous ones or large quantities of less dangerous ones cannot be discharged into the air or streams. Furthermore, radioactivity cannot be destroyed by burning, chemical treatment, or any other known process. The disposal of radioactive waste materials presents a problem which has not been solved as yet. The methods used by the U. S. Atomic Energy Commission (1950) are described as follows: "Gaseous and airborne wastes are controlled by filtration and dilution with air; mildly radioactive liquids by holding them for a time while they decay into nonradioactive forms, and by filtration and dilution with uncontaminated water; more dangerous liquids are concentrated and run into safe storage; miscellaneous contaminated materials are buried; incinerators are being developed." Radioactive waste materials which are used outside of the plants operated by the Atomic Energy Commission should be handled in accordance with the regulations of the Isotope Division of this Commission.

**HEALTH SUPERVISION AND MONITORING.** The health supervision of persons exposed to radiation hazards in the Atomic Energy Plants, insofar as their radiation exposure is concerned, is under the direction of "health physicists." In industries where the radiation hazards are not great, the supervision of radiation exposures is the responsibility of the industrial hygienists who should have special training in health physics. In medical and educational institutions using radioactive isotopes, radiation protection committees or specially trained persons should be designated to supervise the use of radioactive materials.

The duties of the health physicists and industrial hygienists are as follows: (1) to aid in the design of plants and equipment so that protective measures can be incorporated in the planning stage; (2) to make frequent radiation surveys of all areas and equipment where radiation exposures may exist; (3) to provide individual monitoring meters to all persons exposed to external radiation hazards and to calculate from these the extent of exposure; (4) to make analyses of the expired air, urine and feces, where necessary, to determine the degree of storage of radioactive substances in the body; (5) to recommend the removal from the work area of all persons who show signs of having an excessive external or internal radiation exposure; (6) to inform management and supervisors regarding the radiation hazards; (7) to supervise all personal protective measures; (8) to conduct an educational campaign regarding the safe handling of radioactive materials and safe operation of equipment.

The health physicists are actively engaged in research to determine the effects of radiations, the permissible limits of exposure, the development of protecting measures, the safe disposal of waste products, and the development of radiation detection equipment.

The safe distribution and use of radioactive isotopes is under the direction of the Isotopes Division of the United States Atomic Energy Commission. The chief of the Radioisotopes Branch (Lough, 1951) described the function of this division as follows: "The Isotopes Division determines prior to allocation (of the

isotopes) that a prospective user is equipped by training and experience and with suitable laboratory facilities and instrumentation to use radioisotopes under conditions which will maintain reasonable protection against radiation hazard. This policy markedly minimizes the possibility of improper and careless use of radioisotopes and effectively prevents the development of any widespread radiation hazard in those places where these substances are used. The careful review of applications to determine that conditions are suitable for the use of radioisotopes is effectively supported by the activities of the Advisory Field Service Branch through its consultation on laboratory design and its visits to users at periodic intervals following allocation of radioactive materials. Finally, the dissemination of technical information through the distribution of pamphlets, circulars and reprints serves to enhance the assurance that radioisotopes will be used under safe conditions." The National Bureau of Standards also has published a series of handbooks on standard procedures for handling and disposal of radioactive materials and on methods of measuring radioactivity.

In addition to the environmental control measures, good medical supervision is also necessary. Pre-employment and periodic medical examinations, adequate illness records and their analysis, and other industrial medical procedures are as necessary in the case of radiation workers as in the case of persons exposed to toxic chemicals. These procedures are discussed in Section 6.

The excellent record at the Atomic Energy Plants in regard to radiation illness is a tribute to the work of the health physicists and others who have participated in the health protection program, and, in addition, proves that dangerous radiation exposures can be adequately controlled if a sound preventive program is followed.

## THE EFFECTS OF HIGH AND LOW BAROMETRIC PRESSURES

During the past century, man has extended his horizon up into the sky and down into the earth. He has developed mechanical equipment which will carry him into the stratosphere, where the air pressure is practically zero, or which will enable him to descend many feet below sea level, where the pressure is very great. But man is physiologically adapted to live only at pressures at or fairly close to, sea level and cannot tolerate these great deviations in pressure. The highest altitude at which man can live is between 17,000 and 18,000 feet. He cannot survive at 25,000 feet when breathing air, and he can work only for brief periods at 300 feet below sea level when breathing air. Thus the real problems of high and low pressures are concerned with man's physiological limitations.

Exposure to low atmospheric pressures occurs whenever a person ascends a high mountain or travels in an airplane, unless the cabin of the airplane is pressurized, i.e., unless the cabin is built so that the air inside can be maintained at atmospheric levels. Exposure to high atmospheric pressures occurs whenever a person descends below sea level through water or water-bearing strata, unless the person is encased in a heavy shell which can withstand the pressure of the water. In all other cases, the person descending below sea level must be supplied with compressed air, i.e., air at a pressure equal to the pressure exerted by the water. Occupations which require exposure to abnormally high pressures include work in compressed air shafts and caissons in the building of tunnels, bridge piers, and mine shafts; and in diving operations in the salvage of ships, in underwater construction, in underwater exploration, and in the collection of pearls, etc.

**The Pressure of the Air and the Effects of Pressure Per Se.** **THE PRESSURE OF THE AIR.** The air at the surface of the earth, i.e., at sea level, exerts a pressure equal to about 760 mm. of mercury, or 14.7 pounds per square inch. This is called the normal atmospheric pressure, or one atmosphere of pressure. At higher altitudes this pressure becomes progressively less, until at 50,000 feet above sea level, the pressure of the air is only about 87 mm. of mercury. On the other hand if an air shaft is cut into the earth, the pressure of the air becomes progressively greater, the greater the depth of the shaft. This increase in pressure is, however, very slight compared to the increase in pressure which exists at the same depth below water or water-bearing strata, because the weight of a column of water is much greater than the weight of a similar column of air. For example, the pressure of the air at a depth of 100 feet below the surface of the earth in an open air shaft would be only a few millimeters greater than that at sea level, whereas under water it would be four times the pressure at sea level. Under water, the

pressure increases at the rate of one atmosphere (760 mm. of mercury, or 14.7 pounds per square inch) for each 33 feet depth below sea level. Thus, at 300 feet below sea level, the pressure is equal to 10 atmospheres or 147 lbs. per square inch.

**THE EFFECTS OF PRESSURE PER SE ON THE BODY.** Although both high and low pressures have marked effects on the human body, these effects are not due to the pressure per se. Living organisms, marine animals, and the tissues of higher animals can withstand the mechanical effects of very high pressures (well over 100 atmospheres). Man can tolerate hydrostatic pressures from low levels up to those which are far greater than would occur in any conceivable circumstance at the present time. This tolerance is due to the fact that the pressure exerted on the surface of the body is transmitted equally to all of the tissues of the body; hence, the pressure relations are the same throughout the body. Even sudden changes in atmospheric pressure exert no harmful mechanical effects except where air is trapped in closed cavities, such as in the middle ear if the Eustachian tube is closed, in the lungs if the glottis is closed, and in the sinuses and digestive tract if blockage occurs. If it is not possible to equalize the pressure in the middle ear and sinuses with the external pressure, pain, hemorrhage, and congestion of the tissues may result from the difference in pressure inside and outside the cavities. The tympanic membrane may be ruptured by a pressure differential of 5 to 10 pounds. In descending from a high altitude, the pressure in the middle ear usually can be brought to the atmospheric level by swallowing, which opens the Eustachian tubes. If these tubes are partially blocked, a forced expiration, with the nose and mouth closed, may equalize the pressure, although this procedure may drive infectious material into the tubes in some cases.

**The Effects of Abnormally High and Low Gas Pressures. THE COMPOSITION AND PRESSURE OF THE GASES IN THE AIR, ALVEOLI AND BLOOD.** In order to understand the effects of high and low atmospheric pressures, it is necessary to review briefly the composition of the air and the pressure exerted by each of the gases in the air. The air is composed of 79 per cent nitrogen, 20.96 per cent oxygen, 0.04 per cent carbon dioxide, and traces of a few other gases. The pressure which is exerted by each gas in the air depends on the atmospheric pressure and the proportion of the gas in the air. Thus, at sea level, where the atmospheric pressure is 760 mm. of mercury, oxygen exerts a partial pressure of 159 mm. ( $760 \times .2096$ ), nitrogen, 600 mm. ( $760 \times .79$ ) and carbon dioxide, 0.3 mm. ( $760 \times .0004$ ). A reduction in the partial pressure of a gas in the air, such as oxygen, is produced either by reducing the total pressure of the air or by reducing the percentage of the gas in the air. At high altitudes, the composition of the air is the same as that at sea level, but, since the total air pressure is less, the partial pressure of each gas is less. Similarly, the partial pressure of a gas in the air is increased either by increasing the pressure of the air, or by increasing the percentage of the gas in the air. For example, when the air is at two atmospheres of pressure, the pressure of the oxygen is twice that at sea level (318 mm.), or equivalent to air containing 42 per cent oxygen at sea level.

The composition of the air in the alveoli is about 80.3 per cent nitrogen, 14.2 per cent oxygen, and 5.5 per cent carbon dioxide. Water vapor is also present, since alveolar air is saturated. At sea level, the partial pressures of these gases

in the alveoli are: nitrogen, 571.8 mm.; oxygen, 101.2 mm.; carbon dioxide, 39.9 mm.; and water vapor, 47.0 mm.

The amount of any gas dissolved in the blood depends on the pressure of the gas in contact with the blood. Also, the amount of oxygen taken up by the hemoglobin varies with the pressure of the oxygen in the alveolar air up to a maximum of about 100 mm. At high altitudes, when the partial pressure in the air falls, the pressure of oxygen in the air and alveoli decreases and the amount of oxygen absorbed by the blood is less. At high pressures, the partial pressures of the gases in the alveoli are increased, more oxygen and nitrogen are dissolved in the blood and in the body tissues. The physiological effects of high and low barometric pressures are the result of these changes in the gases of the blood.

THE EFFECTS OF REDUCING THE PRESSURE OF THE GASES IN THE AIR. The effects of high altitude are attributable to the reduction in the partial pressure of oxygen. At sea level, the partial pressure of oxygen in the air is 159 mm. of mercury, and in the alveoli, 101 mm. of mercury. At 25,000 feet, the pressure of oxygen in the air is less than 60 mm., and in the alveoli, about 30 mm. This partial pressure of oxygen in the alveoli is equivalent to that produced by breathing air containing 7 to 8 per cent of oxygen at sea level. If pure oxygen is breathed at 25,000 feet, the oxygen pressure in the alveoli is about 185 mm., which is more than enough to maintain the normal oxygen level in the blood. At 50,000 feet, the total pressure of the air is only 87 mm., the pressure of oxygen in the air is 18 mm., and in the alveoli approximately zero. Breathing pure oxygen at 50,000 feet is of no value, since the water vapor pressure in the alveoli (47 mm.) plus the partial pressure of carbon dioxide (39 mm.) is equal to 86 mm. or approximately equivalent to the barometric pressure. Thus, it is impossible for man to survive at 50,000 feet even when breathing pure oxygen.

As the pressure of oxygen in the alveolar air falls below 101 mm., the amount of oxygen and thus the tension of oxygen in the blood falls. The body attempts to compensate for the fall in oxygen tension in the blood chiefly by an increase in rate and depth of respiration. This increase in respiration "blows off" the carbon dioxide from the blood, leading to temporary alkalosis. If the person remains at the high altitude, a readjustment of the acid-base balance is produced slowly by excretion of this excess alkali. A second factor which makes it possible for the tissues to secure oxygen at high altitudes is dependent on the inherent shape of the oxyhemoglobin dissociation curve. At low oxygen tensions of the blood, a proportionately larger percentage of hemoglobin is dissociated when passing through the capillaries of the tissues than is liberated at high oxygen tensions of the blood. A third mechanism which plays a role in the adjustment to high altitude is an increase in the concentration of hemoglobin in the blood. A fourth compensatory mechanism at high altitudes is an increase in cardiac output—stroke volume and heart rate—but this adjustment is of lesser importance than the increase in ventilation.

The symptoms which result from ascent to high altitudes vary with rate of ascent, altitude reached, duration of exposure, degree of acclimatization, and personal capacity to adjust. It is possible to ascend in an airplane to greater heights with fewer symptoms if the ascent is rapid and the duration of exposure is short, than to ascend slowly and remain longer. On the other hand, when a person climbs

to high altitudes, it is necessary to climb gradually in order to develop acclimatization. The symptoms of anoxia are well known. The more common signs of anoxia are headache, sleepiness, fatigue, nausea, vomiting, loss of muscular coordination, impaired vision and hearing, psychological changes such as loss of memory and irrational behavior, paralysis, coma and death. Some persons faint without warning at relatively low altitudes. The symptoms which are most commonly found in persons flying to various altitudes, as listed by Armstrong (1943), are shown in Table 27-1.

Table 27-1. General effects of high altitude

ALTITUDE IN FEET	EFFECTS
4,000	Increased depth of respiration. Pulse rate may be increased but later returns to normal. Possible rise in blood pressure.
5,000	Decrease in night vision. Oxygen should be used at night.
10-12,000	Increase in lung ventilation when ascending at 200-1,000 ft. per minute. Generalized body distress in a few and mental anxiety. Changes in blood pressure—some show marked fall. Headache and fatigue if subjects remain 2-4 hours. Oxygen should be used above 10,000.
12,000	Tired, depressed, sleepy or euphoric. Visual acuity less than 50% of normal. Beginning of psychological symptoms. Lung ventilation increased 20-100%.
14,000	Deterioration of voluntary muscular control.
12-15,000	Oxygen should be used if 2 or more hours exposure.
15,000	Oxygen should be used always. Impairment of ocular muscle balance.
16,000	May be fatal to some people. May be loss of sense of touch and pain. Impairment of hearing.
15-18,000	Severe headache, nausea, vomiting, dizziness, mental confusion, muscular weakness and prostration with exposures of 2-6 hours.
20,000	Impairment of vision, loss of consciousness in 15 minutes.
24,000	Severe headache, nausea, vomiting, dizziness, mental confusion, muscular weakness and prostration after 15-20 minutes.
25,000	Coma. Death may occur in 20-30 minutes.
30,000	Loss of consciousness in 1 minute. Decompression sickness may occur.
40,000	Allowable limit with oxygen.
44,000	Absolute limit with oxygen.

In aviation, carbon monoxide also presents a hazard. There is some evidence that any given partial pressure of carbon monoxide produces more acute symptoms at high altitudes than the same partial pressure produces at sea level, i.e., the effects of carbon monoxide are enhanced at high altitudes.

The anoxia produced at the lower barometric pressures may be prevented by breathing oxygen, if the altitude is not too great. All aviation authorities advise that oxygen be available at altitudes above 8,000 feet (or at cabin pressures maintained at comparable levels) and consider the use of oxygen as mandatory at altitudes above 12,000 feet. The Civil Aeronautics Board has certain rules which specify the altitudes at which oxygen must be supplied to pilots and passengers of

commercial planes. The specific requirements vary with the duration of exposure. The military forces also have regulations regarding the use of oxygen in military planes. Because of the marked effect of anoxia on vision, oxygen may be necessary at lower altitudes during night flying. Certain procedures have been shown to increase the altitude to which men can fly without ill effects. These include: the breathing of oxygen before as well as during a flight; the addition of carbon dioxide to the oxygen; voluntary increase in pulmonary ventilation rate and depth during the flight; pressure breathing, i.e., increasing the pressure of the air breathed over the ambient pressure, and previous acclimatization by living at high altitudes for two weeks.

One of the public health problems presented by commercial aviation concerns the possible effects of altitudes on persons with certain diseases. Information on this subject is available from the experience of military authorities in the transportation of battle casualties and of commercial airlines that have carried many ill persons. The general opinion is that persons with the following conditions should not travel by airplane, unless the interior of the cabin is maintained close to the atmospheric level: angina pectoris, if an attack has occurred recently or if attacks are easily induced; recent coronary occlusion; shock; severe anemia; severe asthma; pneumothorax; hypertension, if severe and accompanied by complications; decompensated valvular heart disease; pneumonia; severe bronchitis; overwhelming infections and communicable diseases; and possibly gastro-intestinal ulcers. Diabetic patients should follow their regimes carefully. Except for these severe illnesses, the anoxia encountered in commercial aviation should present no hazard to passengers. Patients with heart disease who can walk and do a moderate amount of work can fly without encountering any greater stress (McFarland, 1953).

**THE EFFECTS OF THE GASES IN THE AIR AT HIGH PRESSURES.** *Effects of Nitrogen at High Partial Pressures.* Although the nitrogen in the air has always been considered as physiologically inert, recent experiments have shown that it exerts a narcotic action when its partial pressure is increased. At air pressures equivalent to three atmospheres of air, the effects of nitrogen begin with a feeling of stimulation. Beyond four atmospheres, the narcotic action becomes more pronounced, and at 10 atmospheres (equivalent to 300 feet below sea level) the impairment of higher mental functions, deterioration of neuromuscular coordination, and alteration of behavior are very marked. Loss of consciousness may occur at pressures in excess of 10 atmospheres. The narcotic effect reaches its maximum after a few minutes of exposure and is enhanced by carbon dioxide. If the nitrogen in the compressed air is replaced by helium or hydrogen no such symptoms occur, and divers can work and think clearly at a depth of 500 feet. Therefore, in order for men to work efficiently, it is recommended that helium and oxygen mixtures be used in place of air for operations at depths greater than 150 feet below sea level. It is essential to substitute helium for nitrogen if work is to be carried on at depths greater than 300 feet.

*The Toxic Effects of Oxygen at High Partial Pressures.* Air containing 60 to 70 per cent oxygen can be breathed indefinitely. However, when pure oxygen is breathed at sea level (equivalent to the pressure of oxygen in air at five atmospheres) pulmonary irritation with edema and, possibly consolidation of the lungs results. The limit of endurance to this pressure of oxygen varies from 7 to 17

hours, or possibly somewhat longer, according to some reports. Other symptoms such as slowing of the pulse, pallor and impaired neuromuscular coordination also have been reported. At higher pressures, oxygen exerts a toxic effect on the body. Three atmospheres of pure oxygen or 15 atmospheres of air can be tolerated for only about three hours. This pressure is equivalent to the partial pressure of oxygen in air at a depth of 500 feet below sea level. When the pressure of oxygen is equal to three atmospheres, sufficient oxygen exists in physical solution in the blood to supply the tissues of the body without any dissociation of the oxy-hemoglobin of the blood. Four atmospheres of pure oxygen can be tolerated for only 30 minutes, as convulsions begin after 45 minutes of exposure. At seven atmospheres convulsions occur without warning after about five minutes. Death may result if the pressure is not lowered rapidly, but recovery is rapid if the oxygen pressure is reduced. Experiments have shown that dogs, which were repeatedly exposed to oxygen pressures sufficient to cause convulsions, exhibited no harmful effects and even developed a certain degree of tolerance to these exposures. The explanation of the toxic effect of oxygen is not clear; it may be due in part to disturbance in the normal carriage of carbon dioxide by the blood and disruption of enzyme activity leading to tissue acidity (Bean, 1945).

*The Effects of Carbon Dioxide at High Partial Pressures.* Carbon dioxide exerts no serious physiological effects at sea level until the concentration increases to about 3 per cent, when stimulation of respiration is sufficient to cause hyperpnea. The inhalation of air containing between 6 and 7 per cent carbon dioxide for short periods causes little mental impairment or deterioration of manual skill, but is distressing since marked dyspnea results. At concentrations above 10 per cent, depression of the central nervous system and heart occurs; respiration becomes slower and more shallow; the heart beat is slow and weak; loss of movement and reflexes follows; and coma results. Death occurs at concentrations of about 20 per cent or higher as a result of the cessation of respiration. The effects of carbon dioxide are attributed to the interference with the transportation of oxygen, the depression of tissue oxidation, and the increase in acidity.

When the air pressure is increased, the partial pressure of the carbon dioxide is increased proportionally, so that the effects of any concentration are equal to the effects of a higher concentration at sea level. Furthermore, some authorities claim that equivalent partial pressures exert more harmful effects in compressed air than at sea level. Case and Haldane (1941) recommend that the concentration of carbon dioxide in compressed air should be kept below a partial pressure equivalent to 3 per cent of carbon dioxide at sea level, while Behnke (1940) suggests .5 per cent as the upper allowable limit.

When air is compressed, not only are the partial pressures of the gases normally present in the air increased, but also the pressure of any contaminating gas, such as carbon monoxide, would be increased likewise and would consequently exert a greater physiological effect than at sea level.

*The Effects of Sudden Decrease in Pressures—Decompression.* When a person, who has been exposed to air under higher pressure, is decompressed (i.e., brought back to normal pressure) too rapidly, or when a person ascends rapidly from sea level to a high altitude, certain characteristic symptoms may develop. In the case of underwater work at high pressure, these symptoms usually appear within the

first few hours following the decompression but may not develop for 12 hours or longer. The most frequent symptom is severe pain in the muscles and joints of the arms and legs which is commonly called "bends." Itching and rash of the skin, vertigo, nausea, vomiting, epigastric pain, fatigue, dyspnea (usually spoken of as "chokes") and shock may occur. In some cases, central nervous system symptoms, such as paralysis of the skeletal muscles or bladder are apparent. In others, symptoms of cardiac failure or pulmonary emboli are evident. Death may occur rapidly or may follow secondary complications. Aseptic necrosis of the bone is reported to follow much later in some cases.

The symptoms of compressed-air illness are due to the presence of nitrogen bubbles within the blood vessels. The nitrogen bubbles are formed because the excess nitrogen, taken up by the tissues and the blood while the partial pressure of the nitrogen was high, cannot be eliminated from the body if the pressure is lowered rapidly. This excess nitrogen can no longer be held in physical solution at the lower pressures and nitrogen bubbles are formed. This reaction is similar to the production of bubbles when a bottle of charged water is opened. The excess oxygen, which is absorbed at the high pressures, is held by the tissues and does not form bubbles, but carbon dioxide contributes somewhat to the bubble formation. As the air pressure is lowered the bubbles expand in size and aggregate, forming gas emboli which obstruct the flow of blood and lead to anemia of the tissues. The nitrogen bubbles are all intravascular except in the fat tissue where they may occur extravascularly.

The location and size of the bubbles depend on the relative solubility of nitrogen in the various tissues, on the duration of the exposure, and on the circulation. Nitrogen is about five times as soluble in fat as in the body fluids, hence more nitrogen can be held by lipoid tissues, such as the nervous system and bone marrow. The duration of the exposure is important because the longer the exposure up to the saturation point, the greater is the quantity of nitrogen taken up by the tissues. Tissues with an adequate circulation absorb and eliminate nitrogen rapidly, but those tissues with a poor circulation and few anastomoses absorb and eliminate the nitrogen slowly and are most affected by air emboli. The bubbles may be caught in the capillaries of one tissue and later be released into the general circulation, thereby producing delayed symptoms. The symptoms depend on the location of the emboli and may simulate many other diseases, since the emboli occur in various parts of the body.

The most important measure for the prevention of compressed-air illness is a slow rate of decompression. Standard schedules of decompression have been adopted by a number of states. Another preventive measure is the inhalation of pure oxygen in place of air during the later stages of decompression. The value of this treatment lies in the fact that the partial pressure of nitrogen in the inhaled air is reduced to zero and, therefore, the nitrogen can be eliminated from the body fluids much more rapidly. Oxygen can be used only at pressures lower than those equal to a depth of 60 feet because of its toxic effect. Recently, helium has been used in place of nitrogen in the compressed air supplied to men working under high pressures. Helium is much less soluble in fat and body fluids than nitrogen so that the total amount of helium which is absorbed by the body tissues at satara-

tion is only about 40 or 45 per cent of the nitrogen saturation capacity. Furthermore, the rate of diffusion of helium in the body fluids is greater than that of nitrogen, and the time required for the elimination of helium is only about 50 per cent of that required for nitrogen. Helium also diffuses through the skin. Another factor which is of the greatest importance for the prevention of compressed-air illness is the proper selection of personnel. Since fat tissues absorb a large portion of nitrogen when under high pressures, men with excessive amounts of fat tissue should not be employed for such work. The treatment for compressed-air illness consists in immediate recompression in a decompression chamber, as soon as any symptoms appear, followed by very slow decompression.

Nitrogen bubbles or air emboli may also occur when a person ascends rapidly from sea level to an altitude of over 25,000 feet. The mechanism is the same as in the case of rapid decompression from high pressures to atmospheric pressure. However, the condition is much less serious since the total body content of nitrogen at sea level is much lower than that at high pressures. The bubbles are all intravascular and central nervous system damage is not common. Air emboli in aviation may be prevented by breathing oxygen or helium-oxygen mixtures before the flight, thus eliminating the nitrogen from the body. The symptoms can be relieved by descending to a lower altitude, since the nitrogen then goes back into solution.

Explosive decompression, i.e., a drop in pressure from one atmosphere to one-tenth or less of an atmosphere in a fraction of a second may occur if a person is shot out of a pressurized plane at high altitudes, such as 50,000 feet. This rapid change in pressure may be injurious but not necessarily fatal. The chief dangers lie in the anoxia which results from the low oxygen pressure and in the expansion of gases in the body. If the glottis is closed, rupture of the alveolar blood vessels may occur and air may be aspirated into the circulation. The sudden rise in the intrathoracic pressure may interfere with the venous return to the heart. Expansion of the gases in the gastro-intestinal tract may cause hemorrhages. At 60,000 feet oxygen passes from the blood stream into the alveoli. Intravascular bubbles may form but they do not present a major hazard.

## NOISE

In recent years the effect of noise has become an important public health and industrial problem because of the increase in number and extent of noisy sources.

Exposure to excessively loud noises occurs in aviation, in military operations and in many different types of industries such as boiler factories, steel mills, textile plants, can factories, ship yards, airplane factories, etc.

**Characteristics of Noise.** Noise is discordant sound which results from non-periodic vibrations of air. The chief characteristics of noise are pitch, quality, and intensity. The pitch is determined by the number of double vibrations (dv) or cycles per second which strike the ear. The quality is contingent on the form of the various sound waves contributing to the noise. The intensity at each pitch depends on the amplitude of the vibrations set up by the vibrating body. The intensity varies inversely as the square of the distance from the source. The loudness, as perceived by the ear, depends on the intensity of the sound reaching the ear and also on the pitch, since the acuity of hearing varies with the pitch. Sound may be intensified by placing the vibrating object in contact with other objects which in turn are then set to vibrating. Sound waves may be reflected from walls and objects, thus contributing to the over-all noise level.

**Units Used in Expressing the Intensity or Pressure of Sound.** The sound level may be expressed either in terms of physical units or in terms of decibels. The latter is more commonly used.

**SOUND INTENSITY AND PRESSURE EXPRESSED IN PHYSICAL UNITS.** Sound intensity is defined as the flux of energy per second and per unit of surface ( $\text{cm}^2$ ) at right angles to the direction of propagation and is expressed in watts per square centimeter; or it is defined as an acoustic pressure in dynes per square centimeter (baryes or bars).

The reference base customarily used in acoustics for energy flux (intensity) is  $10^{-16}$  watts per square centimeter; for sound pressure the reference base is  $2 \times 10^{-4}$  dynes per square centimeter.

**DECIBEL SCALE.** The decibel (db)\* is the unit commonly used to express the intensity or the pressure of sound. It is one-tenth of a bel, a unit named after Alexander Graham Bell. The bel is not an absolute unit but a ratio of the unknown intensity or pressure to the respective reference base given above, i.e.,  $10^{-16}$  watts per square centimeter for intensity and  $2 \times 10^{-4}$  dynes per square centimeter for pressure. In the measurement of sound, the impedances are such that the sound pressure ratio is equal to the square root of the corresponding sound intensity ratio.

\* The symbols "db" and "dv" must not be confused: "db" is the abbreviation for decibels sound intensity, "dv" is the abbreviation for double vibrations per second or pitch.

Because of the wide range of acoustic energy to which the ear responds, the logarithm of the ratio is used instead of an arithmetic scale thus:

$$n(\text{in db}) = 10 \log_{10} \frac{\text{unknown intensity}}{\text{reference intensity}} = 20 \log_{10} \frac{\text{unknown pressure}}{\text{reference pressure}}$$

$(10^{-16} \text{ watts/sq. cm.})$ 
 $(2 \times 10^{-4} \text{ dynes/sq. cm.})$

At a frequency of 1,000 double vibrations per second the normal threshold of hearing is approximately equal to the reference points in the physical units. The significance of the decibel scale can be seen from the following example:

20 db =  $10^{-14}$  watts/sq. cm. = 100 times the reference value

50 db =  $10^{-11}$  watts/sq. cm. = 100,000 times the reference value

80 db =  $10^{-8}$  watts/sq. cm. = 100,000,000 times the reference value

Instruments are now available for measuring the over-all sound level and also for analyzing the pitch of the more important sounds contributing to the noise.

**The Intensity and Pitch of Normal Sounds and Noises.** The average human ear can perceive sound which falls in the pitch range between 15 and 15,000 double vibrations (dv) per second. Some persons can hear sounds of considerably higher pitch. The chief range of speech is usually between 500 and 5,000 dv per second although here again the limits may go up much higher. At frequencies above and below approximately 2,000 cycles per second, a greater intensity of sound is necessary to produce the same sensation of loudness as compared with the 2,000 range. Some idea of the intensity of sound measured in terms of decibels may be obtained from an examination of Table 28-1. Audible sounds above 120 decibels may be felt as well as heard. The range of vibrations below 15 dv per second is called infra-audible, and that above 15,000 or 20,000 ultra-audible. These terms have been adopted by The American Standards Association, although some persons use the terms ultrasonic or supersonic in place of ultra-audible.

**The Effects of Noise.** The effects of sound or noise can be discussed under the following topics: (1) the effect on the ear, which is the most important aspect; (2) the psychological effects; (3) the effects on the body as a whole; and (4) the effects of ultrasonic sound.

**THE EFFECTS OF NOISE ON THE EAR.** Excessive noise may produce a masking effect so that it is impossible to hear normal speech unless it is more intense than the noise. Of much greater importance, however, is the fact that noise can cause both temporary and permanent impairment of hearing. Damage to the ear may result from single short exposures (such as gunfire), from continuous noise, or from repeated impact noise (such as drop hammers or presses). The noise level necessary to produce hearing loss varies with intensity and duration, is greater with high-pitched sounds, and depends on the susceptibility of the individual. When the level of intensity is not too high or the noise not too prolonged, the ear may recover from the temporary hearing loss if sufficient time is allowed. Recovery appears to be very slow and may require a period of days or even up to six months depending on the length of exposure. Exposure to higher levels of intensity for brief periods (such as 145 to 180 db) or to lower levels for longer periods may lead to permanent hearing loss. The loss of hearing occurs usually about one-half

Table 28-1. Noise intensity created by common sources expressed in decibels

	DECIBELS
Jet engine	up to 140
Drop hammers	up to 130
Hammer blows on steel plate	up to 115
Boiler shop	up to 105
Punch press	up to 105
Pneumatic drill 10 ft. away	up to 90
Heavy street traffic	80
Ordinary conversation 3 ft. away	40-60
Vacuum cleaner	50
Average residence	35
Low whisper 3 ft. away	20

octave above the predominant tone of the noise, and in general is above 2,000 and especially at 4,096 cycles per second. The loss of hearing is due to damage in certain areas of the cochlea.

The data are not yet sufficient to determine the specific levels of noise required to produce damage to the ear, but certain tentative levels subject to revision when more data become available have been expressed by a group of authorities\* in this field. Their statement was in part as follows: "it seems probable . . . (1) that most persons exposed for several hours daily to noises at intensity levels above 120 decibels, whatever the "composition" of the noise, will in a matter of months suffer permanent damage to hearing; (2) that for most industrial noises at "overall" levels of 100 to 120 decibels, exposure for several hours daily for a long period of time will cause permanent damage to hearing in a considerable proportion of persons, the proportion being higher the more closely the noise approaches the intensity level of 120 decibels and the more the noise is dominated by high-pitched components; and (3) that the hearing of a few very susceptible persons may be permanently damaged by exposure for many years to certain noises at levels between 90 and 100 decibels." † It is difficult to assess the role of noise in cases of hearing loss because many persons, particularly men, develop progressive hearing loss of a similar nature as they grow older. Infections and other diseases also complicate the picture.

Detonations causing about 160 db may rupture the tympanic membrane but the effect of this rupture on hearing is usually temporary and complete recovery may occur. When the tympanic membrane is ruptured the loss of hearing is over the entire frequency range and is present only in the affected ear.

**PSYCHOLOGICAL EFFECTS OF AUDIBLE NOISE.** The effects of noise on work efficiency and fatigue have been discussed in a number of publications. Because of the many variable factors in such studies, it is difficult to draw any very definite conclusions regarding the psychological effects of noise. Claims have been made that a reduction in the intensity of noise increases efficiency and reduces fatigue, but no sound evidence exists at the present time to support this claim. Sudden unexpected noises are reported to cause a rise in blood pressure and intracranial

\* Report of Consultants on Occupational Loss of Hearing to the Workmen's Compensation Board of the State of New York, December 1953.

† The decibel levels mentioned in this report are based on the standard reference level of 0.002 dynes per sq. cm. This report has been criticized severely by other authorities because no account is taken of the pitch of the noise components.

pressure, a reduction in salivary and gastric secretions and in contractions of the stomach. Such effects undoubtedly reflect emotional reactions.

**THE EFFECTS OF NOISE OR SOUND ON THE BODY AS A WHOLE.** Except for the effect on the ear and possible psychological aspects, sound in the audible range up to 120 db does not appear to produce any injury to man. When men are exposed to intense sounds of about 150 db in the frequency range below 2,000 cycles per second (especially 700 to 1,500 cps), certain reactions may occur (Eldridge and Parrack, 1950). The skull, jaws, thoracic wall, and large muscle groups appear to vibrate. Dizziness, weakness of the knees, unsteady gait, headache, and nausea may occur. If continued for some minutes, fatigue, irritability and a sense of apprehension appear. These symptoms all disappear with the cessation of the noise.

**THE EFFECTS OF ULTRA-AUDIBLE SOUND.** With the development of jet airplane engines, the problem of ultra-audible sound became one of importance to man. Since it had been shown previously that ultrasonic sound transmitted through liquid media caused disruption of bacteria and other micro-organisms, and killed frogs and fish in a few minutes, it was thought that such frequencies might produce harmful effects on man. Early experiments with furred animals supported this belief, since ultra-audible sound at intensities above 150 db transmitted through air were found to be lethal for mice, rats, and guinea pigs. However, it has been proved that the effect of ultrasonic sound on furred animals is due entirely to the fact that such sound is absorbed by the animal and produces sufficient heat to raise the body temperature to the lethal point. This excessive heating effect could not occur in man since less than 0.5 per cent of the energy present in ultrasonic frequencies is absorbed from the air by the human body. Transmission through a liquid medium would, however, present different problems.

**Prevention of Noise Deafness.** Injury due to loud noises in industries may be prevented by: (1) mechanical and engineering measures, (2) personal protective equipment, and (3) proper selection of personnel.

The mechanical and engineering measures are the best methods of preventing hearing loss due to noise. These measures include a reduction of the over-all noise level at the source, reduction in the transmission of the noise through the surrounding structures, such as vibrating bases, reduction of air transmission by enclosures, reduction of the reflection of the noise from the surroundings by sound-absorbing materials, and isolation of the noisy processes. Where more than one source contributes to the over-all noise level, the program for the reduction of noise should be directed to the source causing the loudest noise. For example, a noise at 80 db is 100,000,000 times the threshold level whereas a noise at 60 db is only 1,000,000 times the threshold level. The two noises together give a total sound which is 101,000,000 times the threshold value. It is evident that reduction of the 60 db noise will be of almost no benefit as long as the 80 db noise remains.

Personal protective equipment consists of ear plugs (so-called ear defenders) or ear muffs. Ear plugs made of dry cotton are of little value. Treating the cotton with petrolatum will increase the effectiveness. Commercial ear plugs are also available. The most efficient ear defenders will reduce the noise level between 25 to 35 db for high pitched sounds. Their efficiency for reducing low pitched sounds is much less. Ear defenders are uncomfortable, require careful fitting, and may less

to infections of the ear. Ear muffs also will reduce the intensity of sound. They can be fitted and supervised more adequately and offer less chance of infection than ear plugs. Ear muffs, plus ear plugs, will reduce the noise more than either type alone. All personal protective equipment requires constant supervision and effectiveness depends on the cooperation of the employee. According to Eldridge and Parrack (1950), personal protective devices are of less value at sound intensities above 145 db since "bone conduction of sound to the ear can be expected to be sufficient to produce significant hearing losses."

Since there is a marked variation in the reaction of different individuals to the effects of noise, employees who are less sensitive to noise should be selected for noisy industries. It is believed that persons who show temporary deafness early in the exposure to noise are likely to develop permanent hearing loss if continued in the exposure. On the basis of this theory, it has been suggested that audiometer tests be made before employment and at intervals during the first few weeks of exposure to noise. They should be continued periodically thereafter, the frequency depending on the noise level and the characteristics of the audiogram. Workers showing temporary hearing loss during their early exposures to noise should be transferred to other jobs before any permanent damage occurs. Pre-employment audiometer tests are of utmost value in excluding persons with pre-existing hearing impairments from employment in noisy industries. Periodic audiometer tests protect the worker from further injury and the employer from unjustified compensation claims.

## ATMOSPHERIC POLLUTION

The problem of atmospheric pollution has commanded the attention of health authorities only during the past few years. Complaints about the pollution of the air by smoke and industrial wastes have been prevalent for many years. However, until recently little action has been taken to prevent such contamination. Smoke abatement ordinances were passed in some cities but, except in a few instances, these regulations were not effective. Public health departments, in general, were not concerned about atmospheric pollution, since this subject was considered an economic rather than a health problem. As a result, most industries discharged their waste materials into the air without regard to the effect on surrounding communities. Private dwellings, public buildings, railroads, and automobiles contributed their share to the general contamination of the air.

The interest of health authorities in the problem of atmospheric pollution was aroused about 1945 or 1947 when the Los Angeles smog situation became acute (Stern and Greenburg, 1951). The dramatic episode at Donora, Pennsylvania, in October, 1948 (Schrenk and others, 1949), however, was the major event which focused the attention of all health officers and, in fact, the entire nation on this problem. Hardly had the newspapers carried the story of Donora across the country, than every health commissioner became concerned for fear that a similar experience might occur in his jurisdiction. As a result, tremendous interest in air pollution has developed among health authorities, industrial managements, and the general public. Epidemiological and laboratory research has been initiated; the scientific and technical literature has become extensive; and laws and ordinances have been passed. Thus, atmospheric pollution suddenly has become a major problem in public health.

**Nature of Atmospheric Contaminants.** Foreign substances, most of which are harmless, are present in the air at all times and at all places. The term atmospheric pollution applies only when an excessive concentration of foreign matter which adversely affects the well-being of the individual or causes damage to property, plant, or animal life exists in the air. Atmospheric contaminants may occur in the form of gases and vapors or as aerosols composed of finely divided solid or liquid particulates which remain suspended in the air. (Definitions of the specific types of contaminants which may exist in the air are given in Chapter 32.)

A number of substances may contribute to the pollution of the air. The materials which, at the present time, are believed to be the most important contaminants are: the sulfur compounds, especially sulfur dioxide, sulfuric acid mist, and, to a lesser extent, hydrogen sulfide; the fluorine compounds, especially hydrogen fluoride; chlorine and hydrogen chloride; carbon monoxide and carbon dioxide; oxides of nitrogen; ammonia; ozone; various hydrocarbons; chlorinated aldehydes

ketones and nitriles; formaldehyde; acrolein; organic peroxides; and many other organic compounds including mixtures, such as soot and tar. Zinc, lead, arsenic, and other metallic dusts and fumes also may occur. The chemical and physical properties of these various substances when present in the air and their reactions with one another in the air are not completely understood. Even the sulfur compounds, which have been studied more extensively than any of the other substances, present a number of unsolved problems. Photochemical reactions, catalytic oxidation, adsorption of gases and vapors on particulate matter, solution of gases in liquid aerosols, condensations, and many other reactions contribute to the complexity of the problem. In addition, the nature of the organic material is often difficult to determine.

The contaminating substances listed above may result from many different types of industrial processes. Large amounts of sulfur dioxide are produced by smelting operations, chemical plants and oil refineries; sulfuric acid mist is produced by acid plants; the fluoride compounds are commonly emitted from aluminum plants, phosphate fertilizer plants, refinery processes, and chemical industries. Pulp mills, sewage disposal plants, stockyards, gas plants, steel mills, and many other types of industries contribute to atmospheric pollution. A large part of the atmospheric pollution originates from the burning of fuels, both solid and liquid. For example, the combustion of coal yields sulfur dioxide, fluorine, carbon monoxide, carbon dioxide, finely divided carbon, fly ash, and various organic compounds, including aldehydes, soot, and tar. Fuels are burned by practically all industries, in every home and public building, and by railroads, boats, and automobiles. Even the burning of trash in private homes produces organic and inorganic compounds which may add to the pollution of the atmosphere.

In addition to the materials which are thrown into the atmosphere by combustion of fuels and industrial processes, there are a number of natural substances which may contaminate the air. The most important of these from a health standpoint are the spores, pollens, and dusts from arid regions. Thus, the atmosphere may contain many varied types of pollutants.

**Meteorology as a Factor in Air Pollution.** EFFECT OF WEATHER IN THE PRODUCTION OF SMOG. The degree of atmospheric pollution is greatly influenced by weather and the complicating effects of topography. According to Willett (1950) the two elements of the weather which play a major role in air pollution are: "(1) precipitation (i.e., rain or snow) by which pollutants may be permanently removed from the atmosphere and (2) air motion, or wind, by which local concentrations of pollutants may be widely dispersed throughout the atmosphere."

Heavy rain is a most effective type of precipitation for removing hygroscopic oxides. Snow is more effective in removing soot and other solid particles. Only falling precipitation (rain and snow) is effective in removing contaminants; smogs have no cleansing effects.

Two types of air motion, horizontal and vertical, play a role in the dispersion of atmospheric contaminants. Turbulent winds which blow horizontally at the ground level can effectively remove pollutants. On the other hand, smooth horizontal air flow, rather than dispersing the pollutants, may carry them along the ground in a narrow band of high concentration to a neighboring community. Vertical wind movement is much more effective than horizontal wind movement for removing atmospheric materials away from human contact and for wide dispersion; first,

because the pollutants are removed immediately away from the ground level, and second, because dispersion increases with the height from the ground, due to the fact that the horizontal wind velocity is greater in the upper atmosphere than at ground level. Vertical winds depend on the gradient between the temperature of the air at the earth's surface and that at higher levels. Under normal conditions the air at the earth's surface is warmer than the air above the surface. Since warm air rises, vertical air motion occurs away from the ground. Under exceptional conditions, the temperature differential may be reversed, that is, the temperature of the air may be greater at the upper levels than at the ground. Under such a condition, which is known as a "temperature inversion," a cold layer of air hangs close to the ground and vertical air motion is suppressed. According to Willett (1950): "This is the only condition which permits the accumulation of atmospheric pollutants to dangerous concentrations. Such layers of cold air form at the ground, and collect in valleys and low-lying places generally, during periods of settled weather, clear skies and light winds, primarily during the colder part of the year and at night, in the absence of solar heating of the ground and lower atmosphere. The central portions of stationary or very slowly moving high pressure areas, with their light winds and absence of cloudiness or precipitation are most favorable to the development of extreme conditions of smog (local industrial pollution). Such stagnant smog conditions are likely to become most extreme in the autumn (October, November) after the sun has lost its summer heat and the nights have become long and cool, but before the stronger winds and rapid weather changes of the winter season have set in." The local accumulation of atmospheric pollutants is further increased by the presence of a heavy smoke layer at the ground, especially if fog is also present. This layer filters out the sunlight and thus prevents the sun's rays from heating the lower layer of air. In deep valleys such smogs may prevent any mixing of the contaminated air with the upper atmosphere for several days. "It was exactly this condition of a stagnant high pressure area, with extremely light winds surface and aloft, and the persistence of smog and relatively low temperatures in the valley for four days in succession which culminated in the Donora incident at the end of October, 1948. . . . An even more lethal smog development occurred in the Meuse Valley, near Liège, Belgium, in December, 1931 [*sic*!], under general conditions of weather and local topography which were almost identical with those at Donora" (Willett, 1950).

**USE OF WEATHER DATA AND SELECTION OF TOPOGRAPHY TO PREVENT SMOG DISASTERS.** In order to prevent disasters such as those which occurred in Donora and Liège, new plants which expect to discharge large quantities of waste materials should be located in areas where the regional weather conditions and the topography of the land are favorable for the removal of atmospheric contamination. Unfavorable types of topography include low areas in deep valleys and inland locations far from extensive water surfaces. In the absence of wind, the cool night air from the higher areas settles down into the valleys and leads to a temperature inversion and a retention of pollutants. The most favorable locations to prevent the accumulation of atmospheric contaminants are on a high elevation or well up on a steeply sloping terrain, and or on locations in close proximity to extensive water surfaces. The water surface allows wind movement without the frictional resistance caused by

rough terrain, and the temperature contrasts between water and land favor local winds.

For industries which are already located, hazardous conditions can be prevented by the use of weather forecasts to determine the approach of an unfavorable smog condition. When such weather conditions are anticipated, operations can be reduced and the discharge of waste materials temporarily suspended. In some cases the regular discharge of waste materials into the atmosphere may be timed to fit weather conditions which favor the rapid dispersal of contaminants.

**Effects of Atmospheric Pollution on Health.** In considering the effects of air pollution on health, several questions must be considered: (1) Can acute exposures cause direct damage to health? (2) Can chronic exposures to low concentrations of air pollutants over prolonged periods affect health? (3) What is the role of pre-existing disease in susceptibility to acute or chronic exposures? and (4) Does exposure to air contaminants lower resistance to other diseases such as infections?

**ACUTE EXPOSURES.** Four acute episodes of illness and death due to atmospheric pollution have been reported and well documented: the Meuse Valley disaster in December 1930; the Donora disaster in October 1948; the Poza Rica accident in November 1950; and the London experience in December 1952. In the Meuse Valley disaster the meteorological conditions over a five-day period favored the accumulation of fog, smoke and industrial wastes from the plants in this narrow valley south of Liège. Sixty-three persons and some cattle died on the fourth and fifth days after only a few hours of illness. The symptoms were those of acute respiratory irritation. Death occurred chiefly among elderly and ill persons, although some illness occurred in healthy adults and children. Autopsies on some of the cattle showed pulmonary edema. The cause of the Meuse Valley disaster was never determined, since no air analyses were performed during the smog period, but the scientists who investigated the conditions after the disaster believed that the irritant gases, especially the sulfur and fluorine gases, were responsible for the illnesses and deaths.

In the Donora episode, the smog lasted four and one-half days. A marked increase in illness began on the third day and 17 deaths occurred on the fourth day. Altogether 20 persons aged 52 to 84 years died, and many others became severely ill. Pre-existing disease of the cardiorespiratory system was present in the majority of the fatal cases. The symptoms of the illness included irritation of the respiratory tract and other mucous membranes. Autopsies of three cases showed edema, hemorrhage, purulent bronchitis, and bronchiolitis. As in the case of the Meuse Valley episode, the exact cause of the illness at Donora was not evident. Studies indicated that no single substance was the responsible factor but that more likely a combination of a number of irritant gases and fumes caused the irritations and deaths.

In the Poza Rica accident, large amounts of hydrogen sulfide escaped from a sulfur recovery plant over a period of 20 minutes. Twenty-two persons died and 20 were hospitalized with symptoms of acute hydrogen sulfide poisoning. A number of animals also died.

In London during the period of December 5 to 8, a peculiarly dense fog occurred. Excess illness became noticeable on the third and fourth day of the fog. Examination of the mortality in London during and following this period indicated that approximately 4,000 deaths could be attributed to the fog. The increase in

deaths paralleled an increase in the concentration of sulfur dioxide and smoke in the atmosphere. The deaths decreased subsequent to the fall in the concentration of these substances. The majority of the excess deaths occurred in infants and elderly persons and was attributable to disorders of the respiratory and circulatory systems. The specific causative agents were not clear. The average concentration of sulfur dioxide in the air, although increased, was not excessively high.

In addition to these acute episodes, there are other incidences which can be cited where illness in groups of persons has resulted from atmospheric pollution. The recent cases of lung damage due to beryllium furnish one of the most significant examples of illness resulting from atmospheric contamination by industrial wastes. Ten cases of beryllium granulomatosis occurred among persons who resided within three quarters of a mile of a plant which discharged beryllium compounds into the atmosphere. As far as could be ascertained, these persons had had no other exposure to beryllium except through the atmosphere. These cases, which are described in Chapter 32, indicate the grave danger of atmospheric pollution by materials which, in minute amounts, are able to cause serious illness in susceptible persons.

The irritating smog which occurs periodically in Los Angeles is another example of atmospheric pollution which affects groups of people. In this instance the outstanding symptoms are irritation of the eyes and some lacrimation. The current theory is that the contaminants which are discharged into the air are not immediately irritating but that complex chemical reactions occur in the air in the presence of sunlight leading to the production of irritating substances. Specifically, these substances are considered to be organic peroxides and other oxidation products, produced by photochemical oxidation of the hydrocarbons in the air, mediated through nitrogen oxides. Ozone also appears to play a role. The contaminants which are oxidized are presumably the unburned hydrocarbons from automobile exhausts, organic compounds from burning of refuse, discharges from petroleum and other industries and products from the combustion of fuels. Although the air pollution in Los Angeles produces marked irritation, epidemiological studies thus far have not revealed any effects on general sickness or mortality.

Atmospheric pollution with naturally occurring contaminants such as pollens cause allergic reactions in many susceptible individuals. Allergic reactions also have resulted from atmospheric contamination by industrial wastes. In one instance, persons who lived a mile away from a plant which crushed castor oil beans exhibited severe allergic reactions to this material.

The examples cited above are almost the only well-known instances where atmospheric pollution has caused specific illness in man. Whether this scarcity of evidence indicates that atmospheric pollution rarely causes severe illness or whether it merely reflects the difficulty of assessing the role of atmospheric pollution as an etiological agent in disease cannot be answered at the present time.

**CHRONIC EXPOSURES.** The specific examples of illness and irritation cited in the preceding paragraphs have resulted either from relatively high concentrations of harmful materials or from low concentrations of especially hazardous materials. In addition to these acute specific reactions, health authorities are concerned about the effects of daily exposures to low levels of contaminants which exist in the air of many cities. Studies in Cincinnati and Donora (Kehoe, 1950) have shown, how-

ever, that the extent of atmospheric pollution in an average community atmosphere under normal weather conditions is far below that which might be expected to cause harmful effects. The data presented in Table 29-1 shows the concentrations of certain chemical substances which were found in the air of Cincinnati and Donora, in comparison with industrial standards. It is evident from this table that the concentrations of chemical substances in the air of these communities is extremely low under normal conditions in comparison with concentrations which are considered safe for the majority of workers in industry.

In order to determine whether the low concentrations of irritating materials which existed at Donora under usual circumstances affected the health of the population, the Public Health Service studied the morbidity and mortality records over several years preceding the disaster. The results indicated that the population of Donora did not have higher morbidity or mortality rates than comparable control

Table 29-1. Comparison of maximum allowable concentrations of certain substances in industrial atmospheres, with concentrations found in certain community atmospheres

Concentrations in parts per million by volume, and in mg. per cu. M.

SUBSTANCE	MAXIMUM ALLOWABLE CONCENTRATION *	CONCENTRATION IN COMMUNITY ATMOSPHERES		
		Cincinnati		Donora
		Rural and residential	Commercial and industrial	
Carbon monoxide	100 p.p.m.	Nil to traces	50.0 p.p.m.†	Nil to traces
Chlorine	1 p.p.m.	0.04 p.p.m.	0.055 p.p.m.	0.04 p.p.m.
Fluorine (as hydro- fluoric acid)	3 p.p.m.	0.003 p.p.m.	0.006 p.p.m.	0.005-0.0075 p.p.m.
Oxides of nitrogen	25 p.p.m.	0.10 p.p.m.	0.10 p.p.m.	0.18-0.40 p.p.m.
Sulfur dioxide	10 p.p.m.	0.15 p.p.m.	0.12 p.p.m.	0.32-0.39 p.p.m.
Cadmium	0.1 mg.			<0.001 mg.
Lead	0.15 mg.	0.0015 mg.	0.0035 mg.	0.02-0.032 mg.
Manganese	6.0 mg.	0.004 mg.	0.004 mg.	
Zinc	15.0 mg.	0.001 mg.	0.003 mg.	0.015-0.77 mg.

† Actual observations range from traces up to 50 p.p.m., the latter being infrequent and of short duration.

From Kehoe, R. A., Proc. First National Air Pollution Symposium, Pasadena, Calif., 1950, p. 117.

groups. Only 1.5 per cent of the persons in the Donora area had a history of chronic bronchitis as compared with 1.2 per cent which was found for the general population in the National Health Survey.

Studies of industrial workers who have been exposed during the course of their work to the same chemical contaminants as exist in community atmospheres, but in even higher concentrations, have not shown injury to health in the majority of the situations studied. However, in the case of atmospheric pollution a number of substances may be present in the air simultaneously, so that synergistic effects may occur, the physical properties of the contaminants may change allowing greater penetration into the lungs, or even the chemical properties may be altered by reactions in the air. Furthermore, the acute episodes described above indicate that chronic pulmonary and cardiovascular diseases, which probably are not common in industrial workers, increase susceptibility to environmental irritants.

Thus, although the evidence at present indicates that atmospheric contaminants under normal conditions in the average city are below the level where they would be expected to affect health, no definite statement regarding chronic effects can be made until more scientific data and epidemiological studies have been made.

**EFFECTS OF ATMOSPHERIC POLLUTION ON SUSCEPTIBILITY TO RESPIRATORY INFECTIONS.** It has been assumed by many persons that exposures to atmospheric pollutants may predispose to infectious diseases of the respiratory tract, such as colds, bronchitis, pneumonia, and tuberculosis. However, sound evidence to support this view is lacking at the present time. Attempts have been made to obtain data bearing on this problem from three sources: (1) statistical studies relating the morbidity and mortality rates of population groups with the degree of atmospheric pollution in their community, (2) experimentation on animals, and (3) studies of industrial workers exposed in the course of their work to the same materials which are found as contaminants in the atmosphere. Data from all three of these sources are subject to certain limitations. Morbidity and mortality rates are affected by so many variable factors that it is almost impossible to determine the specific role of any one factor, such as atmospheric pollution. Furthermore, in these studies, the character and extent of atmospheric pollution has not been measured with any degree of accuracy. Thus, conclusions based on such studies cannot be accepted without further confirmation. Although much valuable information may be obtained from animal experimentation, care must be taken in applying the results obtained on animals directly to man. Industrial studies have supplied the most reliable data on the effects of atmospheric pollution on susceptibility to respiratory infections, but these have been few in number and, furthermore, the results of such studies may not be directly applicable to atmospheric pollution problems because many more contaminating substances may be present at the same time in atmospheric exposures than are usually present in industrial exposures. The following brief review, taken from a paper by Baetjer (1950), will serve to indicate the type of data which are available at the present time regarding the effects of smoke, irritant gases, and dusts on susceptibility to respiratory infection.

Smoke produced by the burning of coal and other fuels is a contaminant of universal interest which has been the subject of several investigations. One study of autopsies in the Pittsburgh district (Schnurer, 1938) indicated that the incidence of pneumonia, bronchitis and emphysema increased in direct proportion to the degree of pneumoconiosis. It was assumed that the pneumoconiosis was produced by the smoky atmosphere of Pittsburgh. Another similar investigation produced the opposite result, namely, that there was no evidence of a relationship between the high incidence of pneumonia in the Pittsburgh area and the degree of pigment deposited in the lungs, although healing by organization of unresolved pneumonia was consistently higher in all of the more advanced grades of anthracosis (Haythorn and Meller, 1938). Laboratory experiments conducted by Vintner and Baetjer (1951) showed that prolonged exposure to smoke produced by the combustion of bituminous coal did not lower the resistance of rats to Type 1 pneumococci injected intrabronchially, although the smoke contained 10 to 30 p.p.m. of carbon monoxide, 0.8 to 1.6 p.p.m. of sulfur dioxide, and 50 to 100 times the concentration of total solids normally present in the air of cities.

Irritant gases favor the invasion of the respiratory tract by infectious agents where severe damage to the mucosa has occurred. However, there is little evidence that prolonged inhalation of air containing sulfur dioxide, chlorine, nitrous fumes, and other irritant gases in low concentrations lowers resistance to acute infections of the respiratory tract. Kehoe and others (1932) compared the health of 100 workers who had been exposed for some years to concentrations of sulfur dioxide (varying from about 10 to 100 p.p.m.) with that of a control group. The incidence of colds was not significantly different in the two groups, although the duration of the illness was extended in the exposed group. However, a significantly higher incidence of nasopharyngitis, which was considered as arising from the local irritation, was found in the exposed group. Evans (1940) reported that the incidence and the death rate of pneumonia and other pulmonary infections were not higher than normal in men who were constantly exposed in their daily work to low concentrations and occasionally to higher concentrations of hydrofluoric acid, chlorine, hydrochloric acid gas, sulfur dioxide, sulfur trioxide, sulfuric acid fumes, phosgene, and other irritant gases. A study made at the Kaiser Shipyards during World War II indicated that the incidence of pneumonia among their 15,000 welders was not greater than the rate for all workers in these shipyards, although welders are exposed to irritant gases and fumes (Collen and others, 1944).

The effects of irritating gases on susceptibility to tuberculosis have been studied more extensively. According to Gardner (1942), neither acute nor chronic exposure to irritant gases lowers resistance to tuberculosis. The tuberculosis rates in men who were gassed during World War I were no higher than the rates among the Army men who were not gassed. Similarly, animals subjected to war gases or to irritating fumes from welding were no more susceptible to tubercle bacilli than were their controls. Men exposed to irritating gases in industries have not shown a higher rate of tuberculosis than that of comparable control groups. The tuberculosis rate in Donora residents was found to be low.

The data available at the present time indicate that neither acute nor chronic exposure to carbon monoxide lowers resistance of men to respiratory infections. Similarly, experiments have shown that exposure to carbon monoxide does not lower the resistance of animals to either pneumococcal or tuberculous infection.

The data on hard rock or mineral dusts have been contradictory. The dust storms in the Middle West during 1935 were reported to have caused a marked increase in morbidity and mortality from acute infections of the respiratory tract (Brown, 1935). Some studies of industrial workers exposed to high concentrations of mineral dusts have shown normal rates for acute infectious diseases of the respiratory tract, whereas other studies have shown high pneumonia rates. However, in the latter cases, the high pneumonia rates may be attributed to the sudden changes in temperature and chilling rather than to the dust exposure. Exposure of rats to silica, feldspar, and other dusts does not lower their resistance to pneumococcal infections (Baetjer and Vintinner, 1944). Free silica dust ( $\text{SiO}_2$ ) is the only mineral dust which appears to lower the resistance of men and animals to tuberculosis, but exposures capable of producing this effect occur only within industry and do not present a problem in atmospheric pollution.

From this brief review, it is evident that no conclusions can be drawn regarding the effect of atmospheric pollution on susceptibility to respiratory infections. There

is no evidence to indicate that atmospheric pollution plays a major role in susceptibility to such diseases.

**RELATION OF ATMOSPHERIC POLLUTION TO LUNG CANCER.** The rapid rise in the death rate due to lung cancer in recent years has focused considerable attention on the possible role of atmospheric pollutants in the production of this disease. Such substances as nonspecific atmospheric dusts, irritant gases, dust from tarred roads, exhaust fumes from automobiles, soot and tar from burning coal and oil and various waste products from industrial operations have been suggested as possible etiological factors contributing to the increase in the incidence of lung cancer. A number of statistical studies have been made in an effort to determine the role of these factors. However, the same caution must be exercised in accepting the results of statistical studies on atmospheric pollution in relation to cancer as was mentioned above in relation to respiratory infections. In the case of lung cancer, it is even more difficult to determine the role of atmospheric pollution since presumably many years are required for the development of this disease. The statistical studies on the role of environmental factors in lung cancer have been carefully reviewed by Hueper (1942). This author has pointed out the many contradictory and confusing results which have been reported.

Considerable evidence exists to indicate that irritation of the lungs per se by irritant gases, such as the war gases, and irritant dusts, such as free silica, does not predispose to lung cancer. On the other hand, chemical analyses of the air in urban locations and of the exhaust fumes of automobiles have shown the presence of certain specific carcinogenic agents such as benzpyrene. However, no evidence exists at the present time to prove that these materials can produce lung cancer in man and, if so, whether the concentration in the air is sufficient.

Thus, at the present time, it is not possible to determine the role of atmospheric contaminants in lung cancer nor to explain the rise in the incidence of this disease on the basis of atmospheric pollution.

This review of the effects of atmospheric pollution on health indicates that atmospheric pollution exerts a major effect on health only under very unusual circumstances. There are no data at the present time to indicate that the usual concentrations of contaminants in the atmosphere are a major hazard to health.

**Other Effects of Atmospheric Pollution.** Although it is difficult to prove that atmospheric pollution has any significant effect on health, except under very unusual circumstances, the economic effects of atmospheric pollution are very well known. In fact, under normal daily conditions, the economic damage produced by air pollution appears to be the most important aspect of this problem. It has been estimated that the losses due to air pollution in this country amount to about one and one-half billion dollars per year.

Sulfur dioxide, hydrofluoric acid, chlorine, some organic compounds, and other substances may cause spotting and burning of the leaves of plants, destroy seedlings and crops, retard the growth of trees, and exert other harmful effects on vegetation. These atmospheric impurities can affect plants directly, in some cases, or indirectly by pollution of the soil. Sensitive species can tolerate only very low concentrations of sulfur dioxide in the air, about 0.1 to 0.2 p.p.m. These concentrations are far lower than the concentration of 10 p.p.m., which is believed to be safe for man. Areas located at considerable distance from the source of pollution may

be affected. For example, sulfur dioxide emitted from smelting plants may affect vegetation as far as 12 or 15 miles from the plant.

Contamination of the atmosphere with some substances may produce harmful effects on cattle. The fluorides present the greatest danger in this respect. Herds of cattle have been seriously affected or even entirely destroyed by eating foliage contaminated with fluorides discharged from neighboring industries. The disease is manifested by a more or less pronounced cachexia with roughening of the coat, diarrhea, loss of weight, fall in milk production, tremor, and marked abnormalities of the bones which lead to a stiff and laborious gait. Death of the cattle may result.

In addition to these effects on vegetation and cattle, other economic losses result from atmospheric pollution. Sulfur dioxide, sulfuric acid mist, hydrogen chloride, nitrous oxides, and other substances which contribute to the acidity of rain and fog cause corrosion of building materials and metals. Hydrogen sulfide discolors lead paint. The fluorine compounds cause etching of glass windows. Ozone may be a factor in the oxidation and deterioration of rubber goods. Tar and soot adhere to surfaces on which they impinge. Tons of solid materials accumulate on the ground and buildings. In 1936, Pincus and Stern (1937) estimated that the soot fall in New York City amounted to between 150 and 200 tons per square mile per month in industrial areas, to about 50 tons in residential areas, and to between 15 and 35 tons in suburban areas. The cost of the cleaning and repairing necessitated by atmospheric pollution is tremendous.

Atmospheric contaminants also interfere with the amount of sunlight which penetrates to the earth. Some years ago, the United States Public Health Service (Ives, 1933) measured the average loss of daylight due to the atmospheric pollution of cities. This study indicated that under some circumstances, 50 per cent of the ordinary daylight was lost as a result of pollution of the atmosphere. The average loss of daylight was around 15 to 20 per cent. Atmospheric contaminants not only reduce the amount of visible light but also may prevent a large amount of the ultraviolet radiation from reaching the earth. In addition to filtering out the sunlight, aerosols cause scattering of the rays of light and thus interfere with visibility. This scattering of light depends not only on the concentration or number of particles per unit volume of air but also on the particle size and index of refraction of the material. Droplets about 0.5 micron in diameter are most effective in scattering light, whereas larger droplets may absorb light. The reduction in visibility due to the scattering of light rays by aerosols is easily observed when driving an automobile at night in a fog.

A number of atmospheric contaminants such as hydrogen sulfide, the mercaptans, the organic peroxides, and many other organic compounds produce unpleasant odors. These may be very disagreeable and are often the chief cause of annoyance among persons residing in communities where such contaminants are discharged into the atmosphere. As far as is known, offensive odors do not produce any direct damage to health, but they may lead to a loss of appetite or even to nausea.

**Prevention of Atmospheric Pollution.** The prevention of atmospheric pollution is an extremely costly operation. It has been estimated that industries are spending many millions each year to prevent contamination of the air. The cost is so excessive that complete elimination of industrial waste discharge into the air can never

be approached. However, the pollution of the air can be greatly reduced by various types of control measures. The first and most important preventive measure is to avoid the production of waste materials wherever possible by a change in plant process. For example, in the burning of fuels, the output of smoke can be reduced by the use of low volatile fuels and, more important, by improved combustion efficiency. Smokeless domestic stoves and industrial equipment for adequate combustion of fuels are now available. Suppression or removal of waste materials at the source is the second important procedure. Acid gases, and vapors may be removed by scrubbing and absorption; dusts and fumes may be caught by filters, collectors, precipitators, etc.; some organic contaminants can be burned; some materials can be neutralized; and some may be recovered by chemical reactions, such as oxidation. In certain cases, recovery of waste materials has resulted in economic gain to the industry, but for the most part the cost of the operation far exceeds the value of the material recovered. A third procedure to prevent undue accumulation of waste products in the atmosphere is to discharge these products into the air through high stacks. Stacks, if sufficiently high, are satisfactory for the dispersion of gases but not for dusts unless the particle size is excessively small. Increasing the height of discharge stacks and the temperature of the discharged air will create better diffusion of the contaminants in the air. The mass rate of emission from stacks is more important than the concentration of the contaminant in the discharged air. Stack emission should be in accordance with meteorological conditions as noted earlier in this chapter. Atmospheric pollution may be prevented by locating plants where the character of the meteorological conditions and topography are favorable to discharge purposes, as discussed earlier in this chapter.

By these and various other methods it is possible to reduce the concentration of atmospheric pollutants to levels which are not harmful to man, animals or plants, and which will greatly reduce the damage to property.

## RESUSCITATION

Since man can survive only a very few minutes without oxygen it is absolutely essential that artificial respiration be applied immediately whenever normal respiration ceases as a result of drowning, electric shock, the inhalation of carbon monoxide, respiratory paralysis, blockage of the airway, etc. In this chapter, artificial respiration suitable for emergency and field use will be considered. Procedures applicable only to hospital use, such as phrenic nerve stimulation, will not be included.

**General Principles of Respiration.** Before considering the various procedures and equipment which may be used for artificial resuscitation, it is necessary to review certain fundamental principles of respiration and circulation. In normal inspiration, the thoracic cavity is enlarged by contraction of the diaphragm and the other inspiratory muscles; the pressure inside the lungs falls below atmospheric pressure, and air flows into the lungs. The negative pressure in the thorax during inspiration assists in the return of the venous blood to the heart since the pressure on the veins in the abdomen is greater than the pressure on them in the thorax. Under normal conditions, expiration is effected by a passive return of the chest to its original size by relaxation of the muscles. In forced expiration, the contraction of the expiratory and abdominal muscles decrease the size of the chest. During expiration, the pressure in the thorax increases above the atmospheric level and air is forced out of the lungs. The greater pressure on the veins in the thorax than in the abdomen temporarily retards the venous return to the heart during expiration. Since the output of blood from the heart depends on the rate of inflow of blood from the veins, the venous return is a very important factor in maintaining a normal supply of oxygen to the tissues. Thus, in considering the various procedures of artificial resuscitation, their effect on the circulation as well as their ability to supply air to the lungs must be considered. For example, a method which supplies an adequate volume of air to the lungs but which interferes with the circulation may be less desirable than one which provides less oxygen but assists in the return of blood to the heart. Only when sufficient oxygen actually reaches the tissues, can the cells function and the respiration and circulation be restored to their normal condition.

**Methods of Artificial Respiration.** **MANUAL METHODS.** Artificial resuscitation may be administered either by manual or mechanical methods. The various manual methods of artificial respiration which are more or less commonly in use today are shown in Figure 30-1. The Eve method, although not strictly a manual method, is included in this category since it does not require any specially built apparatus. Another manual method of artificial respiration, the pole top method (Kouwen-

From Gordon, A. S., and others, J.A.M.A. 144:1456, 1950.

Fig. 30-1. Manual methods of artificial resuscitation.

1, Normal respiration; 2, Silvester method; 3, Schafer prone pressure method; 4, Eve rock-g method; 5, Nielsen method; 6, combination of Nielsen and Schafer methods; 7, hip-lift method; 8, combination of the hip-lift and Schafer methods.

hoven and others, 1940), was devised for the resuscitation of linesmen suffering electric shock while working at the top of a pole. In the pole top procedure, the rescuer ascends the pole and administers artificial respiration by rhythmic pressure on the abdomen while on the pole, thus avoiding the loss of time in lowering the patient to the ground.

The manual methods of artificial resuscitation fall into four general groups depending on their mode of operation:

1. Methods by which forced expiration is induced by decreasing the size of the thorax. Forced expiration may be produced either by pressure on the thoracic cage (Schafer method) or by an upward movement of the diaphragm by pressure on the abdominal organs (pole top method). The inspiration is passive and depends on the elastic recoil of the thoracic muscles when the pressure is removed, or on the return of the abdominal organs to their original position.

2. Methods by which inspiration is induced by enlarging the size of the thorax. This may be accomplished by a movement of the arms (first stage of the Silvester method) or of the trunk (hip lift method). Expiration results from a return of the arms or trunk to normal posture.

3. Methods by which induced inspiration is combined with forced expiration (Nielsen, Eve, Silvester, hip-lift-Schafer methods).

4. Method by which air is forced into the lungs by blowing into the mouth, thus increasing the pressure at the mouth intermittently (mouth to mouth insufflation).

In all of these methods, except the mouth to mouth method, there may be some slight interference with the venous return during the expiratory phase. It is claimed that the Eve method assists the venous return to a greater extent than any of the other manual methods.

**MECHANICAL METHODS.** The "mechanical" methods of artificial resuscitation include those methods which utilize specially designed equipment. These methods may be classified into two types according to the pressure relationships which they create:

1. Mechanical resuscitators which force air into the lungs by creating a greater pressure at the mouth than exists in the thorax. This principle is used in the bellows type and positive pressure resuscitators where air is blown into the lungs at pressures above atmospheric pressure.

2. Mechanical resuscitators which produce alternating positive and negative pressures at the mouth. By these methods air is forced into the lungs under a pressure greater than atmospheric pressure and is sucked out of the lungs by a pressure at the mouth which is below the atmospheric level. During the positive pressure phase the venous return to the heart is greatly retarded. The cardiac output may be decreased 30 to 40 per cent in some cases. However, this decrease may be compensated for by a more rapid return during the negative pressure phase if the pressure and time for inspiration and expiration are properly regulated.

**COMPARISON OF METHODS.** For many years, the Schafer method of artificial respiration was the official method in the United States. However, recent experimental investigations on humans by Gordon and others (1950) showed that the methods which produce both active inspiration and active expiration, so-called

push-pull methods, result in much better pulmonary ventilation than the methods which produce only either active expiration or active inspiration. The three so-called push-pull methods are the Nielsen method, the Silvester method, and the hip-lift-Schafer method. The last method is difficult to perform, and the supine position of the Silvester method favors obstruction of the airways. Thus the Red Cross, Armed Forces, and other official agencies have adopted the modified Nielsen method as the recommended procedure. The other two methods should be used when the condition of the patient make the Nielsen method unsuitable.

The use of mechanical resuscitators has been the subject of many arguments in past years. Some authorities believed that mechanical resuscitators might damage the capillary walls during the positive phase and might create congestion, pulmonary edema, or atelectasis during the negative phase. However, in recent years mechanical methods of artificial resuscitation have been more widely accepted. Well-controlled experiments have shown that intermittent positive pressure is not dangerous if the pressure relations are properly adjusted, and that larger volumes of air can be introduced into the lungs by mechanical methods than are usually supplied by manual methods. The unfavorable effect of positive pressure resuscitators on the cardiac output can be eliminated if the pressure changes are properly adjusted. Authorities are not yet in agreement regarding the value and possible dangers in the use of negative pressures except that methods producing negative pressures should not be used in cases where pulmonary edema is present.

The desirable features for mechanical resuscitators have been summarized in a report recently published under the auspices of the Council on Physical Medicine of the American Medical Association (Motley and others, 1948). In this report Motley and his associates stated that the ideal type of resuscitator equipment for use on man (producing effective artificial respiration with a minimal disturbance to the circulation) should embody the following characteristics:

"It should be simple and sturdy in construction and operation, small and compact in size . . . The respirator apparatus should stand steam sterilization if expiration occurs through part of the device . . . Expiration should not occur through the flow-sensitive respirators with reversing pistons . . .

"The mask pressure curve should increase gradually during inspiration up to a peak not in excess of approximately 25 cm. of water, and after reversal occurs the pressure drop should decrease rapidly to a final pressure near atmospheric . . . The mean mask pressure during the expiratory period should be as low as possible. [Inspiratory time should not exceed expiratory time. This type of mask pressure curve permits the right side of the heart to compensate during expiration.] There is no apparent advantage of including negative pressure in the cycle.

"Alternating frequency rates should maintain a respiratory rate between 10 and 20 per minute.

"The volumes of pulmonary ventilation provided should be on an average from 10 to 15 liters per minute.

"A regulator line pressure should be provided that takes into account the pressure drop in transmission for the particular type of respirator used and provides peak pressures from 10 to 25 cm. of water (7.4 to 18.4 mm. of mercury).

"The mask most suitable for use in this study has been one having a wide, flatable, thin, soft rubber cuff built over a sponge-type cushion base and detach-

able from a light weight transparent plastic facepiece . . . This type of mask has provided the best leakproof fit and the least dead space."

**Types of Gas to be Supplied.** In addition to discussing the methods of resuscitation, it is necessary to consider the gas—air, oxygen, or oxygen-plus carbon dioxide—which should be administered in artificial resuscitation. Almost all authorities recommend that oxygen when available, rather than air, be used in artificial resuscitation. For many years it was thought that oxygen with 7 or 5 per cent carbon dioxide was more effective in restoring normal respiration than was oxygen or air. In recent years this view has changed. The American Medical Association and Red Cross now recommend that oxygen rather than a mixture of oxygen and carbon dioxide be administered to asphyxiated victims. Oxygen-carbon dioxide mixtures should not be used in any case in which the patient has ceased breathing because under these circumstances oxygen lack, increased blood carbon dioxide, and acidemia are usually present (Dill, 1952). The only situations in which the carbon dioxide mixture may be beneficial are in cases of carbon monoxide poisoning when the patient is still breathing or when hyperventilation precedes cessation of breathing.

An instrument which reduces the pressure of compressed oxygen to atmospheric levels and supplies it to the mouth of a victim through a face mask is usually called an "inhalator." Inhalators must not be confused with mechanical resuscitators since they do not force the oxygen into the lungs under pressure. The inhalators can be used in conjunction with manual methods of artificial respiration or with manually operated mechanical instruments. Oxygen is always supplied with the automatic mechanical equipment. Prolonged use of pure oxygen is, however, dangerous.

The important points which should be borne in mind when considering artificial resuscitation were summarized in a joint statement issued by the American Medical Association, Council on Physical Medicine, and the American National Red Cross (1948). The points listed were as follows:

"The air passages must be free from obstruction. The tongue sometimes presses back into the pharynx, shutting off the airway. The first aider should insert two fingers far back into the mouth and press downward and forward on the tongue. Thus the tongue is brought into proper position. If the victim lies prone, the tongue will then remain in this position. If the victim is not prone, it may be necessary to have an assistant hold the tongue in good position with a handkerchief. Fluid or vomitus may also obstruct the passageway somewhat. If the victim is prone such fluid usually flows out quickly while artificial respiration is given. However it may be advisable to wipe out the mouth, reaching far back with a handkerchief.

"These measures of bringing the tongue forward and of removing other obstruction should be accomplished at once. If only one first aider is present, he should execute these measures between compression, starting after the first one.

"If an accepted resuscitator is at hand, it may be substituted for manual artificial respiration with assurance that sufficient ventilation will occur. Manual artificial respiration, however, is all-important while the rescuer awaits a resuscitator. Use of the manual method should continue while the resuscitator is being adjusted, so that the victim's lungs constantly receive air.

"If a person has not been breathing for five to ten minutes, the chance of su-

vival is slight, even if the most efficient inhalators or resuscitators are used. Nevertheless, an attempt at resuscitation should be made when the slightest chance for recovery exists. Artificial respiration should never be stopped when a pulse or heart beat can be felt. Recovery of normal breathing may be long delayed, especially in cases of electric shock. Most patients recover within about one-half hour, but some have been resuscitated after several hours of artificial respiration."

The most important thing to remember in patients who have ceased to breathe is to start artificial resuscitation immediately. Lapse of a few minutes may mean the difference between recovery and death.

An excellent review of the many complicated factors and unsolved problems in artificial respiration has been published by Whittenberger (1955).

## INDUSTRIAL HEALTH, DISEASES OF OCCUPATION

ANNA M. BAETJER, SC.D.

### 31

#### INTRODUCTION

##### SCOPE AND MODERN CONCEPTS OF INDUSTRIAL HEALTH

Industrial health has become an increasingly important field during recent years. It has advanced not only as a result of the general development of public health and preventive medicine, of which it is a part, but also because of recent social trends which emphasize the rights of the working man and his importance to industry. Furthermore, because of the need for maximum production during wartime, tremendous impetus was given to the industrial health movement by both World Wars I and II.

Industrial health, according to the broadest concept, is concerned with all factors which influence the health of people at work. It is, in reality, preventive medicine and hygiene as applied to the working people, including not only persons who are employed in factories, but also farmers, miners, storekeepers, clerks, professional persons, and all others who are gainfully employed in any type of occupation. The objectives of industrial hygiene are twofold: (1) to determine if the working environment or any other conditions of work are harmful to the health of the workers and to prevent these harmful effects, and (2) to promote the maximum health and well-being of people at work. Thus industrial hygiene has both a preventive phase and a positive or constructive phase.

**Preventive Phase of Industrial Health.** On the preventive side, industrial health is concerned with occupational diseases due to all types of harmful chemical substances such as lead, benzol, or silica. Of equal concern are the physiological effects and diseases resulting from the physical factors of the industrial atmosphere such as the temperature of the air or radiant energy. The abnormal stresses of the work itself, due to posture, repeated motion, or improper work methods, also fall within the scope of industrial health. In addition to the specific occupational diseases, industrial health is concerned also with the effects of the working environment and conditions of work on comfort and ability to work, on degenerative diseases, and on resistance to infectious diseases.

In addition to the principal phases of industrial health, as outlined in the preceding paragraph, certain other preventive activities fall into this field. These include cooperation in other health programs for the prevention of industrial infections such as anthrax, and other communicable diseases which may be spread

through the working environment. The study and control of atmospheric pollution is another phase of preventive industrial health. This subject falls within the scope of industrial health because a large part of the foreign substances which contaminate the outdoor atmosphere are waste products from industrial operations and because their control is the responsibility of industry. The prevention of industrial accidents, although not usually the responsibility of industrial health personnel, requires the close cooperation between industrial health and safety programs.

The relation of industrial health work to nonoccupational diseases also must be mentioned. Industrial health programs within industry can contribute greatly to the prevention of nonoccupational diseases through the medical examinations of industrial workers and analyses of medical records. Industrial health personnel, both in private industry and in government agencies, serve as a means of contact whereby general public health programs can reach large groups of adult workers.

**Constructive Phase of Industrial Health.** A complete industrial health program is concerned not only with the prevention of diseases and stresses resulting from the occupation or the working environment, as outlined in the preceding discussion, but it also has as its objective the promotion of maximum health and well-being of people at work. This aspect of industrial health, which involves cooperation with many other special fields, includes the following: the determination of the optimum conditions of work, such as lighting or ventilation; the design of machinery and processes which will place a minimum of stress on the body; the determination of the best types of work for persons of different ages and different physical and mental capacities; the rehabilitation of handicapped persons; the promotion of good human relations and mental hygiene in industry; and other phases.

Like any other scientific and technical work, advances in industrial health depend on research studies. Thus, biological, chemical, medical, and engineering research form an important phase of industrial health. The toxicological effects of chemical substances, the effects of extremes of temperature, noise and radiant energy, and the physiological reactions to work are examples of biological investigations in this field. Studies in the basic principles for the removal of dusts and gases and in the design of machines and processes to fit the workers are types of engineering research. The development of chemical methods for analyzing the contaminating substances in air and chemical studies on biological materials are subjects for investigation by the chemists. These and many other research studies are a fundamental part of industrial health.

It is obvious from the facts just outlined that an industrial health program, in the broadest sense, depends on cooperative activities in many different fields and requires the participation of persons trained in many different disciplines: engineering, chemistry, medicine, physiology, toxicology, physics, and others. A constructive industrial health program is not the work of any one group but the combined effort of many groups working together.

In this section of the book, only the functions which are the direct responsibility of persons engaged in industrial health work will be included.

THE INDUSTRIAL POPULATION

Before discussing the various aspects of industrial health, it is necessary to become familiar with the extent and distribution of the working population in this country. The total number of employed persons in the United States has been increasing steadily throughout the years. This trend from 1880 to 1954 is shown by decades in Figure 31-1. The maximum number of employed males in any

Fig. 31-1. Number of gainfully employed persons in the United States, 1880 to 1954 (1880 to 1940, total labor force; 1940 to 1954, employed labor force). In order to show the recent trends, the numbers are plotted for each year separately between 1940-1954.

year up to the present time was approximately 43 million, and of employed females was almost 19 million.

The distribution of this employed population according to broad occupational and industry groups is also of interest. The number and per cent of gainfully employed persons in the various major occupational groups for the year 1954 are given in Table 31-1. The only recent data giving the distribution of the population according to industrial groups is for the month of April, 1954. These figures are presented in Table 31-2.

Table 31-1. Employed persons, 14 years of age and over, by major occupation group and by sex, for the United States, 1949 (arithmetical means of quarterly estimates)

MAJOR OCCUPATION GROUP	MALES		FEMALES		MALES AND FEMALES	
	Total Number	Per Cent	Total Number	Per Cent	Total Number	Per Cent
Total number employed	42,377,000	100.0	18,861,000	100.0	61,238,000	100.0
Professional and semiprofessional workers	3,433,000	8.1	2,017,000	10.7	5,450,000	8.9

Personal and domestic services	1,160,000	2.80	2,764,000	16.90	3,924,000	6.79
Amusement, recreation and related services	367,000	0.88	119,000	0.73	486,000	0.84
Professional and related services	2,059,000	4.97	2,275,000	13.91	4,334,000	7.50
Government	1,843,000	4.44	677,000	4.14	2,520,000	4.36

From Current Popu. Rept. Series, U. S. Bureau Census, P-60, #6, p. 26, Feb 1950.

In addition to distribution by industry and occupation groups, several other characteristics of the employed population are of interest. For industrial health purposes, it is important to note the number of persons employed in different sized manufacturing establishments, since large plants can support their own industrial health programs, whereas small plants must depend on group services and government services. In Table 31-3, the number of plants and workers (as of 1947)

Table 31-3. Number of gainfully employed persons in manufacturing plants and number of plants, classified according to size of plant, based on number of employees (1947)

SIZE OF PLANT BASED ON NUMBER OF EMPLOYEES	NUMBER AND PER CENT OF WORKING POPULATION		NUMBER AND PER CENT OF PLANTS	
	Number	Per Cent	Number	Per Cent
Total	14,294,304	100.00	240,881	100.00
1-4	161,007	1.13	70,384	29.22
5-9	310,880	2.17	46,621	19.35

From United States Bureau of Census, Manufacturing Establishments Classified by Size, Census of Manufactures-1947. Preliminary Report, Series MC100-6, Aug. 1949.

are listed according to the size of the plants, based on the number of employees. This table shows that approximately 90 per cent of the manufacturing plants employ less than 100 workers but that only 25 per cent of the workers are employed in plants of this size. Fifty per cent of the plants employ less than 10 workers. Almost 18 per cent of the workers are engaged in plants employing 2,500 or more workers. It is evident from these facts that industrial health programs must be organized to fit very different situations.

A knowledge of the number of workers engaged in occupations where potentially harmful working conditions of various types exist is of great importance in industrial health. In order to determine this, the United States Public Health Service, Division of Industrial Hygiene, together with the state industrial health units, made a survey of sample industries in 15 states between 1936 and 1939. These surveys covered 16,803 plants employing 1,487,224 workers engaged in (1) "extraction of minerals," (2) "manufacturing and mechanical industries of all types," (3) "transportation industries," and (4) "personal service." The public health authorities calculated the number and per cent of the workers who were exposed in these sample plants to some potentially harmful conditions. On the assumption that the groups surveyed were representative of the industries throughout the United States, they estimated the total number of workers in the United States who might be considered as exposed to materials and conditions of potential health significance. Their figures are presented in Table 31-4. It should be noted that this table does not give any indication of the number of men exposed to

dangerous concentrations of these materials, but merely the number who work in industries where such materials are used or produced.

Table 31-4. Expected number of workers in selected industry groups in United States exposed to specified materials, 1936-1939

MATERIALS	PER CENT OF WORKERS EXPOSED SURVEY(1)	EXPECTED NUMBER OF WORKERS EXPOSED(2)
Number of workers surveyed (basis for percentages in column 1)		1,487,224
Number of workers in selected industry groups in United States (basis for expected number in column 2)		15,175,301

Coal dust, anthracite	0.08	11,473
Hides	0.04	6,586
Aniline and its compounds	0.04	6,434
Amines	0.03	4,659
Selenium and its compounds	0.03	4,113
Radium and radioactive substances	0.01	2,200

From Bloomfield, J. J., and others, A Preliminary Survey of the Industrial Hygiene Problem in the United States, Public Health Bull. #259, FSA, U.S.P.H.S., Washington, D. C., 1940.

## OCCUPATIONAL DISEASES

## GENERAL CONSIDERATIONS

Occupational diseases are usually defined as diseases arising out of, or in the course of, employment. In the strictest sense, this term includes only those diseases which are specific to the occupation, i.e., those in which the etiological agent occurs only in the occupational exposure. However, industrial hygiene is concerned with all types of diseases and impairments to health which are caused or affected by the working environment or by the conditions of work. From this viewpoint, the relation of occupational exposures to diseases, such as the common respiratory infections or circulatory diseases, is of equal importance. In this section, the specific diseases which result directly from industrial exposures and the effects of industrial exposures on susceptibility to infectious diseases will be described.

**Classification.** Occupational diseases can be grouped, according to the causative agents, under four categories:

1. Diseases resulting from exposure to chemical substances such as dusts and gases. The most important of the occupational diseases due to chemical substances are discussed in the succeeding chapters.
2. Diseases resulting from the physical state of the environment such as temperature, radiant energy, and noise. These factors have been discussed in section 5, under environmental medicine.
3. Diseases resulting from the mechanical factors such as pressure, physical strain, and movement. The occupational diseases due to these factors are discussed in Chapter 34.
4. Diseases due to infectious agents such as anthrax, brucellosis, fungus infections. Since these diseases have been discussed in other sections of this book, they will not be considered in this section.

**Incidence.** There are no reliable statistics on the incidence of occupational diseases. Although a number of states have laws requiring the reporting of occupational diseases, these laws are not enforced. Furthermore, many occupational diseases are not recognized because of the lack of characteristic symptoms, the long period of exposure required, the long latent period between the end of exposure and the illness in some cases, and the unfamiliarity of most doctors with the industrial conditions to which their patients are exposed.

Some figures on the incidence of occupational diseases are available from compensation records, but these yield only limited data since occupational disease compensation laws usually cover only those cases causing disabilities of more than

three or seven days' duration or death. However, the United States Public Health Service has collected some statistics on occupational diseases in the various states. The limited data they were able to accumulate are presented in Table 32-1. These

Table 32-1. Incidence of alleged or suspected occupational diseases as reported in 28 states and for Federal employees during a year's period, by nature of disease

NATURE OF DISEASES		TOTAL
All Diseases		43,307
1. Systemic Effects Due To Chemical Agents		2,252
ammonia, 24; anilin, 23; arsenic, 16; benzol or its derivatives, 16; beryllium, 9; carbon bisulfide, 6; carbon monoxide or dioxide, 233; carbon tetrachloride, 32; chlorine, 29; chrome, 154; cyanide, 15; halogenated hydrocarbons, 14; insecticides, 323; lead, 491; mercury, 14; petroleum products, 23; phosphorus, 5; sulfur dioxide, 14; zinc, brass, 84; gases not specified, 202; paint solvents, 33; miscellaneous and not known, 492		
2. Dust Diseases of the Lungs		1,999
asbestos, 21; anthracosilicosis, 233; silicosis,* 1,615; pneumoconiosis, other, and not specified, 130		
3. Respiratory Disorders		667

6. Diseases of the Skin		23,502
7. Miscellaneous Conditions		9,612
allergies (other than skin), 211; cancer, 7; conjunctivitis, 2,034; blisters, abrasions, 567; effects of bites, stings, 1,635; heart disease, 10; neuritis, arthritis, 144; all other, indefinite, not specified, 5,004		

\* Includes 134 cases reported as silicotuberculosis.

† Includes 14 cases of loss of hearing—3 due to radiation.

figures are based on all available published and unpublished data from 28 states and Federal employees over the years 1949 to 1951 (Trasko, 1953). From Table 32-1, it is seen that dermatitis is numerically the leading occupational disease reported, accounting for over one half of the cases. Diseases due to chemical agents and to repeated motion and pressure are next in importance. Although they are numerically less significant than the dermatoses, they are usually more serious.

## OCCUPATIONAL DISEASES RESULTING FROM CHEMICAL EXPOSURES

Practically all occupations involve some chemical exposures. The tailor may be exposed to carbon monoxide from his gas-fired presser; the typist may use an organic solvent for cleaning the typewriter and organic fluids for mimeograph work; the farmer sprays his products with insecticides; the miner is surrounded by coal and possibly silica dust. Similar conditions occur in every other type of employment. Some chemical substances which are encountered in industry have no effect on health. On the other hand, some of them are extremely dangerous and their effects may be manifested in many different ways.

The etiology, symptoms, pathology, and treatment of occupational diseases are discussed in appropriate textbooks and scientific journals which are listed in the bibliography. It is desirable, however, to present here information regarding the relative importance of the more common industrial poisons, their general mode of action and principal effects, their role in susceptibility to other diseases, such as respiratory infections and cancer, and the methods by which their harmful effects may be prevented.

Before reviewing the effects of specific chemical substances, the general characteristics of chemical exposures must be considered.

**Types of Chemical Exposures in Industries.** Chemical materials encountered in industry may occur as liquids, mists, gases or vapors, dusts, fumes, or smoke. Since some of these terms have a special meaning in industrial hygiene work, it is necessary to define them:

**LIQUIDS.** Fluids characterized by the free movement of molecules but without tendency to separate from one another as in the case of gases.

**GASES.** Aeriform fluid having neither independent shape nor volume but tending to expand indefinitely into any volume available.

**VAPORS.** Gaseous materials very near the condensation point or the gaseous form of substances which are normally in solid or liquid state but which vaporize at relatively low temperatures. Vapors tend to diffuse.

**DUSTS.** Finely divided solid particles (0.1 to 150 microns in diameter) formed by the disintegration of solid materials, either organic or inorganic, by such processes as crushing, grinding and abrading. Dusts do not diffuse, they settle according to size and do not usually flocculate in air to any great extent.

**FUMES.** Very small solid particles formed by physicochemical reactions such as condensation of vapors from heated metals and other substances, often accompanied by chemical reactions such as oxidation. Fumes are less than 1 micron in diameter. They flocculate and sometimes coalesce.

**SMOKE.** Liquid or solid particles which are products of incomplete combustion of carbonaceous matter such as coal, wood, oil, gas, or tobacco. Smoke particle sizes range from .001 to 0.3 micron in diameter.

**MISTS OR FOGS.** Droplets formed by condensation of vapors upon suitable nuclei or by breaking up a liquid such as by splashing, foaming or atomizing into a dispersed state.

**SMOG.** A popular term which has recently come into use to describe a combination of smoke and fog in the outdoor atmosphere. This term is also applied to complex mixtures of gases, fine particles of dust and liquid droplets. Smogs are characterized by the general murkiness they impart to the atmosphere.

**Chemical and Physical Properties of the Materials in Relation to Occupational Diseases.** The most important factors which determine whether or not a chemical substance produces damage to health are the chemical nature and physical properties of the material. The rate of absorption, character of the tissue reaction, location of the damage, mechanisms of detoxification and elimination of the substance, etc., all depend on the chemical property of the specific material. For example, the solubility of a material determines the rate of absorption and in some cases the locus of action; thus fat-soluble substances affect some tissues whereas water-soluble substances may affect others. The chemical structure of a material determines its effects on the cell metabolism, its conjugation with other

chemicals, etc. The physical properties are also important. For example, the size of the dust particles affect their penetration in the lungs, their rate of solubility in proportion to the mass, and in some cases, the type of tissue reaction. Thus, fumes, which are composed of very small particles, are usually more dangerous than dusts.

**Locus of Effect of Chemical Substances.** Chemical substances encountered in industry may affect the health of the workers in various ways. They may have a local action directly on the skin, eyes, or upper respiratory tract. They may be inhaled or swallowed and thereby produce damage to the deeper respiratory tract or irritation of the gastric mucosa. They may be absorbed into the blood stream and produce systemic toxic or other harmful effects in one or more of the internal organs. Some of these chemical substances in industries are capable also of causing allergic reactions. These allergic reactions are usually manifest as skin conditions, although allergic respiratory reactions are occasionally produced. Some chemicals may affect the body in such a manner as to alter resistance to infectious diseases or play a role in the development of chronic diseases.

In addition to the specific physiological and toxicological reactions which may result from chemicals, there are two indirect effects which must be mentioned: accidental injury due to the explosive properties of some substances and the psychological effects of disagreeable odors.

**Mode of Entry and Absorption of Chemical Substances into the Body.** Chemical substances in the environment may be absorbed through the respiratory tract, the digestive tract, or the skin. By far, the most important route of entry is through the respiratory tract. Dusts, fumes, gases, vapors, and mists when present in the air are constantly inhaled. Some chemical substances do not penetrate to the deep lung tissue but are absorbed through the mucous membrane of the upper respiratory tract, whereas other substances are absorbed in the lungs. The rate of absorption depends on the solubility of the substance and on the rate of respiration and circulation. Toxic chemicals which are absorbed through the respiratory mucosa enter the systemic circulation and thus reach all tissues of the body before passing through the liver, which is the most important organ for the detoxification of many chemical substances.

On the other hand, chemical substances which are absorbed through the digestive tract may be removed or detoxified by the liver before reaching the circulation. Chemical substances in industrial exposures reach the digestive tract either by swallowing of materials which are precipitated on the upper respiratory tract or by contamination of the mouth through the hands, cigarettes, or food. Much of the material which is swallowed is excreted directly through the feces without being absorbed. The amount which is absorbed through the gut depends on the reaction of the contaminating chemicals with the digestive secretions, with food, with the products of digestion, and other factors.

Absorption through the intact skin is an important mode of entry only for certain compounds. The aromatic nitro and amino compounds such as TNT and picric acid are readily absorbed through the skin. Hydrocyanic acid gas, nitroglycerine, tetraethyl lead, ethylene chlorhydrin, and some other organic chlorinated compounds are other examples. All substances which are soluble in fats may be absorbed through the skin to a certain degree. Almost any substance may be absorbed through damaged skin.

**Individual Tolerance to Chemical Contaminants.** Individual tolerance is an important factor in determining whether a person develops an occupational disease in response to toxic chemicals. It is a universal experience that some workers become ill, whereas others appear to be entirely unaffected by identical exposures. It is sometimes difficult to convince non-medical persons that the occupation is responsible for an illness in one worker when other workers in the same group are not affected. Actually, this is exactly what one would expect in view of the marked variation in physiological functioning, biochemical reactions, and anatomical structure which exist from one individual to another. Even genetically pure strains of animals raised under identical conditions show great differences in tolerance to toxic chemicals. Undoubtedly, nutrition and alcoholism play a major role in individual liability to many occupational diseases. This fact is particularly apparent in the case of organic solvents, such as carbon tetrachloride, which may produce damage to the liver.

**Role of Sex, Race and Age in Tolerance of Chemical Substances.** There have been many statements in the literature that women are more sensitive to occupational poisons than men. This point of view has led to some state laws prohibiting women from working in certain types of chemical exposures. Careful examination of the literature, however, indicates that there is no evidence to support this view. The data on which these statements have been based are contradictory and subject to criticism since the comparisons have been made chiefly between women and men working under different conditions and with different degrees of exposure. The evidence available at present indicates that race is not an important factor in occupational diseases, except possibly in the dermatoses. It is generally stated that young persons are more sensitive to chemical poisons than older persons. However, it is difficult to determine whether there are significant differences within the age groups employed in this country today and, if so, how these differences are due to habits, nutrition, or to other factors rather than to age.

**The Effect of Concentration and Duration of Exposure.** A most important factor in the production of occupational diseases is the degree of exposure, which depends on the concentration of the harmful substance and on the duration of exposure. The effects of harmful chemical exposures increase with an increase in the concentration of the substance and the length of the exposure. However, the effect produced is not a direct function of concentration multiplied by the duration of exposure. For example, if 100 parts of a substance per million parts of air (100 p.p.m.) is a safe exposure for eight hours, it does not follow that 800 p.p.m. is safe for one hour. There are several reasons why this is true. If low concentrations of chemical substances are absorbed, the rate of excretion or detoxification may equal the intake so that no damage results from this material, whereas high doses for shorter periods may lead to retention with harmful results. Furthermore, the type of effect often differs with the concentration.

Exposures to high concentrations may produce an acute reaction which is immediate and severe. On the other hand, daily exposures to low concentrations over many weeks may lead to chronic illness of an entirely different nature. In the latter case, the chemical material itself (such as lead or manganese) may accumulate in the body, or the damage produced by the material, as in the case of benzol or carbon tetrachloride, may be cumulative even though the material does not remain in the body. In some cases, months or even years may elapse before

the end of exposure before the damage is manifest. In the chronic cases, it is often difficult to determine the relation of the occupation to the disease unless the symptoms are characteristic and the occupational exposure is known. The symptoms of most occupational diseases are not specific but are common to many nonoccupational diseases. Thus, the occupational history becomes of major importance in the differential diagnosis of chronic occupational diseases.

**Maximum Allowable Concentrations of Chemical Substances in the Air.** One of the major problems in industrial hygiene is the determination of the maximum concentration of air-borne chemical substances which a worker can tolerate without impairment to his health. Information of this character is necessary not only to protect the health of workers, but to furnish industries and governmental agencies with a basis for evaluating industrial health hazards and for establishing control procedures. Hence, industrial hygienists have attempted to set certain standards. These are known as "Maximum Allowable Concentrations" or "Threshold Limits." These terms are used to indicate the maximum concentration of a chemical substance in the air which is considered safe for daily exposures of eight hours over long periods of time.

Maximum allowable concentrations have been suggested for most of the chemicals commonly found in industry. Individual research workers, governmental institutions, and private agencies have all participated in the effort to define such limits. The Committee on Threshold Limits of the American Conference of Governmental Industrial Hygienists has compiled the most extensive list of these so-called threshold limits, which they revise yearly. This list, with the revisions through April 1955, as adopted by the conference, is given in Table 32-2, pages 1040-1042 (Amer. Conf. of Govern. Ind. Hyg., 1955).

The following excerpts from the 1955 report of this committee should be carefully noted in order to interpret those values correctly.

"Values are given . . . for the maximum average atmospheric concentrations of contaminants to which workers may be exposed for an eight-hour working day without injury to health.

"These values are based on the best available information from industrial experience, from experimental studies, and, when possible, from a combination of the two. They are not fixed values but are reviewed annually by the Committee on Threshold Limits for changes, revisions, or additions as further information becomes available. Threshold limits should be used as guides in the control of health hazards and should not be regarded as fine lines between safe and dangerous concentrations. They represent conditions only within which it is felt that workers may be repeatedly exposed, day after day, without their health being adversely affected. It is felt, at the present time, that workers should not be exposed to a working environment containing any of these substances in excess of the value indicated.

"These values are not intended for use, or for modification for use, in the valuation or control of community air pollution or air pollution nuisances."

In order to use maximum allowable concentrations intelligently, it is necessary to understand the various methods for obtaining such values and their inherent limitations. First, a number of these standards have been based on animal experiments. Since different species and even different strains of the same species vary greatly in their susceptibility to toxic chemicals, it is questionable how far such data are applicable to man. Second, some laboratory experiments have been per-

Table 32-2. Threshold limit value adopted at April 1955 meeting of the American Conference of Governmental Industrial Hygienists

Established Values			
GASES AND VAPORS			
SUBSTANCE	P.P.M.	SUBSTANCE	P.P.M.
Acetaldehyde	200	Heptane ( <i>n</i> -heptane)	500
Acetic acid	10	Hexane ( <i>n</i> -hexane)	500
Acetic anhydride	5	Hexanone (methyl butyl ketone)	100
Acetone	1,000	Hexone (methyl isobutyl ketone)	100
Acrolein	0.5	Hydrogen chloride	5
Acrylonitrile	20	Hydrogen cyanide	10
Ammonia	100	Hydrogen fluoride	3
Amyl acetate	200	Hydrogen selenide	0.05
Amyl alcohol (isoamyl alcohol)	100	Hydrogen sulfide	20
Aniline	5	Iodine	1
Arsine	0.05	Isophorone	25
Benzene (benzol)	35	Mesityl oxide	50
Bromine	1	Methyl acetate	200
Butadiene (1,3-butadiene)	1,000	Methyl alcohol (methanol)	200
Butanone (methyl ethyl ketone)	250	Methyl bromide	20
Butyl acetate ( <i>n</i> -butyl acetate)	200	Methyl cellosolve (methoxy-ethanol)	25
Butyl alcohol ( <i>n</i> -butanol)	100	Methyl cellosolve acetate (ethylene glycol monomethyl ether acetate)	25
Butyl cellosolve (2-butoxyethanol)	200	Methyl chloride	100
Carbon dioxide	5,000	Methylal (dimethoxymethane)	1,000
Carbon disulfide	20	Methyl chloroform (1,1,1-trichloroethane)	500
Carbon monoxide	100	Methylcyclohexane	500
Carbon tetrachloride	25	Methylcyclohexanol	100
Cellosolve (2-ethoxyethanol)	200	Methylcyclohexanone	100
Cellosolve acetate (hydroxyethyl acetate)	100	Methyl formate	100
Chlorine	1	Methylene chloride (dichloromethane)	500
Chlorobenzene (monochlorobenzene)	75	Naphtha (coal tar)	200
Chloroform (trichloromethane)	100	Naphtha (petroleum)	500
1-Chloro-1-nitropropane	20	Nickel carbonyl	0.001
Chloroprene (2-chlorobutadiene)	25	Nitrobenzene	1
Cresol (all isomers)	5	Nitroethane	100

formed on human beings, but such exposures have been limited in duration and concentration and the circumstances do not duplicate actual working conditions. Third, many attempts have been made to determine safe concentrations directly in industry by correlating the concentration of a substance found in the work room air, with the results of clinical and laboratory examinations of the workers and histories of occupational diseases. If no unusual symptoms were found at the time of the examination and no occupational diseases had been experienced, it was assumed that the existing exposure was safe. This method of determining the maximum allowable concentration, although by far the best procedure, also has certain disadvantages. Air samples taken at the time of a survey represent only the concentrations existing at that time. Since chronic diseases result from prolonged exposure, the concentrations responsible for the disease may have been quite different from those existing at the time of the survey. Finally, in some cases, the maximum allowable concentration values have been based entirely on the sensory response of a group of individuals. This is a satisfactory procedure if these substances have only irritating properties, and if it is definitely specified that the maximum allowable concentration values apply only to sensory responses and not to toxic effects. Unfortunately, such a distinction usually has not been made in listing the maximum allowable concentration values.

In addition to the difficulties in determining the maximum allowable concentration values, there are also difficulties in applying these values to industrial conditions. This is due chiefly to the fact that standards, at least those derived from

laboratory experiments, apply only to specific chemical substances. In industry, today, many chemicals are sold under trade names, and the exact composition is not known to the consumer; many of these are mixtures, and many contain contaminants which are far more toxic than the material itself. Thus, it is often impossible to apply the general accepted maximum allowable concentration values to specific working conditions. It is not safe to apply the maximum allowable concentration determined for one substance to even closely related chemical compounds; all new chemicals must be studied individually. In order to meet this problem, most of the large chemical industries maintain experimental laboratories to study the toxicological properties of their products.

Another factor in considering the maximum allowable concentration values is the duration of exposure. Unless otherwise specified, the maximum allowable concentration applies to an eight-hour exposure. Some maximum allowable concentration values have been set for shorter exposures. As discussed above, it is not possible to determine a safe concentration for a one-hour exposure from the usual eight-hour maximum allowable concentration values.

It is apparent from this discussion that maximum allowable concentrations are not fixed standards of safe working conditions. Some are based on very sound evidence; others represent only the current opinion based on the data available at the time; all are subject to constant revision. However, if used intelligently, they are invaluable guides to industries and health authorities in determining healthy working conditions.

**Analysis of Chemical Substances in Air.** In order to determine if the air contains chemical substances in harmful amounts, it is necessary to analyze the air for both the composition and concentration of the contaminants. Methods of sampling and analyzing the air cannot be reviewed here. They are described in detail in a number of books and scientific journals to which reference should be made. The most inclusive references, specifically applied to industrial hygiene, are listed at the end of this chapter.

**Methods of Expressing the Concentration of Chemical Substances in the Air.** The following list indicates the usual form of expressing the concentration of chemical substances in the air for industrial hygiene purposes:

Hard rock dusts: number of particles per cubic foot of air (usually as millions).

Metallic dusts and fumes: milligrams per cubic meter of air.

Gases and vapors: parts of gas or vapor per million parts of air by volume, usually written parts per million (p.p.m.); or milligrams per liter.

In order to convert the volume of a gas to the weight of the gas, i.e., to convert parts per million by volume to milligrams per liter, the following formula must be used:

$$\text{mg./liter} = \frac{\text{gram molecular weight} \times \text{p.p.m.}}{22,400} \quad (0^\circ \text{C})$$

## THE DUSTS

### GENERAL CONSIDERATIONS

**Protection of the Body Against Foreign Particles in the Inspired Air.** Before considering the effects of industrial dusts it is well to review the normal protective mechanisms of the respiratory tract against foreign substances. When dust particles

are inhaled, many of those which come into contact with the mucous secretions of the upper respiratory tract are deposited on the surface of the mucous membrane and subsequently are eliminated. The structure of the nose is admirably adapted to this process, since the upward flow of air is abruptly deflected downward; the larger dust particles are thrown against the wall of the pharynx by this bafflelike arrangement. The cilia, which line the respiratory tract as far down as the bronchioles, sweep the dust particles and mucous secretions toward the mouth. The peristaltic motion in the bronchioles, and the coughing and sneezing reflexes also are important in the removal of foreign particles. Those dust particles which reach the alveoli are phagocytosed by the macrophages in the lungs, and, for the most part, are removed through the lymph channels to the lymph glands. By these various mechanisms the respiratory passages and alveoli are kept relatively free of dust particles. When large quantities of dust are inhaled, some of the dust-filled macrophages will remain in the alveolar tissue.

From the viewpoint of health, the size of the dust particles is of greatest importance. Dust particles which are more than 10 microns in diameter settle out of the air rapidly, and only particles below 5 microns in diameter remain suspended in the air for any length of time. Dust particles larger than 3 microns in diameter are filtered out in the upper respiratory passages. Particles below 3 microns may penetrate to the alveoli and remain there. As the particle size decreases from 3 to 1 micron, the percentage deposited in the alveoli increases, but the retention decreases as the size is reduced from one micron to 0.25 micron. The retention of particles below 0.25 micron has not been investigated, but the retention probably increases again because of the Brownian movement (Brown and others, 1950).

**Classification of Dusts and Fumes in Relation to Health.** The dusts and fumes may be classified into several groups according to their principal effects on health (1) hard rock or mineral dusts or pneumoconiosis-producing dusts, (2) organic dusts of plant and animal origin or allergic dusts, (3) metallic dusts and fumes and other inorganic toxic dusts and fumes, (4) dusts from organic material (see organic compounds).

**Types of Tissue Reaction to Mineral or Hard Rock Dusts.** The hard rock or mineral dusts, i.e., dusts which arise from the crushing of earthy materials, when considered in regard to their effects on the tissues, fall into three groups (Mille and Sayers, 1935):

1. *Absorptive dusts* which are absorbed and do not produce any visible gross damage to the lungs. Examples are: calcite, limestone, calcium carbonate, gypsum and Portland cement.
2. *Relatively inert dusts* which are relatively insoluble and which cause, if anything, only low grade tissue reaction without any effect on pulmonary function. Hematite, carborundum, soapstone, and feldspar are examples.
3. *Fibrosis-producing dusts* which cause marked tissue reaction, the outstanding feature of which is a proliferation of fibrous tissue. Free silicon dioxide (quartz) and asbestos are the important members of this group.

The mineral dusts as encountered in industry are, in general, not toxic to the internal organs, but produce their effects chiefly in the lungs.

**Terminology of Lung Conditions Due to Dusts.** Some confusion has arisen in the medical literature and in compensation cases over the terminology employed for diseases of the lungs due to dust exposures, especially with regard to the term

pneumoconiosis and silicosis. The term pneumoconiosis, as now used, indicates any type of pulmonary reaction to inhaled dust without any implication as to the character or severity of the reaction or to the effect on respiratory function. It is a general term to cover all conditions whether or not they are of clinical significance. The specific types of pneumoconioses are named according to the etiological agent, such as silicosis, asbestosis, siderosis, anthracosis. If the definition of pneumoconiosis given above is used, silicosis is a pneumoconiosis due to the inhalation of free silica dust ( $\text{SiO}_2$ ), and asbestosis is a pneumoconiosis due to asbestos dust. Fibrosis of one type or another is characteristic of these conditions. On the other hand, siderosis is a pneumoconiosis due to the inhalation of relatively pure iron dust which causes no significant fibrosis. Hence, this condition is called a benign nonspecific pneumoconiosis.

### SILICOSIS \*

**Environmental Aspects.** Silicosis has been a well recognized disease for many years. As far back as the seventeenth century, the pathology of stone-cutters' lungs was described, and even the relation of silicosis to tuberculosis was noted. Löhneiss in 1690 said of miners: "The dust and stones fall upon the lung, and the men get lung diseases and at last take consumption." (Teleky, 1948.)

In spite of the fact that silicosis has been known for a long time, the exact mechanism responsible for this lung condition is not understood completely. However, many studies of this disease have been made and a number of facts regarding silicosis have been well established.

**TYPE OF DUST RESPONSIBLE FOR SILICOSIS.** Free silica or silicon dioxide ( $\text{SiO}_2$ ) is responsible for silicosis. This substance occurs in both crystalline and amorphous forms. The crystalline forms include: quartz, chert, sandstone, gritstone, gannister, quartzite, beach sand, jasper, tridymite, cristobolite, chalcedony, tripole, and others. It is believed that all of these forms of  $\text{SiO}_2$  are capable of producing fibrosis when in direct contact with the lung tissue. The common amorphous forms are opal and diatomaceous earth. Gardner stated that opal, although mildly irritating, did not cause progressive fibrosis like quartz, whereas celite, an amorphous silica composed of silicious diatome shells, provoked a progressive fibrosis indistinguishable from the reaction to quartz (Gardner, 1938). According to Vorwald and his associates (1949), "clinical and experimental evidence indicate that both the crude and fluxed calcined diatomaceous earth are capable of producing pulmonary fibrosis, the latter more than the former."

Silica, when combined with other chemical substances as in silicates, in general does not cause progressive pulmonary fibrosis. Asbestos is an exception to this and will be discussed later. Some reports have indicated that certain other silicates such as talc and mica may produce fibrosis, but the evidence is not conclusive at present. Thus, the two most important mineral dusts which have been proved definitely to produce pulmonary fibrosis leading to impairment of respiratory function are silicon dioxide and asbestos.

**INDUSTRIES WITH SILICA EXPOSURES.** Exposure to free silica is commonly found in a number of occupations: in mining operations where the strata of rock

\* Much of the material on silicosis has been taken directly from papers by the late Dr. U. Gardner, former Director of the Saranac Laboratory. These papers (Gardner, 1937, 1938, 1940, and 1942) are listed under General References.

contain a high percentage of free silica; in building and construction work which requires drilling through silica-containing rock; in quarrying and dressing of granite; in work with sandstone and flint; in the manufacture and use of certain abrasives; in sandblasting, metal grinding, and wood finishing; in the ceramic and glass industries; in foundries; in the soap powder industry; in the manufacture and replacement of silica bricks in furnaces; and in a number of other industries. In former years, grinding wheels were composed of sandstone or quartz, but, fortunately, these are being replaced with carborundum and other synthetic abrasive materials which do not yield free silica dust.

**INCIDENCE OF SILICOSIS IN THE UNITED STATES.** In 1940 the United States Public Health Service estimated that about 1,420,500 persons in this country were employed in occupations where there was a potential exposure to free silica (Bloomfield et al., 1940), but the incidence of silicosis in this group was not known. Some authorities estimated that probably only 25 per cent of the men exposed to free silica had silicosis. Studies in different industries have shown that anywhere from 2 to 75 per cent of the workers exposed to silica dust may have silicosis.

The incidence of silicosis varies with a number of factors, the most important being: (1) the concentration of dust in the air, (2) the percentage of free silica in the dust, (3) the duration of exposure, (4) the size of the dust particles, (5) the presence of other dusts, and (6) individual susceptibility.

The incidence of silicosis increases progressively with an increase in the concentration of dust in the air, with the percentage of free silica in the dust, and with the length of exposure. These relationships have been shown in a number of studies. Figures 32-1 and 32-2, which are taken from a study of the pottery industry, illustrate these relationships. Most cases of silicosis require from three to six, and more often, from 10 to 12 years of exposure for their development. However, there are some cases on record in which extensive silicosis has appeared after two years of exposure to high concentrations of very fine silica dust. In general, the higher the concentration of silica dust in the air, the greater the incidence of silicosis. The concentration of silica dust which appears to be safe for the majority of workers, according to the information available at present, is shown in Table 32-2.

The size of the particles is of great importance in determining the effect of silica dust. As discussed above, the penetration and retention of dust particles in the lungs varies with the size. The rate and extent of the tissue reaction is proportional to the surface area of the dust; hence, for any given mass, the smaller the particles, the greater the reaction. Furthermore, the type of tissue reaction varies with the size of the particles. Silica particles between 3 and 0.5 microns produce the typical nodular fibrosis; sub-microscopic sizes produce a diffuse fibrosis. Colloidal silica in a dispersed phase causes bronchoconstriction and almost instant death if injected intravenously in large doses. Some authorities believe that the effects of sub-microscopic particles of silica are more closely related to their colloidal nature than to their specific chemical composition.

The presence of other dusts in an atmosphere containing silica may alter the effect of the silica dust. Certain dusts, such as calcined gypsum, when suspended in the air with quartz dust, cause flocculation of the dust particles. These large conglomerate masses settle out of the air rapidly and are filtered out of the inspired air by the upper respiratory tract. As a result, less free silica reaches the lung tissue.

Other dusts, such as aluminum and iron, in certain forms, produce a more or less stable coating on the silica dust particles and thus prevent the action of the silica particles on the lung tissue. This reaction may occur whenever the two dusts come into intimate contact either in the air or in the lungs. Because of this reaction, it

From Pub. Health Bull., No. 244, 1939.

Fig. 32-1. Percentage of workers with silicosis (all stages) in relation to average dust concentration and length of employment in pottery industry.

has been suggested that aluminum dust might be used for the treatment and prevention of silicosis. (See page 1050.)

**Medical Aspects. REACTION OF THE LUNG TISSUE TO SILICA DUST.** The typical reaction to silica dust is a proliferation of the connective tissue, leading to the

Adapted from Pub. Health Bull., No. 244.

Fig. 32-2. Percentage of workers with silicosis in relation to quartz content of dust and length of employment.

formation of dense, fibrous nodules 3 to 4 mm. in diameter. These nodules form first along the lymph trunks and later directly in the lung tissue. Contiguous nodules may fuse together to form simple localized conglomerate foci. If the exposure ceases, the nodules continue to progress until they have been completely formed but very few new nodules will appear. In some cases, massive conglomerate fibrosis occurs. Most authorities believe that an associated infection, usually tuberculous,

is the most important cause of this conglomerate reaction. Where excessive quantities of exceedingly fine pure silica exist, so-called rapidly developing silicosis may occur. In these cases, the alveolar walls become thickened, microscopic nodes develop throughout the pulmonary tissue, and actively proliferating phagocytes fill the air spaces.

The effect of silica dust is not specific to lung tissue. Silica particles may produce fibrous nodules in almost any tissue and in practically all species of laboratory animals. Various theories have been advanced to explain this tissue reaction to silica particles, but none has been proved. The fibrosis-producing property of silica dust is not due to the mechanical factors of hardness and sharpness of the silica particles nor to silica in dissolved form apart from the particulate form but appears to be related to the crystal structure or surface properties of the dust.

**SYMPTOMS, DISABILITY AND PROGNOSIS IN SILICOSIS.** Simple nodular silicosis, in the absence of infection, does not seriously interfere with ordinary work. Shortness of breath occurs only on sudden, unusual exertion. If further exposure to silica dust is prevented, these men may continue to work and live normally. The clinical symptoms frequently are not commensurate with the roentgenological manifestations.

Massive conglomerate silicosis, on the other hand, may cause severe dyspnea with emphysema and subsequent cardiac involvement. If the disease is not too extensive and is not complicated by tuberculous infection, these patients may perform light work. Large conglomerations and advanced silicotuberculous lesions are incapacitating, and the prognosis is not good.

Silicosis presents one of the most difficult problems in the compensation for occupational diseases, since there are no physiological, chemical, clinical, or roentgenologic tests which indicate with any accuracy the degree of disability below that of complete disablement.

**DIAGNOSIS OF SILICOSIS.** Because of the lack of any specific clinical symptoms, a diagnosis of silicosis must be based principally on a history of occupational exposure to free silica dust and on a characteristic appearance of the roentgenograms, read by a roentgenologist trained in silicosis.

**SILICOSIS AND TUBERCULOSIS.** There is ample evidence from statistical surveys, clinical studies, and animal experimentation that silicosis lowers the resistance to tuberculosis. In fact, tuberculosis is the major cause of disability and death in silicosis. The high rate of tuberculosis among persons engaged in certain occupations involving exposure to silica dust is shown in Table 32-3, which was compiled by the Metropolitan Life Insurance Company (Lanza and Vane, 1934). Even simple nodular silicosis is associated with a definite increase in susceptibility to tuberculosis. According to Gardner: "The infection may develop as a result of reactivation of a pre-existing latent tuberculous focus but opinion today is unanimous that new infections from without are a more common cause. Most or possibly all of the massive fibrous lesions of silicosis are developed on a background of tuberculosis." (Gardner, 1940.)

The clinical picture of tuberculosilicosis differs from that of tuberculosis as usually seen. The symptoms of intoxication are often masked until the condition reaches the advanced stages.

Since exogenous infections are believed to be the chief cause of tuberculosilicosis, it is evident that contacts of silicotics with open cases of tuberculosis should be

Table 32-3. Respiratory tuberculosis in relation to silicosis. Ratio of actual number of deaths to expected number of deaths from respiratory tuberculosis in certain occupations involving exposure to silica dust. Mortality experience of 12 life insurance companies 1915-26

rigidly avoided. In areas where the tuberculosis death rate in the general population is low, the rate among silicotics is also lower than in other less favorable areas. Recent experiments on animals suggest that BCG vaccination may be dangerous in cases of silicosis (Vorwald and others, 1950).

At present, there is no evidence to indicate that exposure to any other inorganic dusts except free  $\text{SiO}_2$  increases susceptibility to tuberculosis (see also Asbestosis, page 1051).

**SILICOSIS AND LUNG CANCER.** There is ample evidence that silica dust does not initiate or favor the development of pulmonary carcinoma. Vorwald and Karr (1938) studied the results of radiologic examination of 12,206 silicotics. Only three silicotics, or 0.005 per cent of the group, were found to have lung cancer. A survey of five industries, covering 15,587 persons and including 1,357 cases of silicosis was made by the Saranac Laboratory. Only one case of pulmonary carcinoma was found in the silicotics (0.074 per cent), and two in the nonsilicotics (0.014 per cent). Autopsy observations made on native and European miners in South Africa, many of whom had silicosis, showed similar negative results. Furthermore, animal experiments also have given no evidence that lung tumors result from exposure to silica dust. Thus, there is no evidence that lung cancer is related in any way to silicosis.

**SILICOSIS AND PNEUMONIA.** There is no evidence, at the present time, to indicate that exposure to silica dust increases susceptibility to lobar pneumonia. Although high mortality and morbidity rates for pneumonia have been reported in some silica industries, such as in foundries and mines, factors other than silica dust appear to be responsible for this. Furthermore, abnormally high pneumonia rates have not been found in other industries and mines where exposure to silica

dust occurs. Laboratory experiments on animals, carried out in the author's laboratory, have shown that exposure of rats to high concentrations of silica dust does not lower their resistance to pneumococci Type I, injected intrabronchially. In fact, under some conditions, the rats were more resistant to the lobar pneumonia following prolonged exposure to silica dust. The relation of silicosis to bronchopneumonia is not clear.

**TREATMENT AND PREVENTION.** There is no known treatment for silicosis which will reduce the fibrosis, although relief of symptoms to some degree may be obtained in some cases. Because aluminum dust produces a coating on silica particles, the inhalation of aluminum dust has been tried as a therapeutic measure. The Council on Industrial Health and the Council on Pharmacy and Chemistry of the American Medical Association summarized the available data in 1949. Their conclusions were as follows: "Studies on the therapy of silicosis thus far have been inadequately controlled. The majority of subjects have reported subjective improvement, apparently of psychic origin. No convincing evidence of objective improvement either of pulmonary function or by roentgen ray has been forthcoming. Certain cases have shown eventual progression by roentgen ray subsequent to aluminum therapy under present conditions of dosage." (Brown and Van Winkle, 1949.)

Prevention is the only positive means of attack on silicosis. With modern engineering technics, there is no reason why silica exposures cannot be reduced to safe concentrations and silicosis completely eliminated in the course of a few years. Until that time comes, all persons working in such atmospheres should be examined clinically and radiologically at frequent intervals by a competent physician. Those with silicosis should be protected from further exposure to silica dust. Persons with tuberculous lesions should not be employed where silica exposures exist.

Measures for the prevention of exposure to dusts and fumes, including silica dust, are discussed under prevention of occupational diseases due to chemical substances, on pages 1086 to 1091.

### ASBESTOSIS

Asbestosis is a pneumoconiosis due to the inhalation of asbestos dust.

**Nature of Asbestos.** Asbestos is a general term which is applied to minerals of fibrous form. These minerals are silicates of varying composition which fall into two distinct groups, serpentine and amphibole. Chrysotile, a hydrous magnesium silicate of the serpentine type, is by far the most common type of asbestos. The amphibole group includes various silicates of iron, calcium, magnesium, and, in some cases, sodium; examples are crocidolite and tremolite. Asbestos fibers are usually from 20 to 500 microns in length, and from 0.5 to 50 microns in diameter. The fibers of crocidolite are much stiffer and straighter than those of chrysotile.

**Reaction of Tissues to Asbestos.** Pulmonary fibrosis results in man and in some animals from the inhalation of chrysotile, the serpentine type of asbestos. This fibrosis differs from that which occurs in silicosis, being a fine, interstitial, diffuse fibrosis around the terminal bronchioles, rather than nodulation. It is believed that fibers up to 200 microns in length can penetrate the respiratory tract if the maximum diameter does not exceed 5 microns. Fibers which are inhaled accumulate in the lumen of the respiratory bronchioles and later in the alveolar ducts but do not seem to penetrate to the alveoli.

It is generally believed that the fibrosis is due to the mechanical irritation of the long fibers (between 20 and 50 microns in length). Presumably the motion of the lung tissue in breathing, combined with the filamented structure and the flexibility of the fibers are responsible for this irritating effect. This theory is supported by the fact that asbestos fibers, unlike silica dust, are inactive when in contact with other tissues, such as the liver, where there is no mobility, and by the fact that they do not cause pulmonary fibrosis if the fibers are short or are ground to small particle size. The stiff, straight fibers of crocidolite do not stay in the walls of the bronchioles, but pass on into the alveoli, and do not appear to cause fibrosis. Fibrosis occurs only where there is mechanical rubbing of the tissue against the fibers. Commercial talc or its component materials, such as tremolite, after prolonged exposure appears to cause a fibrosis resembling asbestosis.

**Clinical Aspects.** The clinical symptoms are due to the fibrosis and the concomitant pathological changes, chiefly emphysema and bronchiectasis. Progressive dyspnea, which can lead to disablement, is the chief symptom. Cough and loss of weight also occur. Death is due to secondary respiratory infection or to cardiac involvement. It is generally believed that the fibrosis will not progress after cessation of exposure.

Diagnosis of asbestosis must rest on a history of exposure to asbestos dust, on the clinical symptoms, and on the radiological examination. The presence of asbestosis bodies in the sputum is not of any diagnostic value. Asbestosis bodies are fibers which are surrounded by an iron-containing coating and which have fractured to give peculiar structures. They may be formed from any fibrous material, including asbestos, but are neither indicative of the degree of exposure nor associated with the fibrosis.

Although some cases of tuberculosis have been reported in asbestos workers, there is no convincing evidence, either clinical or experimental, that asbestosis increases susceptibility to tuberculous infection. A number of cases of lung cancer associated with asbestosis have been found in various autopsy studies especially in Great Britain. Authorities differ in their opinion regarding the possible role of asbestos in the etiology of lung cancer.

There is no known treatment for asbestosis; prevention of exposure to asbestos dust is the only effective weapon against this condition.

**Incidence of Asbestosis.** The incidence of asbestosis in persons working in environments containing asbestos dust varies with the extent and duration of exposure. The disease does not usually appear until after 5 to 10 years of exposure. The incidence of asbestosis increases progressively with the duration of exposure. More than half of the workers with 20 years of exposure have the disease. Studies in asbestos industries indicated that 5,000,000 particles per cubic foot of air is the maximum safe concentration, but recent work suggests that the standards may vary with the percentage of long particles in the dust.

#### OTHER HARD ROCK AND MINERAL DUSTS

**Siderosis.** Exposure to iron oxide produces a benign pneumoconiosis called siderosis. "By itself this mineral provokes no significant fibrosis but merely pigmentation, which has no influence on pulmonary function" (Gardner, 1940). However, roentgenograms of workers exposed to the iron oxide dust show nodular shadows simulating those of silicosis. Clinical studies of these workers, autopsy

findings, and animal experimentation have proved that these shadows are due not to fibrosis but to the radio-opaque iron oxide which had accumulated in foci throughout the lungs. Studies on animals indicate that iron oxide dust does not cause fibrosis or affect the course of experimentally induced tuberculosis.

**Coal Dust.** In this country coal dust has been considered a benign material which, in the absence of free silica, produces only a slight chronic inflammatory reaction with little or no fibrosis and no disability. However, in recent years British and European investigators (Fletcher, 1955) have described two types of pneumoconioses in coal workers. Simple pneumoconiosis is characterized by focal deposits of coal dust around respiratory bronchioles with reticulin fibrosis and, in the elderly, focal emphysema. This condition rarely causes severe disability. Complicated pneumoconiosis, which occurs only in the presence of moderately advanced simple pneumoconiosis, is characterized by massive conglomerate lesions with cavitation and is apparently due to an associated action of coal dust and tuberculous infection. This type leads to a high rate of disability and death.

### DUSTS OF PLANT ORIGIN

**General Effects.** Public health officials are often asked if grain, wood, cotton and other dusts of plant origin produce any harmful effects on the lungs or other tissues. In general, it can be said that these natural organic dusts may cause allergic reactions in susceptible persons leading to a variety of conditions in the respiratory tract, skin or other tissues, and that many of these are irritating to the respiratory tract and skin even when no allergic reactions are visible. In some cases, the effects are due to the smuts, mites, fungi or other parasites which contaminate these dusts. In other cases, the irritation is due to the physical rather than to the chemical properties of the dust. Many natural organic dusts present an additional hazard due to their high degree of inflammability. Dust clouds of flour, wood or tobacco may be explosive.

There is no evidence that any of these dusts produce fibrosis of the lungs, such as is found in cases of silicosis or asbestosis. In spite of statements in the literature that a high rate of tuberculosis exists among workers exposed to cotton, tobacco, and grain dusts, and that exposure to these dusts is partly responsible for this rate, there is no sound evidence to support this belief. Tuberculosis rates are not consistently high throughout the occupations which involve exposure to these natural dusts, and a low standard of living appears to be the major factor in those instances where a high tuberculosis rate does occur. There is also no evidence at the present time that cancer of the respiratory tract, skin or any other tissue is related to the natural organic dusts encountered in occupational exposures.

The three dusts of plant origin which have been considered most frequently to present industrial health problems are cotton, grain, and wood dust.

**Effects of Specific Dusts. COTTON DUST.** The U.S. Public Health Service has recently published a review of the literature on the effects of cotton dust on the respiratory tract (Caminita and others, 1947). The principal points brought out in their report may be summarized as follows:

1. A survey of the literature indicates that "upper respiratory tract affections, ranging from chronic irritation of the nose and throat to bronchitis, complicated by asthma and/or emphysema, and pneumonia are common among cotton workers. No conditions simulating silicosis have been reported. There is no increased incidence of tuberculosis."

2. "There is considerable evidence in support of the assumption that cotton dust is the chief cause of respiratory tract affections among cotton workers, and that it can act as a mechanical irritant, and as a source of allergens, of histamine, and of the toxic metabolic products of micro-organisms."

3. "Four separate disease entities associated with the inhalation of cotton dust have been reported. These are mill fever, byssinosis, weaver's cough, and an acute illness among workers handling lowgrade stained cotton." Mill fever resembles metal fume fever. It is usually attributed to the inhalation of cotton dust. Weaver's cough is an acute illness which occurs among operatives, both old and new, who handle mildewed yarn; examination of the dust revealed *Penicillium*, *Mucor*, *Aspergilli*, and an unidentified fungus. The acute illness which occurs among workers handling low grade stained cotton has been shown to be due to *Aerobacter cloacae* endotoxin resulting from contamination of the cotton while in the field. "Byssinosis occurs in subjects who have had long and continuous exposure to cotton dust. It is characterized by chronic bronchitis complicated by emphysema and, in the later stages of some cases, asthma. It is attributed to the inhalation of cotton dust."

4. Most of the cases of illness in cotton workers have been reported in the foreign literature. "In the United States, the problem of serious dust disease among cotton workers is hardly known to exist. It is possible that it does exist but goes unrecognized or is ignored, or is obviated by labor turnover."

GRAIN DUST. Allergic reactions in susceptible persons may result from exposure to grain dust itself and to the smuts which may infect the grain. So-called grain itch is due to the parasite, *Pediculoides ventricosus*, on the grain. Lung infections may result from contaminating fungi and molds. The hairs from the ripened head of grain are sharp and when inhaled cause direct irritation by adhering to the moist mucous membrane. Grain dust appears to cause a temporary malady like metal fume fever. Insecticides adhering to the grain also may present a hazard.

WOOD DUST. Except for the irritative and allergic effects described above, there is no sound evidence that wood dust produces harmful effects in man. Because of the large particle size and the fact that wood dusts are easily wetted, it is doubtful if any significant amount of wood dust reaches the alveoli. Woodworkers, however, may be exposed to silica dust if they are using abrasives containing free silica and fibrosis of the lungs may occur, but this condition is attributable to the silica and not to the wood dust.

## THE METALS, THEIR DUSTS, FUMES AND VAPORS

From a preventive medical viewpoint, it is desirable to know which of the metals and their compounds encountered in industrial exposures are relatively harmless, which are irritative or damaging to the respiratory tract, which produce dermatoses, and which produce harmful effects on the internal tissues of the body after absorption. Since the effects of the metals vary with the type of compound, with the mode of exposure, and with other factors, it is difficult to make any general statement as to their effects. However, a very general classification can be given which includes the more common metals and their compounds. This grouping applies only to the usual type of exposure found in industry, not to situations where the chemical substances are ingested or injected into the tissues.

1. Metallic dusts and fumes which are believed to be relatively harmless: copper, gallium, indium, iron, molybdenum, palladium, silver (except skin effects), and tin.

2. Metallic fumes which produce metal fume fever: chiefly zinc and magnesium as oxides, although almost any metallic oxide may be effective.

3. Metallic dusts and fumes which, in one form or another, are irritative or produce some harmful effect on the respiratory tract: aluminum (see Shaver's Disease), beryllium, cadmium, chromium, manganese, nickel, platinum, and vanadium.

4. Metals or their compounds which have an effect on the skin (usually when in the form of a salt with chlorine, fluorine, or sulfur): aluminum, antimony, barium, beryllium, calcium, chromium, copper, magnesium (as splinters), mercury, nickel, potassium, radioactive metals, silver, sodium, zinc, and others.

5. Metallic dusts and fumes which may be absorbed and thereby produce harmful effects in the internal organs of the body: antimony, beryllium, lead, manganese, mercury, radioactive metals, thallium, uranium, vanadium, and others.

The metals discussed here have been chosen either because they are widely used and produce serious or unusual injury or because their harmful effects have been recognized only recently. The metals which will be discussed in this section are: aluminum, beryllium, cadmium, chromium, lead, manganese, mercury, and uranium.

#### ALUMINUM

No harmful effects of aluminum dust on the lungs have been reported in the aluminum workers in this country or in England. A peculiar pneumoconiosis due to aluminum has been described by some European scientists. This condition somewhat resembles the symptoms of Shaver's disease described below. However, there appeared to be no correlation between the exposure, the radiological picture, and the symptoms. Unless further evidence is forthcoming, it can be said that aluminum dust in the ordinary concentrations and form found in industries causes no damage to the lungs.

**Shaver's Disease.** A previously unrecognized condition of the lungs has recently been described by Shaver (1947). The symptoms consist of an interstitial fibrosis and profound emphysema leading in many cases to spontaneous pneumothorax. Death has followed in some cases. All of the cases thus far described have occurred in men who were exposed to dense fumes which resulted from heating bauxite, iron, and coke to very high temperatures in the manufacture of corundum. The fumes contain high concentrations of aluminum and silica in exceedingly small particle sizes, even down to 0.05 micron in diameter. The condition has been reproduced in animals and appears to be due to the aluminum oxide fraction of the fume.

#### BERYLLIUM

It was not until World War II that beryllium and its compounds assumed industrial importance. It is not surprising, therefore, that the harmful effects of these substances have been recognized only in the past few years. This metal will be discussed in some detail because the toxicity of beryllium has been recognized only recently and because serious effects may occur from exposure to beryllium both inside and outside of industry.

**Industrial Exposures to Beryllium.** Exposure to beryllium or its compounds may occur in plants producing beryllium from the ore, in atomic energy work, in the founding and use of beryllium alloys of copper and other metals, in the produc-

tion of incandescent lamps, roentgen-ray and electronic tubes; in the manufacture of ceramics, vitreous enamels, gas mantels, textile fibers, etc.; in laboratory research work of various types; and in the manufacture of phosphors for fluorescent lamps, neon signs, and luminous indicators. (A beryllium phosphor was used originally to coat the inside of fluorescent tubes but was abandoned because of its toxicity.)

The most common forms of beryllium include: beryllium metal (which in dust form is probably coated with a layer of beryllium oxide), beryllium oxides of various types, beryllium sulfates, fluoride, hydroxide, chlorides, and carbonates. Beryllium exists in nature as a complex aluminum beryllium silicate known as beryl.

**Effects of Beryllium on Health.** Some of the earlier investigators reported that the beryllium ion was not toxic, and that the toxic properties of some of the beryllium compounds were due to the other ions present in the material, notably, to the fluoride and sulfate radicals. More recent work has indicated that the toxic effects are the result of the action of the beryllium ion itself and are not due to the associated anions, although these may exert an enhancing effect on the action of the beryllium ion.

The principal clinical conditions which have resulted in persons exposed to beryllium compounds are: (1) acute pneumonitis, (2) chronic berylliosis or pulmonary granulomatosis, and (3) skin lesions of various types, including granulomatous reactions. In animals, acute pneumonitis, osteogenic sarcomas, and a number of toxic reactions have been produced; and chronic pulmonary granulomatosis and lung tumors have been reported in some strains of rats.

Acute pneumonitis has occurred in workers exposed to the dusts and fumes of beryllium metal, some of the beryllium oxides, and the sulfates, fluoride, hydroxide, and chlorides. The majority of these cases have occurred in the basic industries using and extracting the beryllium ore. The symptoms of acute beryllium pneumonitis include nasopharyngitis, cough, substernal pains, exertion dyspnea, cyanosis, anorexia, loss of weight, and fatigue. Later, tracheitis and bronchitis develop with a roentgenographic picture of diffuse haziness. The pathological changes are those of a chemical pneumonia with edema, exudate, and hemorrhage. The disease is progressive from onset up to two or three weeks. Death has occurred in some cases, but recovery has been complete within four to five months in other cases. Cases of acute pneumonitis have resulted even from single short exposures to beryllium compounds.

The chronic lung conditions were first noticed in this country in workers using beryllium compounds in the manufacture of fluorescent lamps. Subsequently, cases have occurred in the other industries listed above. However, no cases have been reported in the processing of beryl ore or in the use of finished beryllium alloys containing less than 2 per cent of the element. (Hardy, 1955).

The chronic disease presents a different syndrome from the acute form. One of its outstanding features is the delayed onset. In some cases no symptoms have appeared until months or even years after the end of the exposure to beryllium compounds, whereas in other cases symptoms have developed during the exposure. Continuous loss of weight, dyspnea, weakness, and fatigue are the outstanding features of the disease. The dyspnea becomes progressively worse. Death or considerable disability have resulted in the majority of these cases. The pathological picture is that of a diffuse pulmonary reaction with nodular granulomatous lesions about 1 mm. in diameter distributed fairly uniformly throughout the lungs. Because

of this feature, the early cases were mistakenly diagnosed as Boeck's sarcoid. Some authorities have expressed the belief that the chronic disease is in the nature of an allergic reaction (Sterner and Eisenbud, 1951).

Beryllium is of special importance from a public health viewpoint, not only because of the industrial cases, but also because of the so-called neighborhood cases. Ten persons who had had no industrial exposure to beryllium developed a condition which in every respect was similar to the chronic pulmonary granulomatosis due to beryllium. These patients lived within three quarters of a mile of a plant producing beryllium compounds from the ore. It is believed that fine beryllium dust, through pollution of the atmosphere, was responsible for these cases. Another person, who resided two miles from the plant and who had not worked in the plant, also developed the same disease. The exposure in this case was attributed to the handling of contaminated work clothes of an employee who lived in this house.

The degree of exposure was so low in these "neighborhood" cases and in some of the industrial cases that a threshold limit has not been adopted as yet. However, the Atomic Energy Commission has recommended for their plants the following tentative limits: for inplant exposures, 2 micrograms per cubic meter as an average concentration throughout an 8 hour day and 25 micrograms per cubic meter for any period of time, however short; and for air contamination in the neighborhood of a plant handling beryllium compounds, 0.01 microgram per cubic meter as the average monthly concentration in the breathing zone (Sterner and Eisenbud, 1951).

Skin conditions which result from exposure to beryllium include: contact dermatitis, skin ulcers, sarcoid-like lesions arising spontaneously in patients with the chronic type of lung disease, and subcutaneous granuloma (similar to the lung lesions) resulting from subcutaneous implantations of beryllium compounds. The last type has occurred chiefly in cases where broken fragments of fluorescent lamps have penetrated the skin. In one instance, a 12-year-old boy used a discarded fluorescent lamp from a dump pile as a baseball bat. Pieces of the glass became imbedded in his neck. The doctor cleaned out the wound and sutured it. Some weeks later, the boy developed multiple granuloma, involving the subcutaneous tissue and mandible, as a result of the beryllium from the fluorescent tube which remained in the tissues. The lung and skin manifestations are the chief effects of beryllium exposure which have been reported in man. However, it may possibly produce other effects, since it has been shown that beryllium inhibits the alkaline phosphatase system and that the intravenous injection of beryllium compounds produces osteogenic sarcomas in rabbits. No sarcomas have been reported in man up to the present time.

**Prevention of Beryllium Exposures.** Because minute quantities of beryllium or its compounds are able to cause serious or even fatal injury, extreme precautions should be taken to prevent workers from inhaling the dust or fumes. Skin contact should be avoided and any material that gets into the skin should be removed at once. The general measures for the prevention of occupational diseases, to be described later in this chapter, are applicable to beryllium exposures. Precautions must be taken also to prevent discharge of the material into the outside atmosphere.

The control of beryllium exposures produced by the destruction of fluorescent tubes containing beryllium phosphors presents a somewhat different problem. A

At the request of the United States Public Health Service, the manufacturers of these tubes discontinued the use of beryllium in the manufacture of fluorescent lamps on June 30, 1949. However, stocks of these lamps manufactured previous to this date will probably be on sale for some time. Hence, great care should be used in the disposal of fluorescent lamps. Health and safety authorities \* recommend that such lamps should not be placed in an incinerator but should be destroyed out of doors. They should be wrapped in heavy cartons or burlap bags, broken under water, placed in the disposal container and dumped on a pile where they are completely covered by other refuse. If broken indoors, they should be handled under effective exhaust ventilation. Persons breaking lamps should never breathe the dust and should protect themselves against cuts.

### CADMIUM

The amount of cadmium used in industrial operations has increased greatly during recent years. Cadmium is used for plating metals, as a constituent of alloys, in printing, and in the manufacture of cadmium chemicals, cadmium vapor lamps, pigment, glass, etc. Cadmium may occur also as a contaminant in zinc smelting and refining.

Two types of acute illness may result from exposure to cadmium. The inhalation of cadmium fumes causes a chemical pneumonitis, and ingestion of cadmium leads to severe gastrointestinal irritation.

Cases of chemical pneumonitis in workers exposed to cadmium fumes have occurred chiefly from the application of heat to cadmium-coated surfaces, such as in cutting or welding cadmium plated pipes, plates, rivets, and other materials. Since the cadmium coating does not differ in appearance from other coatings and since the fumes have no specific odor or other warning properties and cause few, if any, symptoms at the time of exposure, most workers are unaware that they have been exposed to a dangerous substance. The symptoms do not begin to appear until about 4 to 48 hours after the acute exposure. The first symptoms are usually dryness of the throat, cough, headache, vomiting, and a sense of constriction of the chest. About 20 to 36 hours after the exposure, symptoms of pulmonary edema appear with pain in the chest, severe dyspnea, and prostration. Death may result from the pulmonary edema or from subsequent bronchopneumonia. If death does not occur, recovery in man appears to be complete, since subsequent roentgenograms are negative. Recent studies suggest that prolonged inhalation of cadmium dust and fumes may possibly produce a chronic illness characterized by proteinuria and emphysema.

Cadmium poisoning by ingestion has resulted chiefly from the use of cadmium-plated food containers. The symptoms, which appear rapidly, include abdominal cramps, severe nausea and vomiting, mild diarrhea, sweating, and headache. Recovery is complete in about six hours. Slight gastric symptoms have occurred in a few industrial cases, presumably from swallowing cadmium dust.

### CHROMIUM

Industrial exposure to chromium occurs principally in the manufacture of chromium compounds from the ore, in the production and use of chrome pigments.

\* Specific directions may be obtained from any state industrial hygiene unit or from the National Safety Council in Chicago.

in chromium plating, in tanning of leather, in fixing of colors, and in bleaching processes.

It is generally believed, at the present time, that pure metallic chromium, chrome ore (ferrous chromite), and the trivalent chromium compounds are not harmful to the body tissues. On the other hand, the hexavalent compounds, the mono- and dichromates and chromic acid, are extremely irritative and corrosive. The important effects of industrial exposure to these hexavalent compounds are chrome ulcers of the skin; ulceration and perforation of the cartilaginous portion of the nasal septum; chrome eczema and occasionally asthma, which are believed to be allergic manifestations; and under certain conditions, bronchogenic carcinoma. Perforation of the nasal septum does not interfere with respiration and is not disabling. Marked gastric irritation may result from the ingestion of chromates, but this condition does not seem to occur in industrial workers, probably because the dust precipitated on the upper respiratory tract does not reach the stomach in sufficient quantity or in its original form. Although damage to the kidneys and other organs has been produced experimentally in animals, no systemic toxic reactions have been proved for men exposed to chromium or to its compounds in industry.

The most serious health hazard of the chromates is due to their carcinogenic property. Cancer of the respiratory tract, chiefly bronchogenic carcinoma, has occurred frequently among men employed in the chromate-producing industry of the United States and Germany and in a few men employed in the chrome pigment industry in Germany. Statistical studies in this country indicate that the incidence of bronchogenic carcinoma is significantly higher in the chromate-producing industry than in comparable control groups. There are no data at the present time to indicate that persons exposed to chromates in other occupations are more than normally liable to cancer of the respiratory tract or that the incidence of cancer in other tissues is excessively high in chromate workers. It is believed that the hexavalent chromium compounds in the form of dust or mist are responsible for the carcinogenic effects, although definite proof is lacking.

### LEAD

**Extent of Lead Exposures.** From the viewpoint of public health, lead is one of the most important of the metals; first, because it produces serious toxic effects; second, because more industrial workers are exposed to lead and its compounds than to any of the other toxic metals; and third, because lead poisoning occurs in a considerable number of children.

**Incidence of Lead Exposure and Lead Poisoning.** From a survey of representative industrial plants in the United States in 1936-39, the United States Public Health Service estimated that about 783,000 workers were employed in industries where lead or its compounds were used (see Table 31-4). No accurate morbidity or mortality statistics on lead poisoning are available since many cases, both in adults and children, are never recognized as due to lead poisoning. For example, between 1931-1940, 26 per cent of all fatal cases of lead poisoning in the entire United States were reported from a city which had only 0.6 per cent of the population of the United States. Most of these cases were in children. There is no reason to believe that the exposure to lead in this city is greater than in other similar cities. The high rate of lead poisoning in this particular city was undoubtedly due to the fact

that its health department maintains an excellent laboratory service for blood lead analysis and to the fact that the pediatric departments in three of its large hospitals are very alert to this condition. This fact indicates that there is a much higher incidence of lead poisoning, especially in children, than is usually recognized.

**Sources of Lead Exposure.** Industrial exposure to lead occurs in the smelting and refining of lead, in the production of storage batteries, in the manufacture and use of lead paints, in the production of tetraethyl lead, in cable sheathing, and in many other occupations in a large variety of industries.

Nonoccupational cases of lead poisoning in children occur chiefly in the summer and at the age of 12 to 24 months when children are teething. It is thought that the children ingest the lead, probably by chewing on window sills, porch railings, cribs, or toys which have been painted with lead paint. In recent years, new toys, furniture, and other articles manufactured in this country for children have not been painted with lead pigments. However, lead poisoning in children still occurs. Most of these cases occur in families of the lower social economic classes who reside in old houses and who may use any available paint to repaint their homes and furniture. Another possible source of lead in these old houses may be the plaster which falls to the floor from walls painted years ago with lead pigments. Other sources of lead poisoning have been reported. A large number of cases of lead poisoning occurred in Baltimore in 1936 when a number of poor families burned discarded battery cases in their kitchen stoves. A child recently developed lead poisoning from swallowing a lead weight which had been attached to a small toy. Thus, lead from various sources may be responsible for the cases in children.

Nonoccupational cases of lead poisoning in older children and in adults are rare. However, some exposure may result from eating fruit sprayed with lead insecticides; from drinking water conveyed in lead pipes, if the water is fairly acid in reaction and has remained for some time in contact with the pipes; from excessive use of colored chalks containing lead; from home production of alcoholic beverages in utensils glazed with lead; and from other such conditions. The use of gasoline containing tetraethyl lead in automobiles presents no hazard to the operator, nor, in fact, to persons dispensing such gasoline at the modern service stations. On the other hand, hazards do exist in the manufacture of tetraethyl lead, in the mixing of it with gasoline, and in the cleaning of the storage tanks. Burning of leaded gasoline in cook stoves, home cleaning of articles with leaded gasoline, and other such exposures also may be very dangerous.

**Relative Toxicity of Lead and Its Compounds.** All lead compounds may be toxic under some circumstances, but some appear to be more harmful than others. The relative toxicity of the various lead compounds has been investigated experimentally in animals by Fairhall and others (1940). Their results indicated that lead arsenate, lead carbonate, and lead monoxide are the most toxic of the lead compounds and that lead sulfide is the least toxic.

**Absorption, Storage, and Elimination of Lead.** In industrial exposures, lead is absorbed in the form of dusts or fumes chiefly through the lungs, and to a small extent, through the alimentary tract. Only organic compounds such as tetraethyl lead are absorbed through the skin. Lead is stored mainly in the bones. Aub, together with his associates (1925), believes that certain metabolic changes in the body subsequently may release the lead which is stored in the bones into the blood stream and thus precipitate an acute attack even though the exposure has

ceased. Kehoe (1947) believes that acute attacks can occur some time after the end of exposure but attributes this poisoning to continuous high levels of lead in the blood which may exist for months after the exposure has ceased. Lead which is stored in the body is slowly excreted after removal from exposure. Excretion may be increased by treatment with the chelating agent, calcium disodium ethylene diamine tetra-acetate (EDTA). Calcium, phosphorus, and vitamin D play a role in the absorption, storage, and mobilization of lead.

**Toxic Effects of Lead.** The toxic properties of lead are believed to be due to an excessive concentration of free lead ions in the circulating blood. It is believed that low concentrations of lead in the blood which cause no toxic symptoms are not harmful to health (Kehoe, 1949).

In general, three types of lead poisoning may result from excessive exposures to lead. The alimentary type, with abdominal colic, constipation, and nausea as the principal symptoms, is the most common type occurring in industrial workers. More severe exposure may lead to the neuromuscular type in which the weakness and paralysis of the extensor muscles of the forearm and other neuromotor symptoms are present. The third type, lead encephalopathy, is rare in industrial cases but is the prevalent type in children. In tetraethyl lead poisoning, nervous symptoms predominate. Lead also causes changes in the red blood cells leading to hypochromic anemia with an increase in reticulocytes and stippled cells. A lead line in the gum margin may occur if hydrogen sulfide, produced by bacterial invasion, is combined with an elevation of lead in the tissues.

Lead poisoning in adults is not usually fatal. The disease is much more serious in children, not only because death results in about 10 per cent of the cases, but because permanent mental damage is reported to occur.

Diagnosis of occupational lead poisoning should be based on the clinical picture, a history of significant lead exposure, and corroborative laboratory findings. The latter should include analyses for lead in the blood and or urine, analysis for urine coproporphyrin and examination of the blood picture. The diagnosis should never be made on the basis of the laboratory findings alone, since these vary with many factors.

**Safe Concentrations of Lead.** Attempts have been made to determine the safe limits of lead exposure for normal persons both in terms of lead intake and in terms of the concentration of lead in the blood and urine. The normal quantity of lead found in the air, food, and water and the highest concentrations which are believed to be safe for the average person are presented in Table 32-4.

Table 32-5 gives the concentration of lead in blood, urine and feces which are believed to represent the safe upper limits for adults. This table also includes the levels which are found in normal persons and in persons with lead exposures of various degrees. Analysis of lead in the feces yields information only on the extent of lead intake immediately preceding the date of collection of the sample.

The blood concentrations in children are somewhat different from those for adults. Clinical symptoms of lead poisoning in children are usually associated with blood lead levels above 0.1 mg. lead per 100 grams of blood. The majority of cases show lead levels between 0.1 and 0.3 mg., with the fatal cases usually between 0.4 and 0.6 mg. per 100 grams of blood.

Safe lead exposures also have been set in terms of the number of stippled red

Table 32-4. Normal and maximum safe lead exposures in air, water and food

Material	Average Normal Exposures	Upper Safe Limits of Exposure
Air	0.05 mg. Pb per 10 cu. meters (Kehoe, 1947)	1.5 mg. Pb per 10 cu. meters air for 8 hrs. per day (Am. Pub. Health A., 1943)
Water	0.02-0.03 mg. Pb per liter water (Kehoe, 1947)	0.1 parts per million or 0.1 mg. Pb. per liter water (USPHS, 1946)
Fruit		0.05 grains metallic Pb per lb. of fruit or 7.1 parts per million as spray residue only on apples and pears (U.S. Food and Drug Adminis., 1940)
Food and drink	0.03 mg. Pb per day (Kehoe, 1947)	0.5 to 0.6 mg. soluble Pb per day (Kehoe, 1943) or even 1 mg. per day (Kehoe, 1940)

cells found in the blood. The normal values, the safe limits, and the number found with lead absorption are given in Table 32-5.

It should be noted that none of the biological criteria of safety listed in the table is infallible, either by itself or in individual cases. In fact, great caution must be observed in the interpretation of such laboratory data. The value in all cases varies with the particular individual, with the extent and duration of the exposure, and with the time at which the samples are collected, i.e., whether early in the exposure or some days after removal from the condition. All of these tests are more significant when done on groups of workers and when followed regularly.

**Prevention of Lead Poisoning.** The most important general measures for the prevention of lead poisoning in industry are the elimination or reduction of the exposures by the various engineering and other methods discussed later (see pages 1086 to 1091). If it is not possible to reduce or maintain the concentration of lead in the air at absolutely safe levels, then it becomes necessary to determine if dangerous amounts of lead are being absorbed by the workers. This procedure requires periodic analyses of blood and/or urine for lead, urine coproporphyrin analysis, and blood cell studies, together with a physical examination. If the occupational exposure to lead is serious, these analyses should be made weekly; if moderate, monthly examinations are sufficient. Annual or semiannual examinations are adequate for low grade exposures. Workers who exhibit signs of abnormal lead absorption should be removed from the exposure. It has been recommended that workers exposed to lead might be rotated so that continuous exposure is avoided. Pregnant women and persons with diseases of the blood should not be employed in lead exposures. Avoidance of constipation and adequate drinking of water are recommended to maintain elimination of the toxic ions, but the habit of taking daily cathartics as a preventive measure should not be encouraged. With regard to the use of ascorbic acid or milk in the prevention of lead poisoning, the Committee on Lead Poisoning of the American Public Health Association stated: "In principle, the administration of ascorbic acid in connection with occupational lead exposure may be regarded in the same light as the common practice of promoting the consumption of milk by lead workers. To the extent that industrial workers suffer from general or specific nutritional deficiencies, any procedure which promotes the correction of these deficiencies is good hygienic practice, but . . . there is no adequate evidence that any dietary regimen, other than one based on general nutritional

Table 32-5. Amount of lead in blood, urine and feces, and number of stippled cells in adults, without lead exposure, following lead exposure, and at upper safe limits

Lead in Urine, Expressed in Milligrams of Lead per Liter of Urine	
Normal values	Average 0.03 (range 0.01 to 0.08 for samples of 1 liter or more; 0.005 to 0.12 for spot samples of 50 ml. or more)
Values indicative of occupational exposure to lead	Above 0.12 to 0.15, but usually not over 0.25 or 0.3, with maximum rarely over 0.5 Above 0.5 indicates unusually severe exposure With brief massive exposure 1.0 may occur
Upper safe limits of occupational exposure	Less than 0.1 for average of a group of workers Less than 0.15 for average of an individual worker generally and above 0.2 very occasionally
Lead in Blood, Expressed in Milligrams of Lead per 100 Grams of Whole Blood	
Normal values	Average 0.03; range 0.01 to 0.06
Values indicative of occupational exposure to lead	Above 0.07 indicates exposure With considerable exposure 0.1 to 0.2 is frequently found; 0.2 to 0.3 is occasionally found; above 0.3 is rare Above 1.0 is usually due to contamination
Upper safe limits of occupational exposure	Range 0.05 to 0.07 Average of 0.05 for group of workers, and 0.065 for individual worker
Lead in Feces, Expressed in Milligrams of Lead per Single Fecal Evacuation Representing 24-Hour Sample (Only Indicates Immediate Lead Exposure)	
Normal values	Average 0.33; range 0.1 to over 2.0
Values indicative of occupational exposure to lead	Above 0.5 as average for a group of workers. Average above 1.1 usually associated with lead intoxication
Upper safe limits of occupational exposure	Below 1.1 for a group of workers
Stippled Cells, Expressed as Number per Million Red Blood Cells	
Normal number	Average of 300 to 350; range from a few cells up to 1,500 or even occasionally up to 6,000
Number indicative of occupational exposure to lead	2 to 8 times normal average In lead intoxication, up to 40,000 temporarily with onset of symptoms
Upper safe limits of occupational exposure	800 to 1,000

Compiled from Am. Pub. Health Ass'n, Report Comm. on Lead Poisoning, 1943

principles, is beneficial under conditions of prolonged occupational lead exposure." (Am. Pub. Health Ass'n, 1943.) EDTA should not be used as a prophylactic measure (Kehoe, 1955).

Prevention of lead poisoning in children would seem to lie chiefly in educating the public, particularly the parents of young children. Improved socio-economic standards, including better housing and nutrition, may also aid in eliminating these cases.

#### MANGANESE

Cases of manganese poisoning have occurred principally among men engaged in the mining and crushing of manganese ore and, to a lesser extent, in metallurgy.

cal industries. Manganese is used as an alloy in the iron and steel industry, in the manufacture of dry cells, glass, paints, dyes and various chemicals; and as an oxidizing and bleaching agent in various processes.

The most important pathological changes which result from exposure to manganese compounds are those which occur in the central nervous system. The characteristic lesion is the destruction of the cells of the basal ganglia and other subcortical areas followed by gross scarring and shrinking. Other parts of the central nervous system also may be affected. The symptoms are similar to the Parkinsonian syndrome. The onset is insidious, with languor and sleepiness followed by weakness in the legs. A masklike face, muscular twitching, stiffness, and tremor develop. The patients show a characteristic gait and emotional disturbances.

Although symptoms may develop within the first three months of exposure, somewhat longer exposures are usually required. If the man is removed from the exposure early in the disease, the symptoms may regress; but well-established manganese poisoning usually leads to permanent total disability without shortening the length of life. Elimination of dangerous exposure and immediate removal from exposure of persons with the slightest symptoms are the only procedures for preventing these tragic cases.

Observations on animals and humans indicate that croupous pneumonia or pneumonitis may also result from exposure to manganese dust.

### MERCURY

Exposures to mercury may occur in many widely different industries, such as in the manufacture of electrical equipment, pharmaceutical preparations, amalgams, munitions, antifouling paint, and other materials. Exposure also occurs in chemical industries and scientific research laboratories, where mercury is used as a reagent. Formerly mercury was used in the felt hat industry, but it has been eliminated from this process in this country.

Mercury vaporizes readily even at room temperatures, especially if it is broken up into small globules, which increase the surface area. Vaporization increases rapidly with an increase in temperature. A tiny globule of mercury weighing 2.8 mg., if completely evaporated in a room 10 feet square and 10 feet high, will give a concentration of 0.1 mg. mercury per cubic meter of air, which is considered to be the maximum safe concentration of mercury vapor.

Mercury may be absorbed through the respiratory tract, the skin, and the digestive tract. It is excreted chiefly in the urine. The metal is a severe protoplasmic poison which may cause acute toxic reactions or, more commonly, chronic illness. The onset is insidious. The chief symptoms of mercury poisoning are: inflammation of the mouth and gums, gastro-intestinal irritation, muscular tremors, and psychic disturbances leading to a peculiar shyness and excitability. Kidney damage may occur.

Some of the organic compounds of mercury, such as diethyl mercury, are extremely toxic. On the other hand, mercury fulminate rarely causes systemic poisoning; dermatitis, sensitization, and inflammation of the mouth and eyes are the chief symptoms.

Certain specific preventive measures, in addition to those common to all toxic dusts and vapors, apply to mercury. Because of its peculiar physical properties, mercury is extremely difficult to collect when it is spilled on floors or table where

the possibility of spillage exists, the floors should be covered with a smooth hard finish without cracks and should slope toward a sump into which mercury can be washed. Rough concrete and wooden floors should not be used. Table tops should be smooth and preferably made of stainless steel. They should be fitted with a trough leading into a jar of water. Walls should be smooth and glossy. Cleaning should be done by flooding with water. Pans containing water should be placed in all locations where mercury leaks may occur. Mercury should be stored in tightly closed containers or under water. Vaporization is prevented when mercury is covered with water and is reduced by coating of the surfaces with polysulfides.

### URANIUM

Uranium when absorbed into the body is one of the most toxic elements. Fortunately, it is absorbed only very slightly through the gastro-intestinal tract or the skin. Part of the uranium is deposited in the bone; most is excreted in the urine. Uranium injures or kills the cells lining the renal tubules and, in severe cases, may lead to uremia and death. If the person survives, regeneration of the cells occurs. Injury to the liver and arteries also has been reported.

### METAL FUME FEVER

Metal fume fever is a temporary malady resulting from the inhalation of heavy concentrations of fresh metallic oxide fumes. Zinc and magnesium are chiefly responsible for this condition, although other metallic oxides may initiate this syndrome. The condition appears some hours after the exposure and resembles the typical sensitization reaction to foreign proteins. The usual symptoms are leukocytosis, rise in body temperature with sweating, chills, dryness of the throat, cough, tightness of chest, dyspnea, and general malaise. Complete recovery occurs in 12 to 24 hours. Persons exposed to metallic oxide fumes develop a temporary immunity to this condition. Metal fume fever does not appear to lead to any permanent damage or to predispose to tuberculosis or pneumonia.

Because metal fume fever resembles acute respiratory infections, such as grippe, it has often been mistaken for a respiratory infection.

Metal fume fever occurs most commonly in galvanizing operations and in welding.

### GASES IN THE AIR

For the purpose of this discussion, the gases in the air may be classified into four groups according to their principal effects.

1. *Natural gases* are those which occur normally in the air and which produce no harmful effects in the ordinary concentrations at normal atmospheric pressures; oxygen, nitrogen, and carbon dioxide being the major constituents.
2. *Asphyxiant gases* are those which prevent the tissues from obtaining oxygen, such as carbon monoxide.
3. *Irritant gases* are those which produce inflammatory reactions of the mucous membranes of the upper or lower respiratory tract or the eyes, such as phosphorus, nitrous fumes, sulfur dioxide, chlorine, hydrogen fluoride, ammonia, acrolein, ozone, and a number of others.

4. *Toxic gases* are those which upon absorption act as tissue poisons; examples are: hydrocyanic acid, hydrogen sulfide, carbon disulfide, arsine and nickel carbonyl.

5. *Narcotizing gases* are those which upon absorption produce an anesthetizing effect of greater or lesser degree, such as nitrous oxide and some organic gases.

In this section, carbon monoxide will be discussed in some detail because this gas presents an almost universal hazard in industries, homes, and public places. The irritant gases will be discussed only as a group, since their effects are similar. For details regarding the individual members of this group, reference should be made to texts and scientific journals dealing with these gases. Four of the more important toxic gases will be considered briefly. The narcotizing gases, other than the organic vapors, present no major industrial health or public health problem and hence will not be discussed. The effects of abnormal pressures of the natural gases in the air are discussed in Chapter 27 and will not be reviewed here.

#### THE ASPHYXIAANT GAS: CARBON MONOXIDE

**Sources of Exposure.** Carbon monoxide is produced whenever organic materials are burned in the absence of sufficient oxygen to transform all of the carbon to carbon dioxide, for example, in the incomplete combustion of coal, gasoline, oil, and other carbon-containing materials. It is produced in the explosion of dynamite and nitroglycerine, in conflagrations, in blast furnaces, in internally lubricated compressors, in automobile and airplane engines, and in innumerable other processes. Automobile exhaust gas contains from 5 to 10 per cent or more carbon monoxide. It is reported that water gas may contain as much as 40 per cent carbon monoxide; producer gas, from 20 to 40 per cent; and coal gas, about 5 per cent. Carbon monoxide occurs only as a trace in natural gas, but incomplete combustion of natural gas may yield higher concentrations. Since gasoline, oil, coal or gas is used in practically every industry, home, automobile, airplane, and ship, potential exposures to carbon monoxide exist almost universally. Furthermore, carbon monoxide is almost odorless, tasteless, and nonirritating, so that persons are unaware of its presence. Thus, prevention of carbon monoxide asphyxiation is an important problem in public health.

**Mode of Action of Carbon Monoxide.** The essential effect of exposure to carbon monoxide is anoxia. The affinity of hemoglobin for carbon monoxide is between 200 and 300 times greater than that for oxygen. Hence, when carbon monoxide is present in the air, the hemoglobin combines with the carbon monoxide and is less available for the transportation of oxygen. Furthermore, carbon monoxide forms a more stable compound with hemoglobin than does oxygen and dissociates much more slowly than does oxyhemoglobin. In the tissues where the oxygen tension is low, the presence of carbon monoxide hemoglobin in the blood tends to prevent the dissociation of the oxyhemoglobin which may be present in the blood. The failure of the oxyhemoglobin to dissociate further increases the tissue anoxia and also interferes with the carriage of carbon dioxide to some extent. Other effects of carbon monoxide, especially on the respiratory enzymes in the cells, have been demonstrated in isolated tissues and in lower animals, but it is doubtful if these play any role in man under the usual conditions of carbon monoxide asphyxiation. Thus, until further data are presented, it may be assumed that the re-

sults of exposure to carbon monoxide in man are due entirely to the interference with an adequate supply of oxygen to the cells.

Carbon monoxide is absorbed through the lungs, rapidly at first and then more slowly, until an equilibrium is reached, beyond which further absorption does not occur as long as the concentration of carbon monoxide in the alveolar air remains constant. The rate of absorption and the total amount of carbon monoxide combined with hemoglobin at equilibrium depends on the partial pressures of the oxygen and carbon monoxide in the alveolar air and on the relative affinities of these two gases for hemoglobin. The rate of respiration, insofar as it affects the partial pressure of oxygen and carbon monoxide in the alveoli, influences the rate of absorption but not the maximum amount of carbon monoxide absorbed. The rate of circulation also influences the rate of absorption. Thus, exercise, which increases respiration and circulation, increases the rate of absorption of carbon monoxide as well as the oxygen requirements of the tissues. The rate of elimination of carbon monoxide is much slower than the uptake, but it can be hastened by breathing oxygen in place of air.

It is usually accepted that concentrations of 100 parts of carbon monoxide per million parts of air can be tolerated for eight hours per day without symptoms, and that 400 p.p.m. of carbon monoxide can be endured without injurious effects for one hour. A concentration of 400 p.p.m. of carbon monoxide causes 40 to 45 per cent of the hemoglobin to be combined with carbon monoxide at equilibrium but only between 15 and 20 per cent in one hour. A concentration of 100 p.p.m. causes only about 15 per cent saturation at equilibrium.

**Effects of Acute Exposures.** The clinical symptoms in man which result from the inhalation of carbon monoxide depend on the rapidity with which a given level of carbon monoxide hemoglobin is reached, on the degree of saturation of the hemoglobin with carbon monoxide, and on the duration of the anoxia. With high concentrations of carbon monoxide in the air, sufficient to cause 60 to 80 per cent saturation of the hemoglobin, weakness followed by loss of consciousness may be the only symptoms preceding death. If the carbon monoxide hemoglobin reaches about 35 per cent saturation rapidly and the duration of exposure is less than a half hour, no very marked symptoms may result. However, if the rate of absorption is slower and the duration of exposure is longer, symptoms may occur with saturations of 35 to 40 per cent. These symptoms include headache, first frontal but later occipital; dizziness; nausea; vomiting; and dyspnea on exertion. Mental confusion and even collapse may occur in some cases. With concentrations below 20 per cent carbon monoxide hemoglobin, the symptoms are usually moderate headache, fatigue, or possible faintness.

Complete recovery occurs following carbon monoxide anoxia in the majority of the acute cases. However, the central nervous system is very susceptible to damage by anoxia, and permanent damage to the nervous tissue may result from prolonged anoxia if it is sufficiently severe to cause coma of long duration. Such severe anoxia may result in permanent psychological, motor, or sensory disturbances.

**Effects of Chronic Exposures.** Repeated exposures to low concentrations of carbon monoxide lead to some degree of acclimatization so that higher concentrations can be tolerated with fewer symptoms. In spite of numerous statements in the literature, there is no sound evidence that repeated exposures to low concentrations

tions of carbon monoxide lead to a chronic condition of carbon monoxide poisoning manifested by circulatory, gastro-intestinal or other disturbances. Medical examinations of traffic policemen who had manned the Holland Tunnel in New York for 13 years showed that they were in exceptionally good physical condition for men of their age. These policemen had had daily exposure to the tunnel air which contained an average of 65 to 85 p.p.m. carbon monoxide with a range from 10 to 235 p.p.m. Their blood carbon monoxide hemoglobin had varied from 0.5 to 13.1 per cent.

**Relation of Carbon Monoxide Exposure to Respiratory Infections.** There is no evidence at the present time that acute or chronic exposures to carbon monoxide lowers resistance to infections of the respiratory tract. Although bronchitis and pneumonia may develop following acute asphyxiation due to carbon monoxide when this is accompanied by a prolonged period of unconsciousness, these conditions are usually attributed to circulatory disturbances or to aspiration of vomitus rather than to bacterial invasion. Experiments performed in this laboratory showed that rats exposed for many weeks to smoke containing 10 to 30 p.p.m. of carbon monoxide, and at times to higher concentrations, did not have a significantly lower resistance to lobar pneumonia when inoculated intrabronchially with Type I pneumococci. It has been reported in the literature that exposure of animals to carbon monoxide does not alter their resistance to artificially induced tuberculosis.

**Prevention of Carbon Monoxide Poisoning.** In industry, the general measures described later as suitable for other toxic gases and dusts are applicable for the prevention of carbon monoxide exposures. There are, however, certain precautions for nonindustrial exposures which might be mentioned here. In the home, prevention consists chiefly in the proper installation, maintenance, and operation of gas appliances. The American Gas Association tests and approves practically all types of domestic gas appliances. Flues should be installed on all fuel-burning appliances where carbon monoxide is produced. The proper ratio of air to fuel will prevent the formation of carbon monoxide in most cases.

Garages and automobiles present some special problems in the prevention of carbon monoxide asphyxiation. The concentration of carbon monoxide may rise to dangerous levels in all commercial garages. Either adequate general ventilation should be supplied or local exhaust attachments should be connected to the waste pipes while the cars are idling. Traffic policemen may be exposed to slightly high levels of carbon monoxide in very congested areas. Concentrations of 200 p.p.m. or more have been recorded under some conditions. Since these concentrations can be tolerated with safety for more than an hour, occasional rotation of duty will prevent any harmful effects in these cases. Greater danger lies in the high concentrations of carbon monoxide which, at times, may exist inside of automobiles. Surveys made of cars selected at random showed in one study that 5 per cent of the cars had at least 300 p.p.m. of carbon monoxide, and in another study 3 per cent of the cars had 100 p.p.m. or more of carbon monoxide. One car had a concentration of 600 p.p.m. Since four hours of continuous exposure to 300 p.p.m. would give over 30 per cent saturation of the hemoglobin with carbon monoxide, such exposures might prove dangerous in some persons. Opening of the windows in the cars did not always alleviate the hazard. Prevention consists in the proper adjustment of the engine and exhaust system. One very important precaution must be mentioned in connection with certain types of heaters used in modern automobiles. The air intake for some of these heaters is placed at the front of the

car under the radiator grill. When such a car is parked within four feet behind a running car and the heater in the rear car is operating, the exhaust from the front car is drawn directly into the rear car. With the windows closed, dangerous concentrations of carbon monoxide have been found in the rear car within one minute. Concentrations of carbon monoxide as high as 1,500 p.p.m. have been found within three minutes when only two feet existed between the rear of the first car and the air intake for the second car. More than four feet of space should be allowed between cars under these circumstances.

### THE IRRITANT GASES

The gases which have an irritating action on the mucous membranes of the respiratory tract and eyes are of great importance in industrial hygiene. Although these gases vary in their chemical structure and in their mode of action, their effects are sufficiently alike so that they may be considered as one group.

**Protective Mechanisms of the Body Against Irritant Gases.** The body has a number of defensive mechanisms to protect the tissues, especially the deeper parts of the respiratory tract, from injury by harmful gases. Some of the irritant gases stimulate the sensory fibers in the upper respiratory tract, and reflexly invoke coughing, sneezing, closure of the glottis, constriction of the larynx and bronchi or even temporary inhibition of respiration. The secretions of the eyes and upper respiratory membranes tend to dilute and wash away irritating substances. The irritation of the upper respiratory tract may be so severe as to drive a person out of the exposure before more serious damage can occur. On the other hand, some gases which produce profound damage to the lower respiratory tract produce only slight irritation of the upper respiratory tract. This reaction is characteristic of exposures to phosgene. Still other gases may give warning effects if the concentrations are immediately high but fail to produce noticeable effects if the amount in the air increases gradually.

**Effects of Acute Exposures.** The acute tissue reaction to irritant gases appears to be essentially the same for all gases although the ultimate result differs according to the principal locus of effect. The reaction is essentially an inflammation with edema and swelling of the mucous membranes, desquamation, and bronchial constriction, all of which tend to block the airways. Pulmonary edema results from exposure to some gases. Those gases which exert their effect on the lower respiratory tract, such as phosgene, often cause no very acute reaction at the time of exposure, except possibly some coughing. The workmen may continue at their jobs unaware that they have inhaled a dangerous gas. After a latent period of several hours, headache, nausea, vomiting, substernal pain, and cough begin to develop. These symptoms become acute usually about 12 hours following the exposure. Dyspnea, cyanosis, and other signs of pulmonary edema appear. Death is due to the resulting anoxia or to subsequent infection. The mechanisms responsible for the pulmonary edema are not thoroughly understood at the present time.

If death does not follow, regression of the symptoms and complete recovery occur in the majority of cases, although some persons appear to have permanent aftereffects. Chronic bronchitis, emphysema, atelectasis, bronchiectasis, and bronchial asthma have been reported in a few cases. These findings in human beings have been supported by experiments on animals. Some animals also show fibrosis of the lungs. However, many of the persons who claim continued dis-

ability after single severe gas exposures have no evidences of any organic injury but exhibit chiefly psychoneurotic symptoms.

**Effects of Chronic Exposures.** Repeated exposures to low concentrations of phosgene and mustard gas in one plant were reported to lead to chronic lung disturbances in some cases. Chronic bronchitis, cough, shortness of breath on exertion, and chest pain were described. The condition did not appear to be disabling, except when complicated by a psychoneurotic component. In another industry, where men had been exposed to sulfur dioxide for many years, a high incidence of nasopharyngitis was found. On the other hand, repeated medical and radiological examination of the industrial workers in a large chemical plant showed no lung damage among workers exposed for 10 years to low concentrations of various irritating gases, including phosgene and sulfur dioxide. Probably, differences in the degree of exposure are responsible for the variations in these reports.

**Relation of Irritant Gases to Respiratory Infections.** One of the problems connected with exposures to irritant gases concerns their influence on susceptibility to respiratory infections. One might expect that the inhalation of irritant gases and fumes would lower resistance to acute infections of the respiratory tract, such as colds or pneumonia. The evidence available at the present time indicates that susceptibility to acute respiratory infections is increased when the exposures are sufficiently severe to produce damage to the respiratory mucosa. However, there is no evidence which indicates that susceptibility to infectious agents is increased after recovery or that prolonged inhalation of irritant gases, in low concentrations and without apparent damage to the mucosa, lowers resistance to acute or chronic infections of the respiratory tract. The incidence of colds and pneumonia in men exposed continuously to low concentrations of irritating gases in smelting and refining plants, in zinc and steel plants, in welding operations, in chemical plants and in other operations have been studied. A review of these studies indicated that the rates of acute respiratory infections in the men exposed to the irritant gases were no higher than those of control groups.

There is also no evidence to indicate that exposure to irritant gases affects susceptibility to tuberculosis. According to Gardner (1942), neither acute nor chronic exposures to irritant gases lower resistance to tuberculosis. This view is supported by: (1) studies of the tuberculosis rates of men who were gassed during World War I, (2) experiments on animals exposed to the war gases, (3) industrial records of men exposed for many years to irritant gases, such as chlorine, sulfur dioxide, sulfur trioxide, hydrochloric acid vapors, and phosgene, and (4) laboratory studies on animals exposed to welding fumes. Dr. Gardner who for many years was Director of the Saranac Laboratory for the Study of Tuberculosis stated: "Sufficient evidence has been cited to indicate that the mere presence of an inflammatory reaction in lung tissue does not alter native reaction to the tubercle bacillus by purely mechanical means. There is no proof that local inflammation favors the implantation of tubercle bacilli nor does it necessarily bring about dissemination of infection from a pre-established focus of tuberculosis. The significant factors responsible for the unfavorable course of a tuberculous process are more likely chemical in nature. . . . None of the evidence available at the present time indicates that dusts, other than free silica, either in pure state or as a contaminant of other materials, or any of the more common industrial fumes or gases have specific action in altering susceptibility to tuberculosis." (Gardner, 1942.)

The possible effect of irritant gases on susceptibility to lung cancer also has been discussed. According to Hueper (1942), there is no evidence at the present time that exposure to irritant gases and nonaromatic vapors plays any role in cancer of the upper or lower respiratory tract.

**Sources of Exposure to Irritant Gases.** Exposure to irritating gases occurs in many different industries and, in some cases, outside of industry. Nitrous fumes may be produced in the manufacture of nitric acid, in the nitration of cellulose and other organic materials, in the manufacture of explosives, dyes, lacquers and films, in bleaching processes, in the metal industry, in welding, and in other processes. Combustion of celluloid and nitrocellulose films also produces nitrous fumes. The liberation of these fumes was presumably one of the factors in the Cleveland Clinic disaster. Phosgene was employed as one of the war gases in World War I. It is produced accidentally when chlorinated hydrocarbons, such as carbon tetrachloride, come in contact with a flame, hot metal, or any other source of great heat. Cases of phosgene poisoning have occurred in industry and in other places as a result of this reaction. A number of cases of phosgene poisoning have resulted from the use of pyrene fire extinguishers in confined places. Sulfur dioxide is formed in many industrial processes, such as in the smelting of sulfide-containing ores and in the combustion of coal and fuels containing sulfur. It is used or produced in many chemical industries. It serves as a refrigerant, as a bleaching agent, and as an antioxidant. Exposure to ammonia occurs mainly from breaks in refrigeration lines and in the manufacture of a number of chemicals. Chlorine is used in laundries, in the sterilization of water, and in many chemical processes.

### TOXIC GASES

Hydrogen sulfide, hydrogen cyanide, carbon disulfide, and arsine are the most important of the toxic gases in industry.

**Hydrogen Cyanide.** Hydrogen cyanide is a liquid which volatilizes at a temperature of 73.4° F. It is evolved from all solutions of cyanide salts in which free caustic is not present. However, in spite of the fact that cyanides are used in large quantities in a number of industrial processes, such as plating and metal hardening, industrial poisoning from the cyanides is rare. Fumigation with hydrogen cyanide offers the most dangerous occupational exposure. Hydrogen cyanide is rapidly absorbed through the skin as well as through the lungs. Its principal action is the inhibition of tissue oxidation. The symptoms of cyanide poisoning are those of anoxemia. The cyanide ion is conjugated with sulfur in the body to form nontoxic sulfocyanides which are eliminated in the urine. Strict regulations are essential in the use of this gas for fumigation purposes. Since it is odorless and tasteless, a warning gas must be added. Gas masks do not offer complete protection since lethal amounts may be absorbed through the skin. It remains in the clothing for some time. Public health codes have been formulated which give specific regulations necessary for the use of this gas in fumigation.

**Hydrogen Sulfide.** Hydrogen sulfide is produced by the decomposition of organic materials containing sulfur. Exposure to hydrogen sulfide, therefore, occurs in tanning leather, rendering fats, manufacturing glue, etc. It is produced in mines where sulfide ores exist and is found in wells. It is used in a number of chemical industries, in the petroleum industry, in the viscous rayon industry, and in chemical

laboratories. Hydrogen sulfide is a particularly dangerous gas because it is not only an irritating gas but also is a systemic poison. The irritating properties of hydrogen sulfide may lead to conjunctivitis, dryness of the nose and throat, diffuse bronchial catarrh and, with acute exposures, to pulmonary edema. When absorbed through the lungs (skin absorption does not occur) it exerts an effect on the central nervous system. In mild doses, depression occurs, whereas excitation follows more severe exposures. Death may result from paralysis of the respiratory center. Recovery, when it occurs, appears to be complete. There is one specific precaution to be noted in the case of exposure to hydrogen sulfide. In low concentrations the odor is so offensive that most persons have ample warning of their exposure. On the contrary, very high concentrations apparently fatigue the olfactory apparatus so rapidly that man cannot smell the odor. Such exposures are extremely dangerous.

**Carbon Disulfide.** One of the most toxic substances encountered in industry is carbon disulfide. It is used chiefly in the viscous rayon and chemical industries and somewhat in the rubber industry. It is a liquid at room temperature but becomes a gas at moderately high temperatures. In extremely high concentrations it may exert an exciting effect on the central nervous system followed by unconsciousness and death. Chronic poisoning is characterized by a toxic effect on all nervous structures, leading to degenerative changes. Polyneuritis, with damage to the motor and sensory nerves, is common. Muscular weakness, tremors, and ataxia may result. Marked visual changes due to optic neuritis and atrophy and to fibrosis and spasm of the retinal vessels appear. The mental symptoms are characterized by irritability, loss of memory, insomnia, confusion and, in more serious cases, by psychoses and by symptoms resembling Parkinsonism. Gastro-intestinal disturbances, skin blisters, loss of libido and other phases of the disease may be present.

Exposure to carbon disulfide may be prevented by the general protective measures described later. Medical examinations should be made weekly in order to detect any symptoms at the earliest moment. Since changes in the retina occur early, tests of vision should be included in the periodic physical examinations for the early detection of carbon disulfide poisoning.

## ARSENIC COMPOUNDS

**Arsine.** The most important arsenic compound from the point of view of industrial toxicology is arsine or hydrogen arsenide,  $H_3As$ . This gas is formed by the action of acids on metals containing arsenic and even by the action of water on hot dross containing arsenic. Arsine is frequently produced in unsuspected locations, since many metals (especially lead, copper, zinc, and aluminum), many ores, and sulfuric acid often contain small amounts of arsenic. Recent deaths due to arsine have resulted from wetting tin dross with water, from the use of aluminum for the removal of arsenic in the refining of lead and from the subsequent handling of the dross, and from cleaning and repairing acid tanks. Arsine may be formed also in the smelting of arsenic-containing ores, in electroplating, in galvanizing, in the manufacture of storage batteries, in pickling operations, in the manufacture of some chemicals, and in a number of other processes.

Arsine is one of the most dangerous gases since it has no warning properties. and, therefore, persons exposed to it may be completely unaware of the presence of this toxic substance. Following exposure, after a short latent period, headache,

nausea, and vomiting occur. Within a day, blood appears in the urine, and in severe cases anuria may occur. Jaundice appears, followed by swelling of the liver and spleen, anemia, kidney damage and pulmonary edema. The symptoms are due to massive destruction of the red blood cells and to the resulting anemia.

**Arsenic Dusts and Fumes.** Exposure to dusts and fumes of arsenic compounds occurs in the manufacture and use of arsenical insecticides, in the refining and smelting of arsenical ores or metals containing arsenic, in the manufacture of glass, and in other industries. The principal effects of industrial exposure to arsenic dusts and fumes (chiefly the oxides and chlorides) are severe dermatitis, conjunctivitis, perforation of the nasal septum, and inflammation of the upper respiratory tract. Chronic systemic poisoning of occupational origin does not appear to be very common. Symptoms of gastro-intestinal irritation and damage to the nervous system are characteristic of arsenic poisoning.

It is generally believed that arsenic compounds can produce skin cancer. Whether such cases can result from skin contact alone or whether the arsenic must first be absorbed or injected into the body is not clear. The possibility that arsenic compounds may cause lung cancer has been suggested by some studies, but convincing proof for this is lacking at the present time.

The use of arsenical insecticides, although potentially dangerous, appears to present only a minor public health problem at the present time. Recently the Division of Industrial Hygiene of the United States Public Health Service (Neal and others, 1941) studied the effects of lead arsenate exposure on orchardists and consumers of sprayed fruits. Among 1,231 persons so exposed, only six men and one woman had a combination of clinical and laboratory findings which could be interpreted as possibly a minimum lead arsenate intoxication.

The spray residue tolerance for arsenic, expressed as arsenic trioxide, on apples and pears has been set at 0.025 grains per pound of fruit by the Food and Drug Administration.

## FLUORINE COMPOUNDS

Fluorides are used in the smelting of beryllium and many other metals, in the refining of aluminum, in the manufacture of steel, in magnesium founding, and in ceramic, glass, enamel, chemical, and petroleum industries. The fluorides are used as insecticides. Fluorine compounds are liberated in the manufacture of phosphate fertilizers and in the welding of stainless steel where fluoride-coated rods are used.

**Acute Effects in Industrial Workers.** The fluoride ion interferes with certain enzyme systems of the body and acts as a general protoplasmic poison. Ingestion of large amounts of soluble fluorides causes marked gastro-intestinal irritation and acute toxic nephritis. Death may occur. Anhydrous hydrofluoric acid, and even aqueous solutions of hydrofluoric acid, cause severe burns of the skin and eyes. Burns from the former are felt immediately, but those from the latter may not be felt for an hour or more after exposure. These burns are so serious that immediate drenching with water, followed at once by medical attention is essential. Heavy neoprene gloves and goggles should be worn where there is danger of contact with these substances. In addition to the skin effects, the chief danger in industry from acute exposures comes from the inhalation of the gaseous hydrogen fluoride

According to Largent, concentrations of 10 p.p.m. or more cause discomfort. With higher concentrations, irritation of the eyes, skin, and upper respiratory tract increase. The inhalation of fluoride dusts also may cause irritation of the upper respiratory tract.

**Chronic Effects in Industrial Workers.** In adults, prolonged exposure to fluoride dust in industry may lead to changes in the bones. According to Roholm (1937), the process is essentially a generalized osteosclerosis with increasing density and thickening of the bone, narrowing of the medullary cavity, periosteal deposits and calcification of the osseous ligaments. The bone changes are most pronounced in the vertebral column and pelvis. The lesions cause some stiffness and reduction of motility. The teeth may show signs of increased formation of dentine and cement. In the Danish cryolite workers studied by Roholm, the general condition of the workers did not seem to be affected, and no lesions other than the bone changes were found. In a few cases described by Møller and Gudjonsson (1932) serious disability occurred. In this country, an increase in the density of the bones and calcification of the ligaments have been found in some industrial workers who had prolonged exposures to high concentrations, but no severe cases with disability have been reported.

The effects of atmospheric pollution with fluorine compounds is discussed in Chapter 29.

**Allowable Concentrations of Fluorides.** The generally accepted maximal allowable concentration for fluorides in the air is 2.5 mg. per cubic meter of air and for hydrogen fluoride, 3 p.p.m. The quantity of fluorine remaining as insecticidal residue on fruits and vegetables is limited by the Food and Drug Administration to 7 p.p.m. of combined fluorine (Food and Drug Administration, 1955).

## THE ORGANIC COMPOUNDS

**Importance of Organic Compounds in Preventive Medicine.** Among the most important chemicals used in industry today are the organic compounds. Already hundreds of different organic compounds are in use and new ones are being produced constantly. Practically every industrial plant, no matter how small, uses some organic compounds in one form or another. Not only are these found in every industry and in almost every type of gainful occupation, but they are used also in every home. Women have become ill from cleaning their clothes with carbon tetrachloride, babies have been poisoned from wearing diapers labeled with an aniline dye and men have died from methyl chloride poisoning due to breaks in refrigeration systems. Many of the organic compounds in sufficiently high concentration in the air can produce acute illness or death, many of them have chronic toxic effects, most of them can cause skin affections, and some of them are highly inflammable. Because of their wide use and their harmful properties, the organic compounds present an important problem to industrial health personnel and to those interested in preventive medicine.

**Source and Nature of Organic Compounds.** The organic compounds are those chemical substances which contain carbon. They are found in plants and animal tissues, and in materials, such as petroleum and coal, which result from the subsequent decomposition of living substances.

The organic compounds which are obtained from the distillation of petroleum

are composed chiefly of the aliphatic hydrocarbons. The crude products include petroleum ether, gasoline, kerosene, fuel oils, lubricating oils, paraffin, mineral oil, asphaltic pitch and other compounds. The materials obtained from the distillation of coal tar are oils which yield the aromatic hydrocarbons (benzene, toluene, naphthalene and anthracene), the phenols and cresols and a residue of coal-tar pitch. From these basic compounds the various hydrocarbons and their derivatives are prepared.

Some of the aliphatic hydrocarbons are gases such as methane, ethane, ethylene, butylene, acetylene, ethyl chloride, etc. Many of the organic compounds are liquids which volatilize readily at room temperature. Because of their solvent properties these compounds are known as the volatile solvents. Many of the organic compounds are solids at ordinary temperatures.

**Chemical Composition and Toxicity of Commercial Organic Products.** It is very difficult to determine the composition and thus the toxicity of commercial organic products. Most of them are sold under trade names, almost all of them are mixtures or contain impurities, and many of them are so newly developed that the toxic properties are not understood. Thus it becomes very difficult for the consumer, whether this be an industry or a private individual, to determine the composition of the chemical substance and whether or not it is safe for use. Information regarding the toxicity of organic compounds may be obtained in some cases directly from the manufacturer. However, statements that the product is nontoxic, without information regarding the chemical nature of the material, should not be accepted. Even published toxicological reports should be interpreted only by persons familiar with this field. The best sources of information on this subject are the industrial hygiene divisions in the federal and state health departments.

**Occupational and Nonoccupational Exposures.** It is impossible to enumerate the industries where exposure to organic compounds occurs since almost every industry either manufactures these chemicals or uses them for one purpose or another. The types of exposure, however, differ greatly. In those industries where these chemical compounds are produced or used in such a manner that their conservation is important, dangerous exposures occur chiefly as a result of accidental leaks and breaks in the equipment, or when cleaning tanks, or when handling, packing or shipping the materials. The chemical, petroleum, explosive and other such industries fall in this group. In other occupations the organic materials are used as solvents for other materials. In these processes, it is desirable for the solvent to be evaporated as rapidly as possible. Here the exposure is more or less continuous but there is less likelihood of sudden high concentrations in the air. Exposures of this type occur in degreasing of metal parts, in the extraction of fats and oils, in dry cleaning and other operations. Organic compounds also are used as solvents of cellulose, gums and resins, etc., in the rubber, rayon, artificial leather and textile industries, and as solvents for pigments in paints, varnishes and lacquers.

In addition to industries, individual persons employ organic compounds as insecticides, rodenticides, dry-cleaning agents, fuel oils, and motor fuels.

The number of persons who are exposed to organic compounds is not known but some idea of the extent of industrial exposures which existed in 1940 can be obtained from Table 31-4, page 1033.

**Absorption and Elimination of Organic Compounds.** The organic compounds encountered in industry are, like the other chemical substances, absorbed through

the respiratory tract. In addition, many of the organic materials are able to penetrate the intact skin and are absorbed directly through this route. Skin absorption is especially characteristic of the nitro and amino derivatives of the aromatic hydrocarbons, such as nitrobenzene, aniline and TNT. Among the other organic compounds which may be absorbed through the skin are phenol, nitroglycerine, tetraethyl lead and methanol and, to a much less extent, the chlorinated hydrocarbons and benzene.

The amount of an organic compound which is absorbed depends on its volatility, on the extent and duration of the exposure, and on its solubility in the body fluids and tissues. Most of the organic compounds are changed into less toxic compounds in the liver or other tissues and are excreted by the kidneys. Some of the volatile compounds are excreted through the lungs.

**Toxic Effects of Organic Compounds.** It is difficult to discuss the toxic properties of these organic materials since they vary greatly in their effects on the body tissues. Even closely related compounds exhibit great differences both in their degree of toxicity and in their specific type of action in the body. Furthermore, the toxic effects vary greatly depending on the condition of the person. Pre-existing organic disease, metabolic disturbances, diet, alcoholism and other factors affect an individual's susceptibility to the organic compounds. For accurate information, reference must be made to books on industrial toxicology where each compound is discussed individually. However, certain general effects appear to be characteristic of the organic compounds as a whole or of the individual classes.

**GENERAL EFFECTS.** One property which is common to practically all of the organic compounds is their narcotic or anesthetizing effect. Their ability in this respect varies directly with their solubility in fat as compared with that in water. Acute exposures to sufficiently high concentrations of these organic vapors may lead to almost instant unconsciousness and death. Recovery may occur with less intense exposures or upon immediate removal from the dangerous environment. With lower degrees of exposure less severe symptoms are found. Headache, vertigo, nausea and vomiting are common symptoms. Convulsions may occur. A state of excitement may precede the depression. Some authorities believe that low grade exposures, although giving rise to no specific symptoms, may produce sufficient drowsiness to constitute an accident hazard under some conditions.

In addition to the acute narcotic effect of the organic vapors, many of the organic compounds exert specific poisonous effects on the body. These systemic toxic reactions may result from a single intense exposure or, more commonly, from repeated exposure to lower concentrations. The organic compounds, because they are fat solvents, remove the oil from the skin and lead to drying and cracking of the skin often accompanied by secondary infections; many of them also cause specific dermatitis. A number of the organic compounds are irritating to the respiratory tract and eyes. Some of the organic compounds are highly inflammable or explosive. These are the general properties of the organic compounds as a whole. The most characteristic reactions for each of the principal classes of organic compounds are given below.

**EFFECTS OF SPECIFIC GROUPS.** *Aliphatic Hydrocarbons.* The aliphatic hydrocarbons act chiefly on the central nervous system, producing a narcotizing or anesthetizing effect. The symptoms of both acute and chronic exposures are characteristic of this reaction. Some of these compounds are also irritating to the respira-

atory tract. Although chronic toxic effects have been attributed to such mixtures as gasoline, benzine and others, they have not been clearly demonstrated.

*Organic Acids.* Exposures to low concentrations of organic acids are not harmful but severe local irritation of the eyes and respiratory tract may result from higher concentrations, and in extreme cases pulmonary edema may occur.

*Esters, Ethers, Aldehydes and Ketones.* These groups of organic compounds are noted chiefly for their narcotic and irritating properties. There is little evidence that they produce systemic toxic effects as a result of exposures in industry. The aliphatic esters, in fact, are among the least toxic of the organic solvents. The aldehydes have only moderate anesthetizing action but are very irritating, not only to the respiratory tract and eyes, but also to the skin. They also may lead to dermatoses as a result of acquired sensitivity.

*Alcohols.* The alcohols, with the exception of methanol, have a comparatively low toxicity. Their effects following inhalation are similar to those produced from the ingestion of these compounds, being chiefly narcotizing and irritating. Methyl alcohol is an outstanding exception. Its narcotic effect is less but its toxicity is far greater than that of the other alcohols. It is decomposed and eliminated from the body very slowly. The chief symptoms of methyl alcohol intoxication include irritation of the mucous membranes, headache, nausea, vomiting, muscular inco-ordination, dyspnea, colic, dilated pupils, impaired vision, blindness, delirium, coma and death.

Methyl alcohol is used extensively in industry, particularly as the solvent for resins, waxes, plastics, dyes, etc.

*Glycols and Their Esters and Ethers.* The glycols or diatomic alcohols are generally considered relatively nontoxic when the vapors are inhaled but they may be toxic when ingested. Propylene and ethylene glycol, which have been used in the sterilization of air, do not appear to produce any damage even in a saturated state. When ingested, they may be harmful. Diethylene glycol, which was used as the solvent for sulfanilamide on one occasion, caused a large number of deaths. Some of the derivatives of the glycols have caused industrial poisonings. For example, dioxane, the secondary ether of ethylene glycol, has been reported to cause hemorrhagic nephritis, central necrosis of liver, gastro-intestinal disturbances, and irritation to mucous membranes. Ethylene glycol monomethyl ether has produced effects on the central nervous system, the blood and the kidneys in a few persons subjected to high exposures.

*The Chlorinated Hydrocarbons.* The chlorinated hydrocarbons form one of the most important groups of organic compounds from the point of view of industrial hygiene. Not only are they among the most toxic of the organic compounds, but they are extensively used both in and outside of industry. Cases of poisoning are reported frequently and a number of deaths have occurred as a result of exposure to the vapors of these solvents. They are noninflammable and certain members of this group are used as fire extinguishing agents.

In high concentrations they exert an anesthetizing effect leading to rapid death due to respiratory failure. They are also irritating to the eyes and respiratory tract and in some cases cause pulmonary edema. Excessive exposures which do not cause fatal narcosis may lead to acute injury of the liver, kidney and possibly other organs. Repeated exposures to lower concentrations produce similar damage. The central nervous system and red blood cells may also be affected. The

most characteristic changes are fatty degeneration or acute yellow atrophy of the liver with swelling and necrosis of the cells, and severe nephritis which involves primarily the tubules. Headache, gastro-intestinal symptoms, dizziness, bleeding from the membranes, jaundice and uremia are the common symptoms. The member of this group which is the most powerful protoplasmic poison is tetrachloroethane (acetylene tetrachloride). Carbon tetrachloride appears to be slightly less toxic but is much more widely used. Trichloroethylene, ethylene dichloride and propylene dichloride are all less toxic.

Methyl chloride and methyl bromide fall into a special class since they cause severe pulmonary edema. Because methyl bromide is particularly effective in this respect, it is rated one of the most dangerous of the chlorinated hydrocarbons.

One of the dangers which may accompany the use of chlorinated hydrocarbons is the formation of phosgene ( $\text{COCl}_2$ ). This gas, which causes pulmonary edema, is produced when the vapors of halogenated hydrocarbons come in contact with open flames, incandescent materials or other sources of heat. A number of fatalities from the chlorinated hydrocarbons have been attributed to the production of this gas.

Because of its wide usage, carbon tetrachloride merits special attention. A number of cases of severe poisoning by carbon tetrachloride have resulted from exposures which were not connected with the industrial processes. One case of poisoning occurred in a man who put out a fire with a carbon tetrachloride fire extinguisher in a small closed space. In another instance three boys died from cleaning their boat with this material. Several recent cases resulted from the cleaning of personal clothing and other objects at home, where only small amounts of the solvent were used. For the most part industries and individuals are unaware of the extreme danger connected with the use of carbon tetrachloride. At the request of the United States Public Health Service manufacturers have agreed to place warning labels on all shipments of this material or similar volatile chlorinated liquid hydrocarbons in excess of 15 fluid ounces or of mixtures containing 24 per cent or over of these materials. However, even smaller amounts may prove hazardous. A brief summary of the symptoms and treatment of carbon tetrachloride poisoning has been published recently by the Council on Industrial Health of the American Medical Association (1946). Copies of this summary may be obtained from this organization.

In recent years, certain dietary factors have been investigated in connection with the hepatitis which results from some of the chlorinated hydrocarbons. Animal experiments showed that a high fat diet and a low protein diet were unfavorable. Methionine appeared to be of some special significance in the prevention and treatment of acute yellow atrophy of the liver from these compounds, especially if associated with a high protein and low fat diet. Choline also appeared to be of benefit. There is a little clinical evidence which supports these results in experimental animals.

*Nitro and Amino Compounds of the Aliphatic Series.* The nitroparaffins are the most common of the nitro compounds. Their chief action is irritation of the respiratory tract and eyes. The nitrites act on the peripheral blood vessels causing a fall in blood pressure. The nitriles, such as acrylonitrile (vinyl cyanide), are extremely toxic. It is believed that hydrocyanic acid is formed from this compound in the body and that this substance is responsible for the toxic properties.

The amino compounds of the aliphatic hydrocarbons do not seem to be of great importance in industrial hygiene. They exert primarily an irritative effect.

*Aromatic Hydrocarbons and Their Chloride and Hydroxyl Derivatives.* The aromatic hydrocarbons include benzene (benzol), toluene, xylene, naphthalene, anthracene and others. Benzene is by far the most important of these compounds, not only because of its toxicity but also because of its extensive use.

In high concentrations the aromatic hydrocarbons all produce acute narcotizing effects similar to the other organic vapors. With very large doses death may occur within a few minutes.

With chronic exposures, benzene is the most toxic of the aromatic hydrocarbons. The symptoms resulting from repeated exposure to benzene vapor are fatigue, headache, vertigo and gastro-intestinal disturbances. Since benzene damages the blood-forming tissues, the chief findings are changes in the blood picture. During the early stages compensatory hyperplasia of the bone marrow may lead to an increase in the number of red and white blood cells but leukopenia and anemia are characteristic of the later stages. Thrombopenia and possibly damage to the vascular walls are responsible for the hemorrhages under the skin and mucous membranes. Injury to the liver, kidney, nervous system and skin have also been reported.

Toluene and xylene are quite different from benzene in their chronic effects, their principal action being on the central nervous system. Naphthalene and anthracene are irritating to the eyes, respiratory tract and skin.

Benzene (benzol) must not be confused with benzine (petroleum ether) which is largely composed of the aliphatic hydrocarbons, pentanes and hexanes. Benzine has a greater narcotic action than does benzene, but it exerts little, if any, systemic toxic effects. Benzene, on the other hand, is one of the most toxic of the organic compounds.

The chlorinated hydrocarbons of the aromatic series, such as chlorinated naphthalene (halowax), cause acute yellow atrophy of the liver and severe skin conditions.

The most important of the hydroxyl derivatives of the aromatic hydrocarbons is phenol. This compound is a protoplasmic poison. The chief effect is on the central nervous system, especially the higher centers.

*The Aromatic Nitro and Amino Compounds.* The most important members of this group of organic compounds are aniline, mono- and dinitrobenzene, trinitrotoluene (TNT), dinitrophenol and beta-naphthylamine. All of these compounds produce serious toxic or other harmful effects.

The characteristic action of aniline, mono- and dinitrobenzene and related compounds is the formation of methemoglobin leading to marked cyanosis. Fortunately, this is a reversible reaction. Damage to the liver, red blood cells and other tissues have been described, but these appear to be less important. Because of the skin absorption, aniline should never be allowed to remain in contact with the skin. Recently a number of cases of aniline poisoning occurred in babies from wearing diapers freshly stamped with an aniline dye. Trinitrotoluene (TNT) is an extremely toxic material which causes aplastic anemia, damage to the liver leading to acute yellow atrophy, some cyanosis probably due to the formation of methemoglobin and dermatitis. It stains the skin yellow and is readily absorbed through it.

Dinitrophenol and dinitrocresol have a somewhat different action from the characteristic effects of this group. The acute disturbance is the marked increase

in basal metabolism, with increase in oxygen consumption, body temperature, profuse sweating, thirst and exhaustion.

Beta-naphthylamine must be mentioned because there is good evidence that this material is an etiologic agent in the formation of bladder tumors. (See under organic chemical compounds in the production of cancer.)

**Organic Insecticides.** In recent years, a number of organic insecticides of great toxicity to man have been developed. Unless adequate precautions are taken, cases of poisoning or even death may occur in persons employed in the manufacture or compounding of these chemicals, in agricultural workers who apply them, in persons who use these chemicals indiscriminately on their own property, in those who ingest them as spray residues on foods, or in others who come in contact with these materials. Because the general public may be exposed to these insecticides, information on their toxicity and methods of treatment are included in this text.

**TOXICITY OF ORGANIC INSECTICIDES.** Organic insecticides differ greatly in their chemical structure and properties and hence in the type and degree of toxicity they produce. A summary of the currently available information on the more common insecticides is given in Table 32-6. The Public Health Service (April 1955) has listed the following general suggestions for the treatment of persons poisoned by insecticides such as those presented in the table. Medical texts should be consulted for specific therapy.

#### GENERAL SUGGESTIONS FOR TREATMENT

In many cases of poisoning, the nature of the toxic agent is not known. The treatment is, therefore, symptomatic and may include:

1. Emesis and gastric lavage if poison has been taken internally.
2. Evacuation of the gut (avoiding oily laxatives where it is possible that an organic solvent or an halogenated insecticide is involved).
3. Thorough washing of the eyes or body if there has been external contact with the poison—wear rubber gloves while aiding the patient.
4. Supportive therapy. (a) Sedatives. Sodium pentobarbital is preferred for acute poisoning because of its rapidity of action. Phenobarbital is useful in maintaining a prolonged level of sedation in persisting neural hyperexcitability or convulsions.

(b) Stimulants. In treating vascular collapse, substances such as adrenalin should be used only after careful consideration, as they are contraindicated in poisoning by the halogenated hydrocarbon insecticides, even though the patient may be in severe depression or coma.

(c) Transfusions. In patients in extremis or extended syncope, transfusions may be indicated except where pulmonary edema is already present. If blood is not readily available or if dehydration is suspected, 5 per cent glucose or normal saline infusions are indicated.

(d) Oxygen therapy. Conventional oxygen-carbon dioxide mixtures should be administered to patients showing cyanosis or severe respiratory difficulty. Patients with pulmonary edema require oxygen under positive pressure as well as postural drainage and dehydration therapy until the exudate is checked.

It is understood that, if the nature of the toxic agent is known, the physician may be able to use a specific antidote to supplement the general treatment. In any event, the importance of general medical care in cases of poisoning should not be underestimated. Even when a recognized antidote is properly administered, the general care of the patient may do as much or more to insure his survival.

Methods for the prevention of harmful effects of insecticides are similar to the methods recommended on pages 1086 to 1090 for toxic compounds in general.

Table 32-6. Toxicity of common insecticides

COMPOUND	COMMON SYNONYMS AND TRADE NAMES	DANGEROUS ACUTE DOSE (GM.)	LOCAL EFFECTS	LOCUS OF ACTION	SYMPTOMS OF ACUTE POISONING	TREATMENT	TOLER- ANCE FOR RESIDUE ON FOOD P.P.M.
Benzene hexa- chloride	BHC, GBL, HCCl <sub>3</sub> , HCH, etc.	30	Irritation; some sensitization	CNS	Excitation, hyperirritability, loss equilibrium, convulsions, depres- sion	General.* Calcium gluconate	5
Chlordane	Lindane (gamma isomer)	7 to 15					10
	Octa-Klor, 1068, Dowklor, etc.	6 to 60	Irritation	CNS	Hyperexcitability, tremors, con- vulsions, depression	General.*	0.3
DDT	Dicophane, Gesarol, Neocid	30	None	CNS	Nausea, diarrhea, vomiting, nervous tension, paresthesia, diz- ziness, tremors, convulsions, de- pression	General.* Calcium gluconate	7
Demeton	Systox, E-1059	12 to 20		Inhibits cholinesterase	See parathion	General.* Atropin	0.75
Dieldrin (aldrin is chemically related compound)	Compound 497, Octalox	10 mg. kg. Much more toxic than DDT. Acute dermal toxicity		CNS	Headache, vomiting, nausea, diz- ziness, hyperexcitability, convul- sions, epileptic-like seizures. Chronic exposures—loss of appetite and weight	General.*	0.1
Diazinon	Prodan Bulan mixture	Unknown. Toxicity <DDT and> methoxychlor	None	Probably CNS	Probably similar to other chlor- inated hydrocarbons	General.*	
Diazotol	DNOG	2		Increased oxidative metabolism	Fever, sweating, rapid respira- tion, fatal hyperthermia. In cold, abolishes shivering with rapid body cooling	General.* Ice bath, O <sub>2</sub> intravenous saline, thioureacl	

Lethanes	Thiocyanates	28 to 70 of concentrates	Irritation			General *
Malathion	4049	Much less toxic than parathion		Inhibits cholinesterase	Depression, convulsions, dyspnea, cyanosis, respiratory paralysis	8
Methoxychlor		450	Slight irritation	CNS	See parathion	General.* Atropin
Nicotine		0.06	Irritation	Nervous systems	Questionable tremors, depression	14
Parathion	E-605, Compound 3422, Thiophos, Niran, Alkron, etc.	0.012 to 0.02 Acute dermal toxicity	Irritation	Inhibits cholinesterase	Tremors, convulsions, curare-like paralysis	2
					Headache, giddiness, disturbed vision, weakness, nausea, respiratory distress, sweating, miosis, lacrimation, salivation, pulmonary edema, muscular tremors, convulsions	General.* Atropin in large amounts. Medical observation for 24 hr.
Pyrethrins	Pyroicide, Kenya flower	100	None	CNS	Incoordination, tremors, muscular and respiratory paralysis	10
Rotenone		200	Irritation	CNS	Stupor, convulsions, respiratory depression	5
Tetraethyl pyrophosphate	TEPP, TEP, Bladex, Fosvex, Nifos, etc.	.025	Irritation	Inhibits cholinesterase	See parathion	General *
Toxephene	Chlorinated camphene, Compound 3956, Alltex, etc.	2 to 7		CNS	Excitement, epileptic form convulsions, depression, respiratory failure	7

\* The general principles of treatment for insecticide poisoning are given in the text. Table compiled from various sources listed under Insecticides in the text references.

However, since many of the insecticides are rapidly absorbed through the skin either in their natural form or in solutions, great care must be taken that such chemicals do not come into contact with the skin. Furthermore, special precautions are required when these chemicals are sprayed from airplanes, by farm machinery or by hand. Information regarding proper procedures for spraying insecticides can be obtained from the Occupational Health Field Headquarters, U. S. Public Health Service, Cincinnati, Ohio. The labels of the containers in which the insecticides are sold also give precautions regarding the handling of these materials. A 1948 federal law requires that insecticide, fungicide, and rodenticide products sold in interstate commerce be registered with the Secretary of Agriculture and adequately labeled for safety. Tolerances for residues of pesticide chemicals on foods are established under authority of the Federal Food, Drug and Cosmetic Act.

**ORGANIC PHOSPHATE INSECTICIDES.** Because the organic phosphates are new chemicals and are very toxic, these compounds will be discussed somewhat in detail. Much of the information presented here was prepared by a group of authorities on this subject and was published in a report of the Committee on Pesticides to the Council on Pharmacy and Chemistry of the American Medical Association, 1950.

The three important organic phosphate insecticides are tetraethylpyrophosphate (TEPP), hexaethyltetraphosphate (HETP), and Parathion (O,O-diethyl O-p-nitrophenyl thiophosphate). These compounds, which are sold under various trade names, are used principally as poisons for the control of aphids, mites, thrips, and other fruit and vegetable crop insects. Parathion is also used as a fumigant. TEPP and HETP hydrolyze rapidly; therefore, the danger of food contamination is less than in the case of parathion, which is absorbed by plants and may remain toxic for several days. These three chemical insecticides may be absorbed through the skin, respiratory tract, conjunctiva and gastro-intestinal tract. They are powerful poisons, since they are potent inhibitors of the cholinesterase enzymes. The chief manifestations, therefore, resemble those produced by excessive stimulation of the parasympathetic nervous system, central nervous system, and somatic nerves. TEPP and HETP are rapidly detoxified in the body and complete recovery follows a single sublethal dose. Parathion is detoxified much more slowly than the other two compounds. After repeated doses, an irreversible inactivation of part of the enzyme occurs which leads to a cumulative toxic action, especially in the case of parathion. Although TEPP and HETP are more acutely toxic than parathion, the latter is the most dangerous because of its greater stability. The acute effects of these poisons come on rapidly and last 6 to 36 hours. Death usually occurs in 10 hours or less. The symptoms should be treated chiefly with atropine. Although these chemicals have been used only for a few years, over 200 cases of poisonings with some deaths have occurred. About two thirds of the cases have been in agricultural workers and the other third in industrial exposures.

Rigid precautions must be taken in the manufacture and use of these toxic insecticides, particularly by agricultural workers. Within industries, they should be handled in enclosed systems or under adequate exhaust, as described later in this Chapter. Since they can be absorbed through the skin and eyes, personal protective equipment, absolute cleanliness, and careful handling are necessary. Empty drums should be washed with hot 5 per cent caustic soda and punched full of holes to prevent their re-use. Empty bags should be buried or burned. If spillage occurs,

should be absorbed in sawdust and then buried or burned. These chemicals should be sprayed in such a manner that they are carried away from the worker by the wind. Thirty days should be allowed after spraying before harvesting. Workers with any symptoms should report immediately to a physician and tell him the nature of the exposure. Grob (American Medical Association, 1950) recommends that periodic determination be made of the cholinesterase of plasma and red blood cells in persons who are frequently exposed to these substances. Persons showing reduced cholinesterase activity should be removed from all exposure until this activity has returned to normal.

**Organic Chemical Compounds in the Production of Cancer.** A considerable number of organic compounds have been shown to produce tumors when tested on laboratory animals. At the present time, proof of a carcinogenic activity in man is available for only a few of these compounds (Hueper, 1942).

Cancer of the urinary bladder has been reported in a number of workers in the organic dye industry. Although aniline has been mentioned repeatedly as the causative factor in these bladder tumors, the evidence both from industrial studies and from experiments on dogs has shown that the causative agent is beta-naphthylamine and that aniline itself is not carcinogenic. There is some evidence also that benzidine is a factor in bladder cancers. Periodic cystoscopic examination of exposed employees is now recommended for workers exposed to these substances.

Cancer of the skin has been reported to result from exposure to organic compounds in several occupations. In the petroleum industry, cancer of the scrotum has occurred in men who worked as pressmen in the paraffin department. It is thought that the carcinogenic substance is probably an aromatic oil contained as an impurity in the wax. It has been shown recently that the higher boiling fractions of petroleum produced by the catalytic cracking process contain substances which will produce skin cancer in a number of animals. Only the fractions which boil above 700° F exert a carcinogenic action. The chemical nature of the carcinogens is not known but it is believed that these substances belong to the aromatic series. No cancers have developed in workers handling this material. The absence of cases in the workers may be due to the fact that production of petroleum by catalytic cracking is a fairly recent process, or to the excellent preventive program which the oil companies have adopted. Cancer of the scrotum in mule spinners has been known for many years in England. The causative agent appears to be the crude Scottish shale oil used to lubricate the spinning machines. The oil soaks into the clothing of the workers and is then rubbed into the skin. The spindle oils used in America seem to be free from this carcinogenic effect, possibly because of greater refinement. Some of the cutting oils also appear to produce skin cancer. The carcinogenic properties of coal tar and pitch are well known. For example, cancer of the scrotum among chimney sweeps has been recognized for many years as an occupational hazard due to the soot.

## THE OCCUPATIONAL DERMATOSES \*

The term occupational dermatoses includes any abnormality of the skin which is related to the occupation. Numerically, the occupational dermatoses are by far

\* The material presented in this chapter has been derived chiefly from the lectures, scientific papers and the books of Dr. Louis Schwartz, formerly Medical Director, Chief, Dermatology section, Division of Industrial Hygiene, United States Public Health Service.

the most important of the occupational diseases and are responsible for more than half of all occupational disease compensation cases. Although occupational skin conditions may cause considerable loss of time from work, they are not usually sufficiently severe to produce permanent disability.

**Protective Mechanisms of the Skin.** The skin has certain barriers against injury. The cornified cells are quite resistant to most chemicals except the strong alkalis. The secretions of the skin form a protective covering against some chemicals and the pigment and thickness of the outer layers of the skin protect against ultraviolet radiation.

**Factors Predisposing to Occupational Dermatitis.** The occurrence of occupational dermatoses depends primarily on the nature of the causative agent and on the duration of exposure. In addition, there are a number of predisposing factors which influence the onset of these skin lesions. The presence of other skin diseases or lesions impairs the resistance of the skin to occupational substances. Lack of personal cleanliness is an important factor since failure to wash the skin or to remove soiled clothing increases the duration of exposure. The type of skin also plays a role. Persons with oily skins, such as Negroes and brunettes, are more susceptible to the oils and tars, whereas those with dry skin are affected more by the defatting agents such as the organic compounds. Younger persons have more acute dermatoses, whereas older persons have more chronic types. Males have a higher rate than females, probably because women take better care of their skin and seek medical attention sooner. There is more dermatitis in summer than in winter due to the fact that less clothing is worn and to the presence of sweat.

**Causes of Occupational Dermatoses.** The etiological factors responsible for the occupational dermatoses may be grouped into four classes: (1) mechanical and physical factors, (2) primary irritants, (3) sensitizers, and (4) biological agents. Among the mechanical and physical factors are heat and cold, and ultraviolet, x-ray, and other radiations (see Chapters 25 and 26). The biological agents encountered in industry do not differ from those which commonly cause skin affections outside of industry. The primary skin irritants and the sensitizers are of much greater importance industrially than the other two classes; therefore, this discussion will be limited to these factors.

A primary cutaneous irritant is defined as "an agent which will cause dermatitis by direct action on the normal skin at the site of contact if it is permitted to act in sufficient intensity or quantity for a sufficient length of time." (Schwartz and others, 1947.) It may exert a direct chemical or physical action on the skin. It may either form a new chemical compound or abstract some essential constituent from the skin. The primary irritants may act: (1) by dissolving the keratin, such as occurs with alkalis or soaps; (2) by dissolving the fat or cholesterol, as with organic solvents; (3) by dehydrating the tissue, as happens with inorganic acids and anhydrides; (4) by precipitation of the proteins, which occurs with some of the salts of heavy metals; (5) by oxidation of the cells, as with bleaches or chromates; (6) by action as reducing agents, such as with some organic acids; and (7) by a keratogenic action, which occurs with some coal tar and petroleum products. There are a number of primary irritants including the inorganic acids, alkalis, and the irritant metals or their salts, such as arsenic or chromium, and most of the organic compounds.

The second class of chemicals which produces occupational dermatoses are the sensitizers. These are usually defined as: "agents which do not necessarily cause demonstrable cutaneous changes on first contact but may effect such specific changes in the skin that, after five to seven days or more, further contact on the same or other parts of the body will cause dermatitis." (Schwartz and others, 1947.) It should be noted that sensitizers are not primary skin irritants but that some primary skin irritants can cause sensitization. The principal substances which produce sensitization in industrial workers are the synthetic dye intermediates, which are formed in the production of dyes from coal tar; the explosives, such as TNT and tetryl; photo developers; formaldehyde; some insecticides and fungicides; the rosins, synthetic resins and waxes; most plants, such as poison ivy; and cashew nut oil.

**Character of Lesions.** The character of lesions found in the occupational dermatoses are not specific for the particular causative agents. Acute and chronic eczema, folliculitis, acne-form lesions, and epidermal proliferation are common to occupational and nonoccupational skin affections. In occupational dermatoses, the site of the eruption usually appears first on the exposed parts or where friction occurs. Other areas may be affected when dust and fumes penetrate the clothing. Distant parts may be affected in cases of sensitization.

**Diagnosis of Occupational Dermatoses.** It is often difficult to determine whether an occupational exposure is responsible for the dermatitis, or if other factors have caused the condition. In order to answer this problem, the history of the disease and the character of the exposure must be known. If the dermatitis does not antedate the employment, but develops during the course of employment, improves within two months when away from exposure and increases again on re-exposure, the condition is probably of occupational origin if there is a substance capable of producing dermatitis present in the occupational environment. Patch tests, if performed intelligently and properly read and evaluated, are of value in the diagnosis of dermatitis resulting from contact with sensitizing agents. Patch tests are of no value in the case of primary irritants. The location and character of the lesion may also assist in determining the cause of the dermatitis.

**Prevention of Occupational Dermatoses.** Prevention of occupational dermatoses depends first of all on the general measures later described which will eliminate, as far as possible, contact of the workers with the dermatitis-producing agents. Where complete avoidance of contact cannot be obtained, personal protective measures should be utilized. These include protective clothing, protective ointments and personal cleanliness.

Protective clothing should cover every part of the body which is exposed to the irritating or poisonous substance, and should be made of materials which are impervious to the dermatitis-producing agent encountered in the particular exposure. Unfortunately, protective clothing is not always intelligently selected. One industry purchased rubber gloves to be worn when handling an organic compound which was a rubber solvent. Often the gloves or boots are too short or too loose at the top so that the harmful material gets inside and is rubbed into the skin. Protective clothing and, in some cases, underclothing must be supplied and laundered daily by the employer. Contaminated work clothing should never be worn away from the place of work.

Protective ointments of many types are available commercially. Some are resistant to water soluble, others to water insoluble substances, some fill the pores with an innocuous fat to keep the fat solvents from attacking the skin oil, and some contain detoxifying agents. Ointments for protection against ultraviolet rays are also available. When applied to the skin these form a film over the skin which may help to protect the skin. In actual practice, the chief value comes from washing them off, since the harmful materials are removed at the same time.

Personal cleanliness is the best safeguard against occupational dermatitis. If severe skin irritants or poisonous chemicals, which can penetrate the skin, touch the skin surface, they should be removed immediately with water. Adequate washing facilities including showers and soap, which will remove the dirt and chemicals but which will not harm the skin, should be supplied. Much dermatitis has been caused by the use of improper chemicals in cleaning the skin. Where particularly irritating or poisonous materials are used, showers should be required on company time. All of the personal measures recommended to protect workers from the occupational dermatoses are equally important to prevent the absorption of poisonous chemicals through the skin.

Pre-employment and periodic examination are important in the prevention of occupational dermatitis, but pre-employment patch tests are not recommended since they may produce sensitization. Workers should consult the industrial physician at the first sign of skin lesions. Authorities in this field believe that employees with mild reactions should be given protective clothing and allowed to continue at work during treatment, since they may develop an immunity to the irritant. Persons with severe dermatitis, who do not develop immunity, should be removed from their occupations or be transferred to other work.

### GENERAL MEASURES FOR THE PREVENTION OF OCCUPATIONAL DISEASES DUE TO CHEMICAL SUBSTANCES

Measures for the prevention of occupational diseases due to chemical contaminants fall into three groups: environmental control; personal control; and medical control.

Environmental controls, designed to prevent contamination of the air and all contact with the harmful materials, are by far the most important methods for protection against occupational diseases. Personal protective measures, on the whole, are of much less value in preventing occupational diseases but at times may be the only possible methods which can be used. Medical procedures are concerned chiefly with the proper placement of workers and the detection of excessive absorption and early toxic signs. Each of these three types will be discussed in some detail.

**Environmental Control.** Since occupational diseases result chiefly from contamination of the working atmosphere, engineering and other methods which prevent the materials from getting into the air are the most important protective measures.

**SUBSTITUTION OF MATERIALS.** The most desirable procedure to prevent dangerous exposures whenever possible is to eliminate the harmful substances from the process and to substitute materials which are nontoxic. For example, steel shot which does not lead to any known lung diseases, may be substituted for the dan-

erous silica sand in abrasive finishing of metal castings, and the aliphatic hydrocarbons can often be used in degreasing operations in place of the more harmful chlorinated hydrocarbons or benzene (benzol). However, substitution of less toxic materials is often not possible. In the case of the organic compounds, the less toxic material recommended as a substitute may be so inflammable that it may present a greater hazard than the more toxic material.

**TOTAL ENCLOSURE.** The best engineering procedure to prevent contamination of the environment consists of enclosing the harmful material in such a manner that it cannot escape into the air, so-called total enclosure. Examples of this type of equipment are tightly covered vats in chemical plants and closed abrasive blasting cabinets. However, totally enclosed processes are not completely satisfactory since the gases, dusts, or liquids may escape through leaks or breaks. Exposures also occur during the filling, emptying, cleaning, and repairing of the equipment. It is often necessary to supplement these units with exhaust systems.

**LOCAL EXHAUST SYSTEMS.** Local exhaust systems are designed to draw air into an exhaust hood by means of suction. When the hood is properly designed, the air current produced by the suction will draw the dusts and gases into the hood. The contaminating material is carried in the air stream through ducts, either to collecting units or to discharge stacks. Dusts may be collected in gravitation, inertial or cyclone separators, settling chambers, in liquid collectors, or by filtration, electric precipitations, impingement, scrubbing, or supersonic sound. Gases may be washed out of the air or treated chemically to reduce them to inert materials. If dusts or gases are discharged into the atmosphere, care must be taken that they do not contaminate nearby operations or the general atmosphere. The design of exhaust systems requires the services of trained industrial hygiene engineers since practically every system presents specific individual problems.

**GENERAL VENTILATION.** Prevention of excessive contamination of the air may be achieved at times by rapid change of air in the workroom. This may be accomplished by forcing air into the workroom or drawing air out of the room by a general exhaust system. General ventilation is more effective in the case of gases than dusts since air movement merely tends to stir up dust.

**WETTING OF DUSTS.** Wet processes for prevention of air contamination with dust involve the application of water to the dust particles as they are formed. Some dusts wet easily whereas others do not. Water sprays are of little value in eliminating most dusts once they get into the air. The dusty water must be removed before evaporation takes place.

**PROCESS CONTROL.** In some cases the process can be organized so that exposure of the workers is held at a minimum, even when dangerous materials are used. An excellent example of this is the common degreasing operation. If degreasing tanks are properly operated, evaporation of the solvent in the air, and thus the degree of exposure of the workers, can be kept at a minimum. Adequate temperature control, slow removal of the objects, little surface agitation, and protection from air currents are all essential in preventing excessive evaporation. Another example of process control is the elimination of carbon monoxide by the proper adjustment of the fuel-air ratio in stoves, motors, etc.

**ISOLATION AND SEGREGATION OF HARMFUL OPERATION.** When it is not feasible to eliminate dangerous operations, it is sometimes possible to isolate or segregate

them so that workers not directly concerned with these processes are not exposed. For example, chemical operations producing highly toxic materials can be located in a separate building. Not only may hazardous operations be isolated in regard to space, but some processes may be postponed until after the majority of the workers have left the environment.

**GOOD HOUSEKEEPING.** One of the most important measures for preventing contamination of the working area is good housekeeping. There are plants, even today, where waste materials capable of producing fatal diseases have settled on the floors, rafters, and ledges, only to be dispersed into the air by the vibration of machinery or the feet of workmen. There are many plants where the daily cleaning consists solely of stirring up the dust with a dry broom. Considerable contamination can be eliminated by good housekeeping procedures such as vacuum cleaning, use of wetting agents in sweeping, proper collection and disposal of waste materials, and immediate removal of harmful chemicals when spilled on the floor or table.

**PLANT AND EQUIPMENT DESIGN.** Exposures to hazardous substances can be prevented by the proper design of plants and equipment. It is far less expensive to incorporate engineering control features into a plant and equipment in the design stage, than to add them after the plant is built and the machinery is installed. Furthermore, the control measures are more efficient when they are designed as part of the original plan.

**UPKEEP OF CONTROL EQUIPMENT.** Like all mechanical equipment, exhaust systems and other control features should be maintained in good repair.

**PERIODIC ENVIRONMENTAL SURVEYS.** Periodic air analyses are necessary when dangerous substances are used in order to assure safe working conditions.

**Personal Control.** When it is not possible or practical to control the environment in which a person works, personal control measures become necessary. These measures include: personal equipment for protection of the respiratory tract, eyes and skin, personal health habits, and other personal procedures.

**PERSONAL PROTECTIVE EQUIPMENT.** *Respiratory Protective Equipment.* Respiratory protective devices, such as gas masks and respirators, are widely employed in industries because they are cheap and can be purchased easily. In many industries, it is assumed that such devices will offer complete protection from harmful materials in the air, if worn during the entire work shift. In reality, however, these devices should be considered only as temporary measures to be used in cases of emergency, for a short period of work or during an interval while environmental control measures are being installed. They may be recommended in rare circumstances if only a very few men are exposed or if the cost of environmental control measures is absolutely prohibitive. They are not adequate for continuous use day after day and should not be used as a substitute for environmental control measures. Furthermore, workers will not wear respiratory protective devices constantly. Anyone who has ever tried to wear even the most modern respirators soon discovers that they are annoying, hot, and uncomfortable. The workers usually hang them on a hook nearby or around their necks, except when the manager or visitors are inspecting a plant.

Respiratory protective devices are, however, invaluable for emergency use, and in some circumstances, they are the only type of protection which can be used. When they are employed, certain precautions should be taken. The type of device pro-

phased must be suitable for the exposure; the device should fit the employee; it should be kept clean and in good condition; and it should be sterilized before being assigned to another employee. The United States Bureau of Mines has developed a system for testing and approving all types of respiratory devices which are submitted by the manufacturers. The approval, if granted, states the type of substance and the circumstances for which the device is approved. The Bureau of Mines' approval number is stamped on each device. Lists of approved models for each specific exposure are published periodically by the Bureau of Mines and may be obtained free upon request. This system of approval has been an excellent safeguard against the use of inadequate protectors.

The personal protective devices which have been approved by the Bureau of Mines fall into five general types:

**Self-contained breathing apparatus.** This type of equipment supplies oxygen directly to the wearer. Hence, it is suitable for any atmosphere. It can be used only for short periods.

**Gas masks.** The cannister attached to the mask filters out the gases or vapors from the air as it is inspired. Gas mask cannisters must be replaced after two hours or less depending on the concentration of the gas in the air. Cannisters are made for individual gases and for a mixture of gases commonly found in industries. These gas masks are similar to those used for protection against war gases.

**Supplied-air respirators.** These respirators are connected with a hose through which uncontaminated air is supplied to the wearer. In some models the wearer draws air through the hose as he breathes, but in the majority of cases compressed air is supplied. Supplied-air respirators can be used only in limited areas and where an uncontaminated air supply is available. Care must be taken that the compressed air does not contain carbon monoxide, which may be liberated by compressors with an internal lubricating system.

**Dispersoid respirators for dusts, fumes or mists.** These respirators cover only the nose and mouth. They are designed to filter out pneumoconiosis-producing dusts, toxic dusts and fumes, mists, or a combination of the various dispersoids.

**Nonemergency gas respirators or chemical cartridge respirators.** These respirators are approved for respiratory protection in atmospheres not immediately dangerous to life or containing not more than 0.1 per cent organic vapors by volume. The cartridges are similar to the gas mask cannisters which are used for organic vapors but are much smaller in size.

**Eye Protective Equipment.** Wherever there is danger of splashing harmful chemical materials into the eye or the possibility of dust, chips, or other solid particles getting into the eye, protective goggles should be required. Heat-treated goggles, which will withstand sharp blows and pressure, are now available at low cost. Individual lenses can be ground in this type of resistance glass. Eye accidents have been greatly reduced in plants where everyone entering the plant is required to wear goggles.

**Skin Protective Equipment.** Protective clothing and ointments have been discussed in connection with occupational dermatoses.

**PERSONAL HEALTH HABITS AND OTHER PERSONAL PROCEDURES.** Personal cleanliness is one of the most important measures in the prevention of occupational diseases of the skin and in the prevention of systemic poisoning caused by absorp-

tion of chemicals through the skin. Frequent washing of the hands, showers at the end of work shifts, and clean work clothes, including underwear, are necessary in some occupations.

Contamination of the mouth with toxic chemicals, either directly or through the hands, should be avoided. The tragic death of the early radium dial painters was due to their habit of moistening the tips of their brushes with their lips.

Since food or tobacco may become contaminated, it is dangerous to take them into the work room where toxic chemical substances are present. A clean place where workers can eat their lunch is desirable under all circumstances, but is absolutely necessary when harmful materials are present. Adequate nutrition and the avoidance of excessive consumption of alcohol are factors in the prevention of some occupational diseases. Where environmental controls are not possible, reduction in the duration of exposure by rotation of jobs may be a sound procedure for preventing occupational diseases.

**Medical Control.** The medical department of a plant or, in the case of smaller plants, the consultant physician can play a major role in the prevention of occupational diseases as well as in their treatment. A medical program directed toward this objective includes the following functions:

**EXAMINATION OF EMPLOYEES.** Medical examinations of employees, which are made at the time of placement, upon return to work after an illness, and at periodic intervals, are all of value in preventing occupational diseases. By the preplacement examination, a physician can exclude susceptible persons from hazardous exposure, such as tuberculous patients from exposure to silica, anemic patients from exposure to benzol, or those with skin diseases from exposure to skin irritants. Examination at the onset or after a nonoccupational illness are important since they help the physician to determine whether the industrial exposure contributed to the illness. Periodic examinations are the most important medical procedure for preventing occupational diseases, since they aid in detecting early signs of excessive absorption of toxic substances or early symptoms of illness. For example, regular periodic blood studies are used to detect excessive lead absorption, and periodic roentgenograms are made to determine the presence of early silicosis or berylliosis. The frequency and type of periodic examination varies with the character and extent of the exposures. Annual examinations may be sufficient for silica exposures, monthly examinations are necessary in some lead exposures, and daily inspection for methemoglobin may be necessary for aniline or nitrobenzene workers. Early detection and treatment often prevent more serious occupational illness.

**ANALYSIS OF MEDICAL RECORDS.** If the medical personnel keeps complete medical records and analyzes them, they can often spot operations in the plant which are producing hazardous conditions. One medical director maintains a chart of the plant layout on which all cases of injury or illness are marked. When abnormal rates are found in any area, the working conditions are investigated.

**KNOWLEDGE OF PLANT PROCESSES AND MATERIALS.** One function of the plant physician is to be completely familiar with every material used or produced in the plant. He should advise the manager concerning the toxicity, the mode of absorption, the type of effect which may result from excessive exposure to the material, and the maximum concentration in the air which is considered safe. He should also suggest the use of less toxic materials wherever possible. It is well for the physician

physician to receive copies of all orders for new chemicals, so that, if toxic chemicals are ordered, he can warn the plant manager about the hazards which these may present before dangerous exposures occur.

One of the duties of the industrial physician is to inspect regularly all processes in the plant which present occupational disease hazards, especially where cases of occupational diseases may be expected.

**EDUCATIONAL ACTIVITIES.** Another responsibility of the industrial physician is to educate the workers in the care of their health. Most authorities believe that workers should be told when their exposure presents a danger to health since this may lead to greater caution in handling the material. Some authorities, however, believe this procedure is unwise since it may lead to unnecessary worry on the part of the worker. The foremen in a plant should be instructed by the physician to watch for any evidences of harmful effects and to report these at once. All workers should be urged to report at once any early indisposition, skin conditions, foreign bodies in the eye, and other symptoms of injury or illness to the medical department. Workers should be carefully trained to avoid unnecessary exposures.

It is evident from the above discussion that prevention of occupational diseases is a cooperative undertaking requiring the active participation of medical personnel, engineers, and the workers. Of even greater importance, however, is the participation of management. Only when management is willing to back up a sound preventive program can occupational diseases be eliminated from a plant.

## GENERAL HEALTH OF THE WORKING POPULATION

### SICK ABSENTEEISM IN THE INDUSTRIAL POPULATION AND ITS PREVENTION

Industrial hygiene, according to the modern concept as outlined in Chapter 31, includes not only the prevention of occupational diseases, but also the prevention of nonoccupational illness and the promotion of the health of the working people, insofar as this is possible within industry. In recent years, the extent of absenteeism due to nonoccupational illness and accidents in the employed population has become a matter of concern to industrial managements. A survey of industries, made by the American College of Surgeons in 1938, indicated that the average worker lost almost 10 days annually due to sickness and accidents. Of this lost time, only 0.1 day was attributed to occupational diseases and 0.6 day was due to industrial accidents. Nonoccupational illness and accidents accounted for the remainder of the days lost. Since absenteeism, especially short-term absences, interferes greatly with production, nonoccupational sickness is a major problem to management as well as to health authorities.

In order to prevent nonoccupational illness, it is first necessary to determine the extent and causes of illness in the working population and to determine the various factors which influence this illness. With the exception of the National Health Survey and a few family surveys in local areas, the data on the extent of illness in the adult working population has come chiefly from industrial sickness records. Medical records covering all types of illness now are kept by many of the larger plants, but published data are available only for illnesses causing absenteeism. Unfortunately, statistics on sick-absenteeism have many limitations. However, considerable information regarding the illness of the adult working population may be obtained from industrial records.

**Incidence and Cause of Sick-Absenteeism.** The most accurate statistics on the incidence and causes of sick-absenteeism are obtained from the records of the industrial sick benefit societies. The United States Public Health Service has been collecting and publishing such data for large groups of workers for many years. The most recent figures from this source, an average for the years 1943-1952, are produced in Table 33-1. Unfortunately, these records cover only disabilities lasting eight consecutive days or longer and hence do not give a complete picture. The majority of absences due to sickness are of short duration; one third of the total number last only one day and two thirds last only three days or less. Data which include these shorter absences are not available for groups of employees.

Table 33-1. Annual number of absences per 1,000 persons on account of sickness and non-industrial injuries disabling for 8 consecutive calendar days or longer, by cause; experience of male and female employees in various industries, 1943-52 <sup>1</sup>

	ANNUAL NUMBER OF ABSENCES PER 1,000 PERSONS, 1943-52 <sup>2</sup>	
	Males	Females

\* The number of days of disability is the number of calendar days from the date disability began to the date of return to work, or to the 372nd day, inclusive.

Number of person-years of exposure: Males, 13,436; females, 2,730.

Reference: Gafafer, W. M., U. S. Public Health Service, Personal Communication, December 1, 1955.

Examination of Tables 33-1 and 33-2 reveals some very interesting facts regarding sick-absenteeism in the working population. First, the frequency and the disability rates of sick-absenteeism are much greater for women than for men for all three of the major disease groups, i.e., the respiratory, the digestive, and the nonrespiratory-nondigestive groups. On the other hand, the severity rate, i.e., the average number of days lost per absence, is much greater for men than for women. In other words, women have more frequent illnesses and lose much more time each year due to sickness, but men have longer illnesses when they are sick. This greater frequency of sick-absenteeism among women occurs for most of the diseases, both acute and chronic, which are common to both sexes. The difference is especially marked for those diseases classified as neurasthenia and the like. The only diseases which occur with considerably greater frequency in men than in women are pneumonia, diseases of the stomach, hernia, and diseases of the heart and arteries. This excess sickness among women has been reported in almost all studies of industrial groups, in surveys of the general population, such as The National Health Survey, and in the records of the Women's Army Corps during World War II.

"The reason for the excess sick-absenteeism among women as compared with that among men is not entirely clear. It would not seem to be due to a difference in sex susceptibility to disease, since the mortality rate for males exceeds that for females at all ages." The excess frequency rate appears to be due, in part, to the fact that women take their minor illnesses more seriously than men, since the average duration of sick-absences is shorter for women than men. "Many persons believe that the excess sick-absenteeism among industrial women is due to the fact that they frequently attempt to do two jobs at once, their work in industry plus their duties at home, which may demand heavy labor, worry, and interference with proper rest." Some women have a less serious attitude toward their work than men and may take time off for minor ailments or report unjustified absences as due to sickness more frequently than men. (Baetjer, 1946.)

The second interesting fact evident from Table 33-2 is the importance of respiratory diseases as a cause of sick-absenteeism. This group of diseases accounts for about 50 per cent of the number of cases each year and also 50 per cent of the annual number of days lost. The respiratory diseases are mostly of short duration with an average lost time per case of about five days. Even when only those absences of more than one week are considered (Table 33-1), the respiratory diseases continue to be the most important group.

On the whole, it seems that men lose an average of about 8 days and women 11 days per person per year due to sick-absenteeism. In general, about 2 to 3 per cent of the male employees and 3 to 4 per cent of the female employees are absent each day because of illness and injuries. However, it must be remembered that these are average figures for a group. Industrial physicians have estimated roughly that about 60 per cent of the sick-absenteeism is attributable to about 15 to 20 per cent of the employees and that many workers lose no time at all through illness.

**Factors Affecting Sick-Absenteeism.** The extent of sick-absenteeism in industry varies with a number of factors, the most apparent being age, season, day of the week, and economic conditions. With regard to age, the incidence of minor respira-

tory diseases decreases with age, whereas the chronic diseases, as would be expected, increase in frequency and duration with age.

Sick-absenteeism is much higher in winter than in summer because of the excess of respiratory infections. Absences due to diseases of the central nervous system and to digestive diseases are reported to be greater in summer. The number of cases of sickness causing absences of eight or more days shows a marked variation according to the day of the week. In one company, about 30 to 40 per cent of the absences begin on Monday and 60 to 70 per cent of them terminate on Monday. This custom of trying to "hold out" until the end of the week to stop work and waiting until the beginning of a week to return to work is quite common. Economic

fig. 33-1. Annual number of absences lasting 1 day and longer due to sickness per 1,000 employees, distribution by year.

Factors appear to influence the rate of sick-absenteeism. There is evidence that the greater the sick benefit allowances, the higher the incidence of sick-absenteeism. When payments are made for absences of short duration the frequency of both short and long-term absences appears to increase. In other words, sick-absenteeism is greater when persons can afford to take time off from work. The incidence of sick-absenteeism has shown marked variations over the past 30 years. The trends in sick-absenteeism for cases lasting one day or longer and for cases of eight days and longer are shown in Figures 33-1 and 33-2. These figures show that absenteeism due to illness was low during the years of depression but increased greatly during World War II. This sharp rise may have been due to the employment of persons who were less physically able to work, to the extra work and worry during war time, or to economic factors. The sick-absenteeism rates for men have returned

toward the normal level since the war, but, in the case of women, the rates for absences of eight days and longer have remained excessively high throughout these post-war years. The causes of these continued high rates are not immediately clear.

There are not enough data at present to draw any conclusions about the relation of sick-absenteeism to type of occupation or to hours of work. Also, it is not possible to evaluate the various psychological factors which affect sick-absenteeism rates.

From Gafafer, W. M., U. S. Public Health Service.

Fig. 33-2. Annual number of absences lasting 8 days and longer due to sickness per 1,000 employees, distribution by year.

**Methods of Reducing Sick-Absenteeism.** Although the prevention of non-occupational diseases is not primarily the responsibility of industry, there are many procedures which can be used within industry to reduce sick-absenteeism and to prevent illness. The medical procedures and industrial hygiene programs are described in Chapters 32 and 35. In addition to the work of the medical and industrial hygiene departments, good personnel and management practices undoubtedly affect the incidence of sick-absenteeism. In recent years, it has become evident that the proper selection, placement, training, and supervision of workers is of great importance, not only for efficient plant operation, but also for the health of the workers. A good placement service requires the cooperation of the medical and personnel departments and knowledge of the physical and psychological requirements of the job. In the larger plants, the personnel department should evaluate the ability, background, education, and skill of the applicants, and the medical department

ould judge their physical and emotional fitness. The medical recommendation and e personnel findings should be matched against the job requirements, and each orker should be placed in a job which is compatible with his physical and psy- nological fitness.

The type of supervision is of greatest importance in industrial health. The fore- an has the opportunity to know his men well, so that he can detect early symp- ms of illness. He can often elicit information concerning the social and economic ctors which are leading to worry and sick-absenteeism. On the other hand, poor upervision can lead to discontent, nervous conditions, and even illness. Good lations between employees, and between employees and management, are also mportant factors in the prevention of sick-absenteeism. Persons who are working a good social environment, who are engaged in work which matches their yysical and mental capacity, and who are properly trained and supervised are ss likely to develop those diseases which are influenced by unfavorable psycho- gical factors than are employees who are working under mental stress.

### ACCIDENTS

**General Considerations.** Accidents have now assumed the fourth place as a use of death in the United States. They rank first as a cause of death for the es 1 to 35 years, fourth for the ages 45 to 64 years, and fifth for ages over years. Not only are accidents important because of the large number of deaths ey cause, but also because of the staggering number of persons who are injured. Approximately 90,000 deaths and 9,050,000 injuries are caused annually by acci- ents.\* The distribution of these cases according to the place of occurrence is

Table 33-3. Number of deaths and nonfatal injuries according to principal classes of accidents, United States, 1954

CLASS	NUMBER OF DEATHS	NUMBER OF NONFATAL INJURIES
all classes	90,000	9,050,000
Occupational *	11,200	1,750,000
Public *	15,500	1,950,000
Home *	27,300	4,100,000
Motor vehicle		
Public	33,000	1,150,000
Occupational	2,800	100,000
Home	200	(negligible)
Total motor vehicle	36,000	1,250,000

From Accident Facts, 1955 Edition, National Safety Council, page 3.

\* Exclusive of motor vehicle accidents.

own in Table 33-3. Although motor vehicle accidents are responsible for the atest number of deaths, home accidents cause by far the largest number of uries. The preponderance of home accidents is undoubtedly due to the fact t more man-hours are spent in the home than in any other place. Occupational idents and public accidents, exclusive of those involving motor vehicles, each se less than half as many deaths as home or motor vehicle accidents.

\* Figures based on 1954 data, published 1955 by the National Safety Council.

Table 33-4. Number and rate of deaths according to type of accident, United States, 1954

TYPE OF ACCIDENT	NUMBER OF DEATHS	DEATHS PER
		100,000 POPULATION (adjusted for age)

Service	2,300	16	380,000	2,600
Trade	1,300	11	340,000	2,880

From Accident Facts, 1955 Edition, National Safety Council, pages 6 and 7

When the death rates are listed according to the type of accident (Table 33-4), it is evident that motor vehicle accidents rank first, and falls second, as the cause of death. However, this distribution varies somewhat according to age. Motor vehicle accidents rank first at all ages under 65 years; drownings are the next principal cause of accidental death in the age group 5 to 44 years, falls rank second in the age group 65 years and over.

**Occupational Accidents.** The accident rate varies greatly for the different occupations. The number and rates for deaths and injuries due to occupational accidents is shown in Table 33-5 for the principal industrial groups. The most dangerous occupational group is that listed as "mining, quarrying, oil and gas wells." The distribution of occupational accidents according to the source of the injury is shown in Table 33-6. The comparatively low accident rates for many occupations

due to the excellent safety programs which are sponsored by the industries. The Workmen's Compensation Laws have been responsible in a large measure for stimulating activity in this field.

Some figures are available to compare the amount of absenteeism from work due to industrial injuries with that due to illness and non-industrial injuries. A study (Accident Facts, 1950) of about 150,000 workers in various industries showed that less than 2 per cent of all absences lasting one day or longer were due to work injuries while approximately 61 per cent were charged to illness and non-industrial injuries. The average number of days of absence due to occupational injuries was 0.6 days per worker per year and 6.5 days for nonindustrial accidents and diseases. Similar figures comparing men and women are given for a public utility company in Table 33-2, page 1097. The injury rates in this company were far lower than the sickness rates. The women employed by this company had higher rates than the men for nonindustrial injuries, but lower rates for industrial injuries.

**Accidents in Public Places.** The number and rate of deaths due to accidents in public places in 1954 is shown in Table 33-7. Motor vehicles are, by far, the most important cause of accidents in this class. When the motor vehicle accidents are analyzed by the death rate per mileage traveled, it is found that more fatal accidents occur in rural areas than in urban areas and more occur at night than during the

Table 33-7. Accidents in public places: number and rate of deaths according to type of accident, United States, 1954

TYPE OF ACCIDENT	NUMBER	DEATHS
	DEATHS	PER 100,000 POPULATION
Motor vehicle	36,000	23.3
Drownings	4,000	2.5
Transportation (other than motor vehicle)	3,500	2.2
Falls	3,100	1.9
Firearms	1,100	0.7
All other	3,800	2.4

From Accident Facts, 1955 Edition, National Safety Council, pages 57, 72 and 73

day. There has been a downward trend in motor vehicle accidents from 1925 to 1954. The number of deaths per 100 million vehicle miles was estimated at between 15 and 20 in 1925, whereas in 1954 it was 6.4. In 1935 approximately 30 out of 100,000 people were killed by motor vehicles. In 1954 the rate was 22.3 out of 100,000. The chief causes of motor vehicle accidents in general is considered to be excess speed, failure to give right of way, driving on the wrong side of the road and driving under the influence of alcohol. A driver or a pedestrian was reported to have been drinking in one out of four fatal accidents. Drivers under 25 years of age seem to have the greatest number of accidents.

**Home Accidents.** The number and rate of deaths according to the type of accident in the home is given in Table 33-8.

Table 33-8. Home accidents. Number and rate of deaths according to type of accident, United States, 1954

TYPE OF ACCIDENT	NUMBER	DEATHS
	DEATHS	PER 100,000
Total	27,500	17.1
Falls (Principal cause in ages over 45 years)	13,800	8.6
Fire burns and other injuries associated with fire (Principal cause 1-44 years of age)	5,200	3.2
Mechanical suffocation (Principal cause in age group under 1 year)	1,400	0.9
Poisons, solid or liquid	1,150	0.7
Poisonous gas	1,000	0.6
Firearms	1,050	0.7
Other	4,600	2.7

From Accident Facts, 1955 Edition, National Safety Council, pages 86 and 87

The United States Public Health Service made a study of accidents occurring in urban homes as a part of the National Health Survey (Britten and others, 1940). The annual frequency of home accidents disabling for one week or more was 4.65 per 1,000 persons. The distribution by age and sex is shown in Figure 33-3. The annual frequency per 1,000 persons was 2.99 for falls, 0.61 for cutting and piercing instruments and 0.38 for burns. Burns were the chief cause of home accidents.

ents in young children, whereas falls were responsible for most of the accidents in the older ages, especially in women. Persons in poor economic circumstances had more home accidents than did persons in the higher economic income brackets. This was believed to be due in part to poor housing conditions.

Male, ———; Female, ..... .

Fig. 33-3. Annual frequency (per 1,000 persons) of home accidents disabling for 1 week or more, by age and sex. (From Britten, R. H., and others, Pub. Health Rep., 55:2065, 1940.)

**Factors Affecting Accidents. SEX.** There is not sufficient evidence at the present time to state whether women are more or less prone to accidents than men, but experience during World War II did not indicate any greater susceptibility of women to accidents. Differences in rates between men and women appear to be due to differences in exposure.

**AGE AND EXPERIENCE.** Industrial accidents are more frequent among young inexperienced employees than among more experienced workers. Home accidents

are more frequent among older persons. The death rate from motor vehicle accidents is highest in the age group 15-24 years and again at the older ages, 65 years and over.

**FATIGUE AND HOURS OF WORK.** Although fatigue undoubtedly affects accidents, there does not appear to be any relation between frequency of accidents and hours of work except when the hours of work are very long (over 60 per week).

**PERSONALITY.** It has been shown that the majority of accidents occur among a relatively small group of people. There is no doubt that certain persons are more prone to accidents than other persons and that these persons are accident-prone in any occupation. Psychiatrists have studied this problem and have described the personality structure of the accident-prone type as a person who is decisive or even impulsive, a person of action, and not of planning or deliberation.

**PHYSICAL DISABILITY.** The relation of physical disabilities to accidents undoubtedly varies with the type of disability and the circumstances. The disabilities associated with old age must be responsible for the high incidence of falls in the older age groups. However, there is no evidence that physically handicapped persons in industry are especially liable to occupational accidents. The Bureau of Labor Statistics studied this problem in 11,000 impaired workers and 18,000 unimpaired workers. An account of this in "Accident Facts" states: "According to this study, workers with serious physical impairments are no worse accident risks in manufacturing industries than workers without impairments who are performing the same kind of work. . . . In fact, the record of disabling injuries was better for the impaired than the unimpaired workers. No disabling injury to an impaired worker could be traced to his impairment nor were any cases found in which the impairment caused an accident resulting in injury to a fellow worker." (Accident Facts, 1950, page 41.)

**Prevention of Accidents.** In the past, prevention of accidents was not considered a function of public health departments, industrial medical departments, or of any other type of medical personnel. In very recent years, this point of view has changed and public health authorities are beginning to take some part in the prevention of accidents. This would seem to be very desirable, particularly since human failure is the principal or contributing factor in the majority of accidents. Armstrong (1949) has recently discussed the problem of accident prevention: ". . . There is no simple solution to the accident problem, nor can a control program be centered exclusively on any of the various elements involved, such as education, engineering science, and technological progress, or physical status and fitness. Education is certainly important; but educational efforts must be aimed at motivation and as yet we are not quite sure how either children or adults should be motivated to prevent accidents. Engineering science cannot provide the whole answer because many people who are exposed to the same potential accident situations will not suffer any mishap, whereas the 'accident-prone' individual will. We should know why. Again, many feeble and infirm people successfully avoid injury and death from accidents year after year, while more physically robust and healthy individuals suffer repeatedly from accidents. These simple facts alone lead to the belief that there are more deep-seated causes of accidents than senility, poor health, and faulty or unsafe environmental conditions. Probably profound emotional and psychological factors are involved. The fact that in the average experience, a large percentage of accidents occur to a surprisingly small percentage of people should arouse the

curiosity of any health officer. Complex, many-sided, and challenging are the factors which must be taken into account in the field of accident prevention. . . .

" . . . Health departments contain all the elements—the epidemiological experience, the statistical knowledge, the engineering talent, the home and other contacts through the nursing services, and the educational facilities—needed to develop an accident prevention program that, with more information as to etiology, should substantially reduce the number of accidental deaths and permanent disabilities. . . ."

### HEALTH PROBLEMS OF WOMEN IN INDUSTRY \*

The number of gainfully employed women in the United States has been gradually increasing throughout the past century and is now between 18 and 19 million as shown in Figure 31-1, page 1030. Their distribution by occupational and industrial groups is given in Table 31-1, page 1030.

The employment of women creates certain health problems which are associated with their normal physiological processes of pregnancy, menstruation, and the menopause. In addition, there are certain other health aspects, which have been discussed, in connection with the employment of women. These include their strength and ability to work in relation to the type of job, their susceptibility to accidents and occupational diseases as compared with men, and their nonoccupational sickness.

**Relation of Industrial Work to Pregnancy.** When large numbers of women in the younger age groups are employed, the problem of pregnancy in relation to their employment must be considered. In 1953, there were over 12 million women between 14 and 44 years of age who were gainfully employed in the United States. Of this number, about 6,500,000 were married, with husbands present. During World War II, it was estimated that three to six new cases of pregnancy occurred per month per 1,000 women workers. There are no sound data available at present to determine whether the gainful employment of women during pregnancy affects the course of pregnancy, diseases of pregnancy, incidence of spontaneous abortions, premature births or infant death rate. Although some studies on this subject have been published, the results are contradictory and difficult to interpret. Health authorities, in general, believe that it is safe for pregnant women to continue work, at least during the first six months of pregnancy and usually longer, if their health permits and if the character of their work is suitable.

Recommendations concerning the employment of pregnant women have been published by various governmental and private agencies and include the following points: pregnant women should not be employed on work which requires heavy lifting, constant standing, constant moving, or good balance; they should not be exposed to dangerous concentrations of toxic chemical substances, such as lead, mercury, carbon tetrachloride, and others, or to ionizing radiation, since such exposures may exert a harmful effect on the course of pregnancy or on the fetus; and they should not work more than 48 hours per week and preferably not more than 40 hours.

\* The material presented in this section is taken directly from a review of this subject entitled *Women in Industry—Their Health and Efficiency* by A. M. Baetjer, Philadelphia, W. B. Saunders Co., 1946.

It is suggested that pregnant women should cease work at least six weeks prior to delivery and should not return to work until at least six or eight weeks after delivery. These suggested periods are not based on scientific data but represent the current medical opinion. Each case should be handled individually on the recommendation of the woman's physician and under the supervision of the medical department of the plant. Pregnant women should be encouraged to report their condition to the medical department with the understanding that their employment will be continued if their health permits. The policy of dismissing pregnant women as soon as their condition is known or of refusing to hire married women because of the possibility of pregnancy is a very undesirable policy and, at times, may be even dangerous. Under such circumstances, women who desire to work will claim to be single and will hide their pregnancy until their condition becomes obvious, which is usually not until the last half of pregnancy. Since the period of greatest danger from the viewpoint of spontaneous abortion is during the first trimester of pregnancy, it is obvious that these women will continue to work without medical supervision during this period and may be exposed to harmful working conditions. On the other hand, when women are encouraged to report their pregnancies and are assured of continued employment, if their health permits, they can be placed on operations free from harmful conditions if their regular work is not suitable.

The fear on the part of industry that accidental trauma or physical strain encountered in industry might lead to abortions and compensation claims would seem unwarranted in view of the infrequency of abortions due to external trauma and the few compensation claims which have been reported on this basis.

**Relation of Work to Menstruation and the Problem of Dysmenorrhea.** The incidence of dysmenorrhea and the resulting lost time varies greatly in different industries since this condition is affected by psychological factors and is often used as an excuse for other causes of absences. Women engaged in sedentary work have a higher incidence of dysmenorrhea than those engaged in more active occupations. Lost time due to dysmenorrhea can be greatly reduced by certain types of exercises, education, provision of a place for rest and simple first-aid treatment. Statements have been made that exposure to toxic chemicals, heavy muscular work, vibration, constant reaching and stretching may cause or aggravate abnormal menstrual and other gynecological conditions, but proof of this is lacking at the present time. Experimental investigations are greatly needed in this field. "On the basis of the evidence available at present, it would appear that the ability of women to perform mental and muscular work is not altered by the menstrual cycle."

The problems associated with menopausal changes do not appear to be important in most industries at present. Many women suffer no ill effects. Even those who have symptoms of irritability and instability can be employed if their condition is recognized. In fact, it is often desirable for these women to be employed.

**The Ability of Women to Work.** Experience during World War II demonstrated "that properly trained women are capable of performing almost all types of work except those involving excessive muscular work. They are reported to be especially capable at jobs requiring manual dexterity and fine coordination." However, "women are, on the average, only 85 per cent as heavy as men and have only about 60 per cent as much physical strength. Therefore, they cannot lift or hold a

heavy weights, they cannot direct as much weight or strength to the pushing or pulling of loads and their grip is not as strong."

"Women are built on a smaller anatomical scale than men. Their standing and sitting heights, their arm length and size of hands and feet are all smaller. Because of this, machines built to the scale of men often require excessive reaching or stretching on the part of women, and the height of the work bench is often unsuitable. In order to make for maximum production and reduction of fatigue, the machine or the operation should be readjusted to the size and strength of women or else women should be properly selected in relation to the physical requirements of the job."

"Women, like men, vary in size and strength, but no significant correlation exists between weight or height on the one hand and strength on the other. The usual concept of employment personnel, that the heavy women are the strongest, is, therefore, not necessarily correct. The employment of heavy women is of advantage only if they can utilize their weight on their jobs. Heavy women whose weight is chiefly due to adipose tissue may make less desirable employees than thinner women."

"The fact that women are less strong than men does not necessarily imply that they will fatigue more easily except on jobs requiring heavy physical labor. Women may fatigue more rapidly than men but, if true, the rapid onset of fatigue is probably due partly to a lack of background training in industrial work and, chiefly, to the fact that they usually have household duties and responsibilities which require many hours of work in addition to those spent in industry."

"There are no data by which to estimate the incidence of strain and stress injuries among women or to determine whether women are more or less susceptible than men to injuries of the joints, such as tenosynovitis, bursitis, etc. resulting from vibration, friction, or trauma."

**Accidents and Occupational Diseases in Women as Compared with Men.** There is no reliable evidence to indicate that women are any less tolerant to the occupational poisons or occupational dermatoses than are men. There is, therefore, no reason why normal women, who are not pregnant, should be restricted any more than men from working at jobs which involve the use of toxic chemical substances. Under all circumstances the exposures should be kept below harmful levels.

"Women have a much lower rate of industrial accidents than men; especially fatal accidents, but a higher rate of nonindustrial accidents (exclusive of automobile accidents). This distribution is undoubtedly due to a difference in exposure. There is no sufficient evidence at present to state whether women are more or less prone to accidents than men, but experiences during the war did not indicate any greater susceptibility of women to accidents. As in the case of men, certain women appear to be more prone to accidents than others, and the majority of accidents usually occur among a relatively small group of employees."

## WORK AND FATIGUE

### INDUSTRIAL FATIGUE

**Nature of Fatigue.** The term "industrial fatigue" is a general expression which is used to describe many different, and often unrelated, conditions of the body. The only characteristics common to the various conditions which are called "industrial fatigue" are a decrease in the output of work and a conscious sensation of tiredness, both resulting from the preceding work. The nature of industrial fatigue is not understood, probably because of the various biochemical, physiological, psychological, and social factors which may contribute to the over-all state of fatigue. The role of these factors will be reviewed.

**BIOCHEMICAL FACTORS IN FATIGUE.** On the basis of fatigue studies on athletes, it was assumed originally that biochemical changes in the blood were responsible for the fatigue which occurs in men performing heavy physical work in industry. Studies of men employed in the iron and steel industry and in other heavy laboring jobs, however, have shown that such work does not lead to an accumulation of acid metabolites in the blood, to oxygen debt, to a fall in blood sugar, nor to an increase of acetone in the urine, which would indicate depletion of carbohydrate. Similarly, biochemical changes have not been demonstrated in the blood of persons engaged in light work requiring repeated coordinated movements. Again, though mental work utilizes carbohydrate material and is very dependent on an adequate oxygen supply, there are no measurable biochemical changes in the blood which account for the fatigue which results from close mental work.

**PHYSIOLOGICAL FACTORS IN FATIGUE.** The majority of industrial operations each day do not require heavy muscular work but rather repeated coordinated movements. Persons engaged in light repetitive work cannot maintain a high speed of production and a normal output indefinitely; their ability to work decreases, and they have a feeling of tiredness or fatigue after working for some time. The fatigue which develops under these circumstances appears to be due primarily to physiological changes in the central nervous system. In any activity involving the repeated use of a nerve pathway over a long period of time, changes may occur in the cell body, the synapse and the nerve ending. It is generally believed that fatigue under such circumstances is first evident in the higher nerve centers. The nature of the changes in the central nervous system are not known. In addition to the fatigue in the nervous system, some muscular changes probably are involved. The physiological changes which result from maintaining a constant posture, as described in the preceding chapter, and from the constant use of the eyes also contribute to the fatigue of industrial workers.

In addition to the physiological changes resulting from work, a number of physiological factors related to the environment also play a role in fatigue. Changes in the circulation and water and salt balance when working at high temperatures, changes in the body resulting from high pressures of nitrogen, and changes in the ear with noise are examples of other physiological factors in fatigue. (See Section 5.)

**PSYCHOLOGICAL FACTORS IN FATIGUE.** In addition to the physiological changes which result from industrial work, there are certain psychological factors, such as boredom, fear, or worry, which are of even greater importance in industrial fatigue. The work may be so monotonous that the output decreases and the worker develops an unpleasant sensation. There are, of course, certain persons who prefer routine and monotonous work and who are able to maintain a high rate of production under these conditions. This situation occurs when the operation becomes almost a reflex act, and the worker can devote his attention to day dreaming or to social conversation with his fellow workers. If, however, the individual devotes his attention to worry over home conditions or to brooding over real or imagined injustices of his work, the output will decrease and the worker will exhibit signs of fatigue. On the other hand, if the work is not monotonous but requires skill and attention beyond the capacity of the worker, here again early signs of a fatigue state may appear.

There is no doubt that fatigue results from mental activity. However, there are no data to indicate the type of alterations in the cerebral cortex which are responsible for this fatigue. In the case of mental work, the degree of interest and other psychological factors determine in a large measure the onset and extent of the resulting fatigue.

The emotional stresses, the constant worry and hurry, the pressure of modern work, the necessity of adjusting to different personalities, the feeling of responsibility, especially in executives, the fear of failure, and the insecurity of many jobs create certain psychological states which constitute the chief factors in the fatigue of many persons. These emotional states have a marked effect on the autonomic nervous system and thus on the fundamental mechanisms of the body and must lead to certain abnormal conditions in gastro-intestinal activity, in the circulatory mechanisms, in the endocrine balance, and in other functions of the body.

**ECONOMIC FACTORS IN FATIGUE.** The economic needs of a worker influence the amount of physical and mental effort which he puts into his work and influence his psychological adjustment to the work; thus, economic factors contribute to the condition of fatigue.

**SOCIAL FACTORS IN FATIGUE.** Industrial fatigue is greatly influenced by the social environment within the plant. The importance of this factor was well demonstrated by the Western Electric Company experiments (Roethlisberger and Dickson 1947). The congeniality of the group working together, the type of supervision, the interest of management, and, especially, the social organization in the plant were found to be the most important factors affecting output and fatigue. Social factors outside of industry also have a marked effect on industrial fatigue.

From the preceding discussion, it would seem probable that fatigue which results from industrial work under normal circumstances is largely due to physiological changes in the nervous system and to psychological factors. Only under certain circumstances do changes in the blood, circulation, water balance, and

Other physiological mechanisms appear to play an important role in industrial fatigue. It is evident from its nature that fatigue may be a normal result of a day's work from which one recovers at night by rest and recreation or that it may be a cumulative state leading to a chronic condition.

There are no adequate methods of measuring industrial fatigue. Because of the many psychological and emotional factors which are involved, the sensation of fatigue is no reliable measure of the changes in the tissues nor is it consistently related to the amount of physical energy previously expended. A person can control his sensation of fatigue and drive himself to continue work, even when exhausted, if the motive is sufficiently great. The work output is decreased in all types of fatigue no matter what mechanism is involved, but because of psychological factors, the capacity to work may not vary in proportion to the amount of previous work and often the output does not indicate the actual capacity to work; it may reflect only a lack of desire to work.

**Prevention of Industrial Fatigue.** The problem of industrial fatigue is one of such complexity that its prevention involves the integration of many factors related to the workers, to the environment, and to the conditions of work. The desirable environment for work is discussed in Section 5. Facts covering the conditions of work are discussed below. In this section, only the conditions which concern the worker will be discussed. Indeed, the psychological and physical conditions of the worker are of greater importance in the prevention of fatigue, than are the conditions of work.

**PSYCHOLOGICAL CONDITIONS.** Since industrial fatigue is affected to such a large extent by psychological factors, the most important measures for the prevention of industrial fatigue are those which concern the psychological state of the workers: the proper placement of employees in relation to their physical and mental capacities, stimulation of interest in the work, provision for some variety in the work, intelligent and understanding supervision, interest of management, job security and financial incentives, a chance for congenial social contacts and group relations, and other similar factors. Such measures are certainly of major importance in the control of industrial fatigue. Since social and economic circumstances outside of industry are often of greater significance in the fatigue of industrial workers than are the conditions at work, the industrial physicians and nurses, counselors and other members of the personnel department should assist in adjusting such conditions when possible.

**PHYSICAL CONDITION OF THE WORKER.** Since many diseases, such as acute respiratory infections, abnormal metabolic conditions, and circulatory disturbances, cause fatigue, the prevention and treatment of these diseases will decrease fatigue in industrial workers. Adequate sleep and recreation are essential in the prevention of fatigue.

Although there is some reason to believe that industrial workers in this country often have faulty diets, there is no convincing evidence at the present time to suggest that malnutrition of the workers in the United States is an important factor in industrial fatigue under normal circumstances. When performing heavy physical work, the total caloric intake should be increased, but the percentage of protein in the diet need not be increased over that recommended for normal requirements. Although prolonged and marked deficiency of some vitamins may lead to fatigue

and weakness, shorter periods of vitamin deficiencies appear to be without any definite effect on the ability to work. Occupations producing unusual physical fatigue do not necessarily demand unusually high vitamin intake. The addition of vitamins to a diet which is already adequate for men doing hard physical work does not appear to improve muscular ability, endurance, resistance to fatigue or recovery from fatigue.

The question of taking food, especially carbohydrate food, between meals has been discussed as a measure for relieving industrial fatigue. Some authorities believe this procedure is generally beneficial, whereas others claim that it is of benefit only in very severe muscular work. The value, if any, of consuming food between meals may be due in part to the rest period and the accompanying change of interest and posture rather than to the food itself.

## METHODS AND CONDITIONS OF WORK

**Methods of Work.** Industrial hygienists are concerned not only with the environment in which a man works but also with the methods of work, with the design of equipment and processes, and with the length and arrangement of the working shifts. Fatigue is decreased, efficiency is greater, and the chances of injury and illness are less when persons are employed at operations which allow normal physiological functioning and which do not place too severe physical or psychological stresses on the body.

Originally, machines and processes were designed without regard to the human element in production, and people did their individual task at any speed or in any manner they preferred within the limits of their equipment. It might be expected that a person would select instinctively the best way of working but this theory is apparently not true. The originators of "time and motion studies" showed dramatically the extent of wasted motion, the inefficiency of many workers, and the improper arrangement of many industrial processes. Although "time and motion studies" have contributed greatly to the efficiency of production, such studies do not indicate necessarily the best method of operation from a physiological point of view.

There have been a few physiological investigations to determine the optimum methods of work, but most of these have been limited to studies of the oxygen consumption and mechanical efficiency of men doing various types of physical work. Although measurements of oxygen consumption give some indication of the desirable methods of doing certain jobs, this procedure is not always advisable. Indeed, an occupation which requires no physical work at all and thus no appreciable increase in oxygen consumption over the basal level may not be physiologically desirable and may even result in loss of muscular strength.

The applied psychologists have contributed more knowledge concerning the proper methods of work than any other group. They have studied the desirable illumination, color, and spacing of objects for rapid vision; the optimum speed and rhythm of work; the best type of coordinated movements for performing specific operations; and many other phases. However, the results of these studies have not been applied to industrial work except in rare instances.

During World War II some physiological and psychological studies and anatomical measurements were made as a basis for the design of airplanes, armored

tanks, radar equipment, etc. At the present time an effort is being made to interest industrial engineers and managers in this problem, so that industrial equipment and processes will be designed to fit the size and the strength of workers and will permit optimum physiological functioning of the workers. The engineering phase of this field is termed "Human Engineering."

**Length and Arrangement of the Working Day.** It is not possible to recommend any general schedule of hours as optimum for the health of workers, because of the great variability in the types and conditions of work, the state of the individual workers, and the many other factors involved. In fact, it is very doubtful if standards for the hours of work will ever be established on a physiological or health basis since this question is so profoundly affected by social, economic and psychological factors. However, there are certain facts regarding the hours of work which are based on sound experience.

During World War I it was found in England that long hours, 70 to 80 or 90 hours per week, could not be tolerated for long periods of time and that the total weekly output was greater if the hours did not exceed about 60 per week. During World War II, following the battle of Dunkirk, the hours of work were increased again to 72 and even 77 per week. Because of the tremendous incentive, the output rose but could not be maintained in spite of the great need for production. After two months the hours again were reduced to 60 per week. All of the available evidence indicates that working hours in manual operations involving a fair amount of physical effort should not exceed 60 to 65 per week for men and 55 to 60 per week for women. Most authorities believe that if a high degree of efficiency is to be achieved, the hours of work should be less than these maximum limits. The general opinion in this country is that 48 hours per week, or 8 hours per day for 6 days, are the maximum hours of work which are desirable, and some people believe that shorter hours of work are advisable, at least under certain conditions. A group of governmental agencies in this country issued a joint recommendation during World War II supporting the 48-hour work week during that period. A number of states also have adopted laws which set the maximum hours of work at this figure.

Increasing the hours of work above 48 per week leads to a decrease in hourly output, although the daily output may rise; but excessively long hours often lead, as shown above, to a reduction in total output. Absenteeism increases progressively with an increase in hours of work. A few studies have indicated that sick absenteeism increased when the hours of work were above 50 per week but it is difficult to evaluate these data because of the many other factors involved. There does not appear to be any relation between accidents and hours of work except when very long hours, over 60 per week, are worked. Women with children or other home responsibilities should work shorter hours than 48 per week.

One day off per week is essential for all workers. If this is not allowed, both the efficiency and total production decrease and absenteeism and accidents increase. Night work does not appear to be much more fatiguing than day work if rest is possible during the off hours and if the hours of work are normal. During World War I the British found no difference in production when the shifts were rotated but some decrease in production in the case of women when the night work was continuous. Some physiologists believe that rotation of shifts is not advisable

because such changes, especially if frequent, interfere with the diurnal physiological rhythms. Since social activities are organized on the assumption of day work, continuous night work often creates dissatisfaction among the employees. Many more studies are needed before it can be said whether night work is or is not physiologically unsatisfactory. Rest pauses in the middle of the morning and afternoon work periods have been shown to be of benefit, especially if there is a change of posture during these periods.

**Effects of Certain Types of Work.** **VIBRATION AND REPEATED MOTION.** Pneumatic vibrating tools, such as grinding and riveting machines, chipping hammers, drills, and other similar tools expose workers to repeated percussion. Large drills used to break rock or paving have a frequency rate of 1,500 to 3,000 blows per minute. Smaller drills and grinders have frequencies of 2,000 to 50,000 blows per minute. The use of such tools may lead to specific occupational diseases, the most common of which is vasospasm or "white fingers." It is generally stated that the rate of vibration is an important factor in the onset of this condition. Tools which give less than 4,000 blows per minute, especially those with 2,000 to 3,000 blows per minute, appear to be the most dangerous. Vasospasm is characterized by the spasmodic contractions of the blood vessels of the fingers which cause the fingers to become temporarily white and numb. The spasms affect chiefly the fingers of the hand which holds or guides the tool, i.e., the left hand. Although these attacks may occur while working in a warm room, they usually come on upon exposure to cold. Upon rewarming, the fingers become pink and severe pain is felt. Between attacks the hand appears normal. If a patient is removed from the exposure soon after the spasms begin, recovery may occur. Once the condition is well established, it does not progress further, but the attacks are likely to continue for many years even after removal from the exposure. The disease does not lead to any changes in the structure of skin, capillaries or arterioles. Vasospasm may appear after a few months of work with a vibrating tool or not until after several years of exposure. Some workers never develop the condition.

Repeated motion may lead to changes in the joints. The most common occupational diseases of this nature are tenosynovitis and bursitis. In tenosynovitis, the repeated use of a tendon or sudden strain on the tendon may lead to rupture of the blood vessels into the tendon sheath. This condition results in pain on exertion. Bursitis, or an inflammation of the synovial mucous membranes which line the various moving surfaces of the body, may result from constant abnormal friction on the tendons, usually at the joint. The movement of the joint becomes limited and painful due to the presence of fluid in the bursa. Pneumatic drills which are held against the shoulder may cause bursitis. Miners who lean continually on their elbows may develop a bursitis of the elbow. Constantly repeated traumatic injuries to the joints may also play a role in degenerative changes of the bones.

Prevention of the harmful effects of vibrating tools may be accomplished by the use of mechanical devices to hold the tool in place of the hand, and in some cases by the use of protective mittens. Nonvibrating tools should be used wherever possible. Early recognition of vasospasm and immediate discontinuation of the work is necessary. Tenosynovitis may be prevented in some cases by the use of rubber pads to prevent constant pressure of joints against hard surfaces, and by changes in posture and methods of work.

**LIFTING AND CARRYING LOADS.** The lifting of loads is a common industrial task which may place severe strain on the body. The usual method of lifting a weight is to bend over at the waist while keeping the legs straight. This method is apt to lead to back strains or hernias. The recommended procedure is to stand close to the object with the feet 8 to 12 inches apart, and to bend the knees rather than the back, so that the strain is placed on the leg muscles. When turning, the workers should shift the position of the feet, rather than twist the body.

The carrying of loads also places certain stresses on the body. Methods which cause displacement of the center of gravity, interference with movement, fixation of the chest, and local strain are not physiologically efficient. The most efficient method is to carry a load equally divided on a yoke from the shoulder; the next best, to carry two equal bundles, one in each hand with arms straight down at the sides. The poorest procedure is to carry loads on one hip. Health authorities are often asked about the maximum loads which should be carried. The Industrial Health Research Board of Great Britain (Cathcart and others, 1927) recommended loads equal to 35 to 40 per cent of the body weight as maximum weights for continuous carriage. Since there is no good correlation between weight and strength, such standards are not very reliable.

**POSTURES AND MOVEMENTS.** Static work is much more fatiguing than dynamic work. When a person stands for a prolonged period of time, there is a tendency, though quite variable among healthy men and women, for the blood to pool in the extremities and the splanchnic area due to the hydrostatic effects of gravity. This stagnation of the blood may lead to extravasation of fluid, swelling of the legs, and, if prolonged, to cerebral anemia. Muscular movement, or even swaying and shifting of position, will assist in counterbalancing this effect and will aid in returning blood to the heart. A constant sitting or bending posture may produce congestion of the pelvic organs and interference with digestion. Improper seats may cause unnecessary energy expenditure to maintain balance or may cause pressure on the nerves and blood vessels of the legs. In maintaining either a constant sitting or standing posture, the tone of the muscles must be adjusted to a fixed position. The constant pull and stretch on the tendons and joints in maintaining a fixed position may set up unpleasant or even painful sensory stimuli. The height and width of the work bench also are important since constant stretching and reaching are fatiguing. Constant walking on hard floors causes a jarring effect on the joints. Concrete floors are the least resilient, whereas floors made of wood or, better still, those covered with linoleum, rubber tile, cork, or other composition materials are much less fatiguing.

An understanding of the physiological stresses imposed by various postures should guide industries in planning their operations and in building their equipment. Changes in posture are very desirable; constant standing is undesirable. The height of work benches should be adjusted so as not to require either constant stooping or constant extension of the arms without support; chairs should be adjusted to the size of the workers; and more attention should be paid to the character of the floor. The proper arrangement of work materials and adjustment of machines to fit the individual worker can alleviate much industrial fatigue.

**Effect of Work and Fatigue on Health and Disease.** One of the important questions in industrial hygiene concerns the effect of work and fatigue on suscepti-

bility to disease and on longevity. It is almost impossible to answer this question because of the many variable factors involved and the lack of adequate data. Animal experimentation is of limited value since it is impossible to reproduce the conditions of work and fatigue in animals comparable to that of humans, except possibly in regard to physical exercise. Statistical studies on man likewise are of little value. However, some idea of the prevailing data and opinions may be obtained from the following brief review.

**EFFECTS OF PHYSICAL EXERCISE ON THE SKELETAL MUSCLES AND HEART.** Laboratory experiments have shown that repeated contractions of skeletal muscles in performing heavy physical work usually lead to an increase in the size, strength and tone of these muscles. Even work which requires maximal contractions of skeletal muscles does not appear to damage the muscles. Exercise of certain types, if repeated regularly, may lead also to an increase in the size and strength of the heart. Exhaustive exercise does not appear to damage the heart. These laboratory experiments support the current opinion that stress produced by heavy physical work does not lead to any irreversible physiological changes in the skeletal muscles, the heart muscle or the blood vessels, provided these tissues are in a normal state. Most cardiologists agree that physical exertion is not a factor in acute coronary occlusion. Authorities differ regarding the relation of severe exertion to coronary insufficiency.

**EFFECT OF WORK AND FATIGUE ON SUSCEPTIBILITY TO INFECTIOUS DISEASES.** The effect of physical exercise on susceptibility to infectious diseases has been studied in animals. The evidence suggests that resistance to acute respiratory infections, such as pneumonia, is lowered when the animals are forced to run to exhaustion, especially if the infection is present before the fatiguing exercise. In man there is ample clinical evidence that physical overstrain has a deleterious effect on the course of active tuberculosis. Rich (1944) attributes this effect to the increase in respiratory movements, which may cause rupture of partly caseous blood vessel or necrotic lesions and mechanical spreading of bacilli or caseous material impregnated with tuberculo-protein. According to Rich "the harmful effects of over exertion are also evident in the case of arrested but not entirely healed tuberculosis." Kammer reported that there were fewer unfavorable reactions among men with inactive tuberculosis when they were engaged in light work than among those engaged in heavy work.

**EFFECT OF EXERCISE ON THE DIGESTIVE TRACT.** Some animal studies have been directed toward a study of the effects of physical exertion on the digestive tract. A recent experiment indicated that muscular fatigue brought about by exhaustive running on a treadmill, abetted the occurrence of gastric or duodenal ulcers produced by chronic histamine stimulation.

**EFFECTS OF EXERCISE AND WORK ON LONGEVITY.** Some studies have been made on the relation of strenuous athletics and physical work to length of life. Studies of deaths among college athletes who graduated some years previous showed that there was no marked difference in the mortality of this group as compared with that of a control group of students who were not outstanding athletes. Mortality and morbidity statistics in relation to occupation are influenced by so many factors that no definite conclusions can be drawn from them in relation to the effect of heavy work on mortality. At the present time there is no conclus-

evidence that fatigue due to exhaustive physical exercise and heavy muscular work in industry increases mortality.

EFFECTS OF NERVOUS TENSION ON HEALTH. It is universally accepted that long hours of work, nervous tension and worry about work are important factors in certain types of circulatory, gastro-intestinal, and other functional and psychosomatic disturbances.

## THE PROMOTION AND REGULATION OF INDUSTRIAL MEDICINE AND HYGIENE

### GOVERNMENTAL AGENCIES

**United States Public Health Service.** The first official industrial hygiene agency in the United States Public Health Service was established in 1914 as the Office of Industrial Hygiene and Sanitation in the Scientific Research Division. Subsequently a Division of Industrial Hygiene was organized. At the present time (1955) industrial hygiene activities are being carried out by the Occupational Health Program of the Public Health Service, located in the Division of Special Health Services, under the Bureau of State Services.

"The Occupational Health Program of the Division consists of field and laboratory research studies of occupational disease; development of measures and standards for application by industry and by organizations engaged in the prevention and control of diseases and health hazards found in the work place; and the advancement of privately financed health maintenance services for workers. Other major activities include consultative services in the fields of occupational medicine, engineering, nursing, toxicology, biochemistry, and statistics and studies of the reporting of occupational diseases and sickness absenteeism. Special advisory assistance is made available to State and local agencies and other organizations on complex problems which arise in the administration of occupational health programs and services. Research activities are centered at the field headquarters in Cincinnati, Ohio, and a field station in Salt Lake City, Utah."\*

The staff of the Occupational Health Program today includes physicians, toxicologists, engineers, chemists, physicists, statisticians, nurses, and various types of laboratory personnel. This unit is primarily concerned with industrial hygiene research and its application; it provides information and assistance in this field to industrial, labor, medical and all other types of personnel concerned with the health of the worker. The Program has no law-enforcing powers and is not concerned with labor-management relations, wages, or any controversial economic problems of industry.

**State and Local Health Agencies.** Until the passage of the Social Security Act in 1935, only a few states had official agencies which were actively engaged in industrial hygiene work. Through the financial assistance of grants-in-aid allowed by the Social Security Law, and under the stimulus of the then Division of Industrial Hygiene of the Public Health Service, the state health departments began to develop

\* This quoted material is taken from Public Health Service Publication No. 165, *Industrial Hygiene*, 1955.

Industrial hygiene programs. In December 1955, 40 states,\* 13 cities, 6 counties, territories and the District of Columbia had active industrial hygiene programs. These programs are administered by the health departments in all states except New York, Massachusetts and Illinois where the industrial hygiene work is under the labor departments. The funds for these units are derived partly from the general health funds of the states and partly from federal grants-in-aid.

The state industrial hygiene agencies are engaged in various types of services. The most important activities are the field surveys of industries. These are performed as a part of routine investigations or upon request from industries. In these surveys the environmental and working conditions are examined. Where hazardous chemical substances exist in the working environment, air samples are collected and analyzed in the chemical laboratories which form an essential part of every industrial hygiene unit. If dangerous substances are found to exist in harmful concentrations, control measures are recommended.

The state agencies also advise industries regarding the incorporation of preventive measures in the design of new plants. Medical evaluation of working conditions is also made by studies of medical records and in some cases by examinations of the workers. The state agencies advise management and physicians concerning the toxicity of materials being used or produced in industry and regarding the diagnosis and treatment of occupational diseases. In addition to these services, the industrial hygiene divisions are actively concerned with atmospheric pollution control, the potential health dangers in the agricultural industry, and the protection of persons exposed to radioactive materials in industries, the control of noise, general ventilation and illumination of industrial plants, and all other industrial health problems.

Considerable work is done in assisting individual plants in organizing or improving health services for their employees. Some units have taken an active role in setting up cooperative medical services for small industries. These units also collect reports of cases of occupational illness and investigate the source of these. Each agency devotes considerable effort to educational activities by informing labor, industry, civic and professional groups on different phases of industrial health. In addition to direct industrial hygiene services, the agencies bring to industry more or less complete health programs by integrating their work with that of other divisions in the state government, unofficial health groups and professional organizations.

**Labor Departments.** The United States Department of Labor was created by Congress in 1913, to foster, promote, and develop the welfare of wage earners in the United States, to improve their working conditions, and to advance their opportunities for profitable employment. In carrying out these functions, the Labor Department has been concerned primarily with the economic and legal aspects of industrial work. The role of the Labor Department in industrial hygiene has been limited chiefly to the promotion of sanitation, to the prevention of accidents, to the regulation of hours of work, and to the control of types of work for women and children. The department has pursued this course chiefly by factory inspection, collection of statistics and support of labor legislation. The Bureau of Labor

\* States not having industrial hygiene programs in 1955 were: Arizona, Arkansas, Delaware, Nebraska, Nevada, North Dakota, South Carolina, Washington.

Statistics, the Bureau of Labor Standards and the Women's Bureau are the present divisions of the Labor Department which are concerned with these aspects of industrial hygiene. The industrial hygiene activities of the state departments of labor, with the exception of New York and Massachusetts, have followed the pattern of the federal department. The labor departments of New York and Massachusetts have separate divisions of industrial hygiene which are actively engaged in all phases of industrial hygiene and safety work.

**Location of Industrial Hygiene Divisions: Health or Labor Departments.** There has been considerable discussion as to whether industrial hygiene work should be located in health or labor departments. If the objectives of industrial hygiene as set forth in this book are accepted, then it is obvious that industrial hygiene is, indeed, public health in industry and, hence, should be the responsibility of the health departments. Only when labor departments engage personnel trained in medicine, public health, and industrial hygiene, as in New York and Massachusetts, are they able to conduct adequate programs in industrial hygiene. Even under these circumstances, the industrial hygiene programs are handicapped by the lack of the other branches of a health department which cooperate to make an all-inclusive health program for industrial workers. A very strong argument against placing industrial hygiene programs in the labor departments rests on the fact that these departments are primarily concerned with economic, legislative and labor-management problems. It is very desirable to have health activities divorced from such controversial and often political issues. Unquestionably, the health interests of the worker can be served best by health departments whose only function is the promotion of health of all persons in all places.

**The Bureau of Mines.** The United States Bureau of Mines was established in the Department of the Interior in 1910. One of its functions is to promote the safety and health of miners. This agency has been actively concerned with the effects of harmful substances encountered in mining and in allied industries and on the control of underground exposures to these materials. The bureau was granted law enforcement power in 1953 but until 1941 it did not have even the right of entry into mines.

**Other Governmental Agencies.** Several other governmental agencies are concerned with industrial hygiene problems of limited groups. The Children's Bureau formerly in the Labor Department but now located in the Department of Health Education and Welfare, deals with certain health problems in the employment of children, and with the effects of industrial work on pregnancy. The Department of Defense, Army, Navy, and Air Force maintain industrial hygiene personnel within the framework of their medical departments. These units are concerned with the health and working conditions of civilians who are employed by the Department of Defense. The Atomic Energy Commission is concerned with the protection of persons engaged in atomic energy work and supports research investigations on the effects of radiation on health.

## NONGOVERNMENTAL AGENCIES

Many agencies and organizations are actively concerned with the promotion of industrial hygiene, such as national professional associations and societies. A list

number of medical institutions, universities, private industries and insurance companies are engaged in research work or in teaching in the various fields of industrial health.

One of the best known of the private institutions is the Industrial Hygiene Foundation, started in 1938 by a group of private industries.\* "It is a nonprofit association of industries for advancing industrial health, improving working conditions and bettering human relations." The staff includes physicians, chemists, engineers, biochemists, and medical technicians. The activities of this organization fall into three categories:

"(1) To give direct professional assistance to member companies in the study of industrial health problems and their solution.

(2) To assist companies in the development of health programs as an essential part of industrial organization.

(3) To contribute to the technical advancement of industrial medicine and hygiene, through research surveys and allied activities." †

## INDUSTRIAL HEALTH PROGRAMS WITHIN INDUSTRY

**Changing Concepts of Industrial Medicine.** Originally medical services in industries were organized solely for the treatment of occupational injuries. Hence, surgeons were employed and the program was one of treatment only. With the growth of workmen's compensation laws, pre-employment physical examinations were added to the program. These were designed to prevent the employment of persons with pre-existing diseases, such as hernia, epilepsy or hypertension, which might lead to occupational injuries. The prevention of industrial accidents was assigned to safety departments, which were organized separately from the medical departments. When the compensation laws were extended to include occupational diseases, the treatment of these diseases was added to the responsibilities of the medical departments, and the pre-employment examinations were extended to detect persons with pre-existing diseases, such as silicosis. The prevention of occupational diseases was, in part, assigned to medical departments. In chemical and other industries where occupational diseases, rather than injuries, were the major problem, physicians, instead of surgeons, were employed. At first, the industries relied on outside agencies, such as governmental industrial hygiene divisions and insurance companies, for advice regarding the special engineering procedures necessary to prevent occupational diseases. In very recent years, the larger industries have developed industrial hygiene engineering divisions either as separate divisions or as part of the medical departments within their own companies.

With the advent of World War II, and with the accompanying labor shortage, became necessary for industries to employ injured veterans and persons with various types of disabilities and handicaps. This situation led to a considerable change

\* By 1955 this organization had almost 400 member companies.

† The quoted material is taken from "Industrial Hygiene Foundation Memo to Members" on Facilities, Services and Membership, 1951.

in the objectives of pre-employment examinations, and thus to a change in their name. Whereas in the earlier days the examinations served primarily to prevent the employment of certain persons, later they served to determine the ability of persons for work so that they could be placed in jobs suitable to their physical capacities. With this change in function, they became known as preplacement examinations.

In very recent years, the more progressive industries have come to realize that measures directed toward the prevention of nonoccupational diseases and toward the improvement of the health of the workers result in benefits to the company as well as to the workers. Analysis of sickness and accident records showed that occupational illness and injuries were relatively unimportant as a cause of sick-absenteeism but that absenteeism due to ordinary nonoccupational sickness and accidents, and the inefficiency of workers when suffering from non-disabling illnesses while at work, were major factors which interfered with production. Thus, programs designed to promote better health of the workers and to prevent disease are now being incorporated into industrial health services. Many industries have found that better labor-management relations follow the establishment of industrial health services when these services are designed for the benefit of the worker and not for compensation purposes. Insurance plans for the payment of medical and hospital services for nonoccupational diseases have been fostered by many industries.

Along with the growth of medicine in industry, interest in industrial health has been developing in the labor unions. In the past, this interest centered in prepayment medical care plans, although some labor union contracts carried clauses dealing with safety and sanitation within the plant. During World War II and the post-war period, the health and welfare provisions in union contracts have increased in scope, and clauses dealing with the health and medical services to be supplied by industry have been included in some instances. In recent years, some of the medical care services operated under union direction have become concerned with preventive medical work and rehabilitation as well as with medical diagnosis and treatment.

From this brief review, it is evident that the emphasis of health programs in industries is changing from surgical services to comprehensive preventive medical services. This trend reflects the growing interest in preventive medicine and the social changes in the world today.

**Current Industrial Health (Medical and Hygiene) Programs.** Modern health programs in industry can be divided into four phases: curative medicine; preventive medicine and health promotion; industrial hygiene engineering; and health research.

**CURATIVE MEDICINE.** The first duty of an industrial medical department is to operate a dispensary for the treatment of occupational injuries and illnesses. Usually the seriously injured are now sent to consultant surgeons. First aid and emergency treatments for nonoccupational illness are given. The immediate reporting and treatment of even minor conditions often can prevent more serious illness. In some large industries and in those in isolated areas diagnostic services for nonoccupational diseases are provided. The results of the diagnostic tests are given to the employees' private physicians upon request.

**PREVENTIVE MEDICINE AND HEALTH PROMOTION.** Medical examinations of employees form a major part of the preventive medical services in industry today. Preplacement physical examinations at the time of employment are designed to determine the physical ability and temperamental qualifications of employees in relation to the requirements of the job. In some industries, very thorough physical examinations, which include chest x-rays, blood and urine studies, electrocardiograms and tests of vision are made. Applicants are then classified as fit for any type of work, physically unfit for employment, or employable only in certain types of work. The jobs are often analyzed as to their physical requirements so that workers can be selected accordingly. Physical examinations are usually performed for the same reason when a worker is transferred to a new job. By means of such examinations, persons with physical or emotional handicaps can be placed in jobs within their limitations. Periodic physical examinations also are performed on all employees in some industries. In other industries, only those workers who are engaged in hazardous occupations are examined periodically, the frequency depending on the nature of the exposure. By such examinations, the early effects of harmful exposures can be detected and preventive measures can be immediately instituted. Physical examinations are given usually when employees return to work after an illness to determine if they have recovered sufficiently for work and if they present a hazard to their fellow workers. In some industries dental examinations of employees are included in the program.

There is no doubt that the physical examination programs in industry can be of great benefit in preventing many cases of serious illness. Whereas private physicians usually do not see patients until they become ill, the industrial physician, through these repeated examinations, often can detect cases of tuberculosis, venereal disease, diabetes, cardiovascular and other diseases in their early stages. By sending these patients at once to their private physician, serious illness may be prevented. Thus, medicine in industry is of great value in the early detection of nonoccupational diseases. In order to make the dispensary care and the physical examination programs of greatest value for the prevention of diseases, adequate records must be kept and analyzed regularly. A study of such records often directs attention to unrecognized hazardous conditions in the plant. Furthermore, such records indicate the workers who have repeated illnesses and may need medical or psychiatric care or who may need the assistance of a social agency.

Supervision of food handlers, vaccination of employees where certain diseases are endemic, nutritional programs, and health education of the employees are all part of preventive medical programs in progressive industries.

The industrial physicians and nurses work with established community agencies which are engaged in rehabilitation, public health, and welfare work.

**INDUSTRIAL HYGIENE ENGINEERING.** The activities of the industrial hygiene engineers are directed toward preventing hazardous exposures in the industry. When new plants are constructed, the industrial hygiene engineer designs the preventive measures so that they can be built into the original plant. In old operations, the industrial hygienist studies all processes to determine whether a harmful condition exists and designs protective equipment where necessary. The industrial hygienist and the plant physician must be acquainted with all of the toxic chemical

substances in the plant. Constant supervision of protective equipment is also a necessity.

In addition to the prevention of hazardous exposures, the industrial hygienist is engaged also in the prevention of atmospheric pollution with industrial wastes. The industrial hygiene program includes supervision of sanitation (food and water), general ventilation, lighting, etc. In plants where exposure to radioactive materials is a major problem, health physicists are employed to supervise the protection of workers exposed to dangerous radiation. The industrial hygienists are also concerned with the design of machinery and processes so that these will place a minimum of stress on the workers.

**INDUSTRIAL HEALTH RESEARCH.** Although most industrial health programs do not include research, industrial medicine offers opportunities for some types of research not available elsewhere. For example, the industrial physician, through the repeated medical examinations, has an opportunity to study the onset and development of chronic diseases over a period of years. Fundamental research problems connected with the occupational diseases can be studied most effectively by the physician who has an intimate knowledge of the exposure. These and many other problems could be the subject of research by industrial medical departments. Some industries maintain toxicological and medical research laboratories.

**Organization of Industrial Health Programs in Large and Small Plants.** The objectives of industrial health services for large and small industries are the same; the only difference lies in the methods of obtaining such services.

In very large industries, the medical departments are staffed by full-time physicians or surgeons, trained nurses, and laboratory technicians; the industrial hygiene staffs include mechanical engineers and chemists, and the safety divisions employ safety engineers.

The smaller industries cannot support complete health services, nor do they require full-time staffs. Often a full-time nurse working under the supervision of a part-time doctor can direct the industrial health work of a plant. In very small plants, only part-time nurses may be employed. Industrial hygiene engineering services can be obtained from state or local governmental agencies free. In some cases a number of small plants located in the same neighborhood have organized an industrial health service to serve all of the plants. Medical, nursing and industrial hygiene engineering services may be included in this arrangement. Small plant health and medical programs have been reviewed by Klem and others. Many insurance companies have developed excellent industrial hygiene departments, because they carry either industrial compensation insurance or life insurance policies for groups of industrial employees. In fact, the insurance companies have been among the pioneers in the field of industrial hygiene. They frequently employ engineers, chemists, physicians, nurses, and other personnel who advise industries in the prevention of occupational diseases and in the promotion of the health of their employees.

The relation of the industrial health services to all other branches of industry is important. The medical, industrial hygiene, and safety services should work closely together. All authorities agree that the health divisions should be directly responsible to top management—the president or vice president.

The number of doctors, nurses, and industrial hygienists required for different sized industries depends on the type of industry and the extent of the program. Similarly, the cost of health programs in industry varies with the size and type of the plant and the character and extent of the program. Special publications should be consulted for information on these phases of industrial medicine (Sappington, 1948; Am. College Surg., 1946; Nat'l Ass'n Manuf., 1941; Gafafer, 1943; periodic reports of the Industrial Hygiene Foundation). Information regarding the organization of industrial medical departments may be obtained from the Council on Industrial Health of the American Medical Association.

**Value of Industrial Health Programs in Industry.** It is difficult to measure the value of industrial, medical, and hygiene services in industry just as it is difficult to measure the value of any preventive medical program. However, practically all companies which provide good health services believe that the benefits both to the employee and the employer far outbalance the cost. The benefits to the employees are obvious: reduction of occupational diseases and accidents, reduction of non-occupational illness by early discovery of diseases and first-aid treatment, improved general health, and less lost time due to illness.

The benefits to industry are perhaps more difficult to evaluate. A good health program results in less absenteeism, less labor turnover, greater efficiency at work, better plant morale, better labor-management relations, and lower compensation costs. Various attempts have been made to estimate the financial value to industry of industrial health programs. One such estimate was made by the National Association of Manufacturers in 1941 on the basis of a survey of 2,064 industries. This survey indicated that a company with 500 employees could expect an annual net profit of \$5,611.00 to result from an industrial health program. This saving was based on a 47 per cent reduction in compensation costs for industrial accidents and diseases, plus a 28 per cent reduction in lost time due to nonindustrial illnesses and injuries, minus the cost of the health and safety program. Additional savings would result also from the accompanying reduction in labor turnover and insurance premiums. Similar calculations by Pharris (1950) indicated that a plant with 150 employees might save over \$7,000.00 per year as a result of an industrial health program.

In addition, as Stern (1946) pointed out: "The establishment of industrial health services involves more than the recognition that they yield long-run savings. It is an acknowledgment that the health of workers is as much of an asset to management as is the care of equipment, and that it is necessary to give as much attention to the effect of industrial materials and processes on the health of workers as to the problems of the pricing and the quality of the products. The limited distribution of industrial medical services bears evidence that the concept of conservation of human resources has not yet been fully incorporated into industrial management policy." The American College of Surgeons (1946) further stated: "In the past, industry has expended considerable effort and vast sums in maintaining its machinery and physical plants and found it to be 'good business.' The human machine in industry should receive no less attention for, after all, the human element is the most important factor in the structure, operation, and product of industrial organization."

## INDUSTRIAL HEALTH LEGISLATION

## GROWTH OF INDUSTRIAL HEALTH LEGISLATION

The growth of industrial hygiene in the United States can be followed, in part, by a brief review of the important legislation dealing with the conditions of work. In this country, the federal government has direct jurisdiction only over the working conditions for federal employees, although it can exert some indirect control over working conditions in private industry through taxation laws, the interstate commerce laws, and, more recently, through certain other types of legislation. Since the control and regulation of working conditions in the United States are primarily the responsibility of the state governments, the progress of industrial health legislation has varied greatly throughout the country, and even today marked differences exist in the laws of the individual states.

The first laws passed which regulated the conditions of work were those dealing with employment of children, hours of work for women, and prevention of accidents. The first child labor law was passed in Massachusetts in 1842. The progress of such legislation, however, was slow. As Stern (1946) pointed out, in the 50 years following this first law less than 12 states had made an effort to limit child work. Legislation concerned with the hours of employment for women began with the Massachusetts law of 1874. Some legal regulations designed to prevent accidents in factories and mines were enacted also in the late nineteenth century. By the end of that century, 14 states had some provisions for the inspection of factories and workshops, 22 states had similar provisions for mines, 21 states had some type of statute relating to the health of employees, and 13 states had laws for guarding certain types of machinery. By 1908, 17 states had regulations requiring devices for the removal of injurious dusts and gases. The laws passed up to this time were under the jurisdiction of the state labor departments, which were responsible for their enforcement.

Legislation relating to occupational diseases began in 1911 when California passed the first law which required the reporting of occupational diseases. Today, 28 states have laws which require that all or specified occupational diseases be reported to the health or labor departments. These laws have not been enforced.

The next major development in industrial health and safety legislation was the passage of the Workmen's Compensation Laws. The specific provisions of these laws will be reviewed in some detail later in this chapter. The first rather limited Workmen's Compensation Law was enacted by the federal government in 1908 for civilian employees engaged in certain hazardous occupations. It was not until 1916, however, that Congress passed a model compensation law for civilian employees of the United States. In the meanwhile, a number of individual states beginning with New Jersey and Wisconsin in 1911, passed such laws. By 1948 every state had passed a Workmen's Compensation Law. These laws are administered by special industrial accident or compensation commissions in some states and by the labor departments in other states.

One of the most significant advances in industrial health legislation occurred with the extension of the Workmen's Compensation Laws to include occupational diseases. The first such legislation was passed in California in 1918; Wisconsin and Connecticut followed in 1919. The passage of such laws has continued steadily

From that time, until by 1955, there were only two states which did not have some type of occupational disease compensation law covering at least part of the employed workers. The Workmen's Compensation Laws have been, by far, the most potent force in stimulating industries in the prevention and control of occupational accidents and diseases.

During the period when the states were enacting compensation legislation, several federal laws of importance were passed. The National Industrial Recovery Act of 1933 included regulations on hours of work, safety, and healthful working conditions for workers under the jurisdiction of the federal government. However, this act was declared unconstitutional. In 1936, the Walsh-Healey Public Contract Act gave the federal government direct jurisdiction over working conditions in the states for the first time. Under this law, the federal government was given authority regarding the safety of workers in industries which held government contracts above \$10,000.00 for the manufacture or furnishing of materials and equipment. According to Stern (1946), this law stipulates: " 'no part of such contract between the company and the government will be performed nor will any of the materials, supplies, articles or equipment to be manufactured or furnished under said contract be manufactured or fabricated in any plants, factories, buildings or surroundings under working conditions which are unsanitary, or hazardous or dangerous to the health and safety of employees.' " The federal Fair Labor Standards Act, which was passed in 1938, extended the principles of maximum hours and minimum wages to all workers in industries engaged in interstate commerce.

The most recent federal law which greatly affected the development of industrial hygiene was the Social Security Act of 1936. This law made it possible for the United States Public Health Service to allot grants-in-aid to each state for the establishment and maintenance of adequate public health services, including industrial hygiene programs. Unlike much of the preceding legislation which regulated either the conditions of employment or the payment of compensation, the industrial health programs initiated under the Social Security Law operate chiefly on a basis of education and service.

A compilation of the current industrial health legislation in state health and labor departments has been published recently by the U. S. Public Health Service (Brasko, 1954). Since these laws and regulations differ widely in the individual states, it is not possible to present them here.

#### WORKMEN'S COMPENSATION LAWS\*

**Objectives of Workmen's Compensation Acts.** Prior to the enactment of compensation laws, it was necessary for an injured worker or his dependents to sue the employer under the common law in order to collect indemnity for an industrial accident. In such a suit, the complaint was required to prove that the injuries were due to the negligence of the employer. The defense of the employer rested

\* This material was taken directly from the following bulletins issued by the United States Department of Labor and published by the United States Printing Office: Bulletin #123, Federal Labor Laws and Agencies, August, 1950 and Bulletin #161, State Workmen's Compensation Laws, September, 1954, and from lectures on Workmen's Compensation Laws given at the Johns Hopkins School of Hygiene and Public Health by Mr. B. E. Kuechle, Vice-President of Employers Mutual Liability Insurance Company of Wisconsin, and Mr. T. C. Waters, Chairman, Legal Committee of the Industrial Hygiene Foundation.

on three points: (1) the employee assumed the risk when he accepted employment; (2) the injuries were due to contributory negligence of the employee; or (3) the employee's fellow worker was negligent.

Under the common law procedure, the costs to the injured employee were high, and a large part of the indemnity, if collected, was spent for court and legal fees. Furthermore, there was a long delay before the injured man received his compensation. The disadvantages to the employer were the cost of defending the case and the unlimited monetary liability.

The Workmen's Compensation Laws have been developed to correct the disadvantages of the common law system. The objectives of the Workmen's Compensation Laws, as stated by Mr. Kuechle, are:

"To furnish certain, prompt and reasonable compensation to the injured employee consisting of medical treatment immediately after the injury and compensation to the injured employee or, in case of death, immediate compensation to his 'dependents.'

"To utilize for the injured employees all of the compensation money, much of which was lost to him under the common law system.

"To provide a tribunal where disputes between employer and employee in regard to compensation might be settled promptly, cheaply and summarily.

"To stimulate accident prevention.

"To provide 'rehabilitation' of workers who, because of their injuries, are no longer able to follow their former occupation."

Thus, under the Workmen's Compensation Laws the employee receives his compensation and other benefits promptly and without expense to himself. He does not have to prove negligence of the employer, but the amount of compensation is limited by law. The employer, in turn, assumes the responsibility for accidents, regardless of fault; but his liability is fixed by law.

**The Federal Compensation Law.** The federal government provides compensation for accidental injuries arising out of employment and occupational diseases under two laws: the Federal Employees' Compensation Act and the Longshoremen's and Harbor Workers' Compensation Act. The former provides compensation for civilian employees including civilian officers of the United States Government. The Longshoremen's Act covers maritime employment on navigable waters of the United States, except the master or members of the crew of a vessel. The principal employees covered are longshoremen and ship repairmen while on board a vessel. The law has been extended to other employments, including all private employment in the District of Columbia and employment outside the United States in the service of contractors with the United States at military, air or naval bases or on public works. Further details of the law and changes in the law can be obtained from periodic publications of the United States Department of Labor. The laws are administered by the Bureau of Employees' Compensation of the United States Department of Labor.

**State Compensation Laws.** Workmen's compensation legislation (covering accidental injuries) has been enacted by every state in the United States and by Alaska, Hawaii, and Puerto Rico. However, many workers are not covered by these compensation laws chiefly because: (1) the laws do not cover all occupations (agriculture, domestic service, casual employment, and in some instances, nonhazardous

employments usually are exempted unless voluntarily accepted by the employer); (2) many states have an elective system rather than a compulsory system; (3) in some states employers of fewer than a stipulated number of employees are exempt; (4) railroad workers and seamen engaged in interstate commerce are not included.

Legislation for the compensation of occupational diseases has been enacted as of December, 1955) in 46 states and in Alaska, the District of Columbia, Hawaii, and Puerto Rico.\* The occupational disease compensation laws are of two types: general coverage, and schedule coverage. The laws in 26 states and in Alaska, the District of Columbia, and Hawaii cover all occupational diseases (general coverage), while those in 20 states and in Puerto Rico cover only those diseases listed specifically in the laws (schedule coverage). The federal law is a general coverage law. The financial provisions in the case of occupational diseases are usually the same as those for accidental injuries except with respect to silicosis, asbestosis, or other dust diseases. In 26 states, benefits payable for silicosis or asbestosis are subject to certain limitations, while in 14 states no benefits are paid for partial disability in silicosis or asbestosis.

Provisions concerning death benefits, provisions for less serious injuries, and other details of the compensation laws vary in the different states.

In some states, medical consultants or medical boards are appointed to pass on medical problems in connection with occupational disease compensation. In some cases, their findings regarding the medical facts are conclusive; in others, they are only advisory in nature.

One of the most desirable features of the Workmen's Compensation Laws is the stimulus given for the prevention of accidents and occupational diseases. Insurance costs vary with the amount of benefits paid. In some laws, penalty payments on employers themselves, even though they are insured, are required where accidents occur because of violations of safety laws. Specific provisions for the prevention of accidents and occupational diseases are written into some compensation laws.

There are many other features of compensation laws, such as second injury benefits, waivers, rehabilitation provisions, etc., which cannot be reviewed here. The various state laws should be consulted for these and other provisions. These laws are summarized periodically in publications by the United States Labor Department.

# SANITARY CONTROL OF WATER SUPPLIES, SEWAGE AND REFUSE DISPOSAL

## 36

### WATER

EDWARD W. MOORE, M.A.

#### GENERAL CONSIDERATIONS

Water is a primary necessity of life; in its absence the higher animals will survive but a few hours or days. In addition, it contributes in a variety of ways to the enjoyment, safety and progress of human existence. The more advanced a human society is, the greater become its water needs and the more complex are the problems of public water supply and use. A statement of the uses of water in a modern community would include: *drinking and culinary uses; ablution and washing; heating and air-conditioning of buildings; watering of lawns, gardens, and parks; street sprinkling and cleaning; display in fountains; creation of hydraulic and steam power; quenching of fires; use as industrial process water; recreational uses, such as swimming and wading pools; and the removal of offensive and potentially dangerous household (sewage) and industrial wastes.* Of these uses, the ones shown in italics are of the most immediate sanitary concern, because water so employed may become a medium for the transmission of disease.

In a modern community, the water supply system, or water works, collects the water from its natural sources—stream, lake, underground aquifer or, rarely, direct rainfall—purifies it if necessary, conveys it to the community, and distributes it to the individual consumer. The average consumption of North American municipalities is 100 gallons per capita daily. The sewerage system, or sewage works, collects the spent water—about 70 per cent of that supplied—purifies it if necessary, and discharges it to the rivers, lakes or tidal waters of the region or, frequently, to the land. The inland bodies of water may therefore serve both as sources of water and as recipients of sewage, thereby creating particularly vexing problems of sanitation.

The works created for these purposes are among the greatest, most enduring, and most costly of the engineering accomplishments of man; portions of systems of great antiquity are still in evidence.\* For the most part, however, little of them can be seen, because many of the major structures are buried in the ground. As civilization became more urbanized, the number and extent of public water supply

\* The date of construction of the Appian aqueduct carrying water to Rome is placed at 312 B.C. Eighteen other aqueducts were constructed at various times until A.D. 226. The one commenced by Emperor Caius and completed by Claudius, according to Pliny, cost 350,000,000 sesterces, or about \$12,700,000.

systems increased. For example, in the United States before 1800 there were only 16 public water supplies, serving 2.8 per cent of the population. By the mid-twentieth century these had increased to more than 13,000 supplies serving about 60 per cent of the population. The balance of the population lives principally under rural conditions and has recourse to small private supplies, sanitary control of which is difficult because of their wide distribution and excessive variation in quality and quantity.

**Classification of Water.** Water collected from natural sources has come into contact with many substances, and by virtue of its erosive and solvent properties has taken some of these into suspension and solution. These substances include organic and inorganic components, gases, liquids, and solids and, in addition, many living organisms. Some of these organisms are normal aquatic organisms; others are harmless, adventitious micro-organisms; but some are pathogens discharged by persons who are suffering from, or are carriers of, a disease that may be transmitted by water. The water then becomes a medium for transmitting infection. It is seldom possible to detect infection directly in water. The likelihood of its existence may be inferred from the degree of contamination. *Contamination* is the introduction into water of human or animal wastes, which may transfer infection, or of other substances, as chemical poisons, which may also render it harmful. *Pollution* is a term used primarily to denote impairment of physical attractiveness. Pollution is the introduction into water of substances of such character and in such quantity that they render it objectionable in appearance, taste, or odor. They may or may not contribute to contamination.

For practical purposes, then, water is classified as clean, polluted, or contaminated. (1) *A clean water* is one which is at all times free from contamination and safe for human consumption, as determined by laboratory analyses, sanitary survey, and continued use. It is also one which is attractive in its appeal to the senses. (2) *A polluted water* is one which has suffered impairment of physical qualities through the addition of substances causing turbidity, color, odor, or taste. (3) *A contaminated water* is one which may carry infection by reason of the addition of human or animal wastes or which has been rendered unwholesome by poisonous chemical compounds.

According to source, waters are divided into three classes: rain water, surface water, and ground water. That which collects in streams, lakes, ponds, and reservoirs is called surface water, and the water which percolates through the soil and collects in underground places is called ground water.

The standards by which the quality of water is judged are constantly rising. There is no doubt that many waters now considered satisfactory will not be acceptable in the future. A water must have more than the negative property of being safe; it should have positive qualities: it should be crystal clear, sparkling and inviting, cool and refreshing, and above all, palatable.

**Properties of Water.** Water is a substance with many unique properties. It is a clear, transparent, tasteless and odorless fluid, colorless in small quantities, pale blue through a deep column. It freezes at  $0^{\circ}\text{C}$  and boils at  $100^{\circ}\text{C}$  under barometric pressure of 760 mm. It is practically incompressible; it has its greatest density at  $4^{\circ}\text{C}$ . The specific heat of water is high, meaning that it takes much heat to warm it and much cold to cool it.

Water rises to a greater height in a capillary tube than any other liquid. Owing to this property, it clings tightly in the soil and rises to a considerable height above the underground water table, thus making vast areas of the earth arable instead of dry desert.

The difference in the amount of water vapor held in the air at varying temperatures is large relative to most other liquids.

Water is the most widely distributed of all substances. The hardest crystals and the driest rocks contain appreciable quantities; in fact, crystals could not form were it not for the action of water.

Practically all substances dissolve to some extent in water; it is the most nearly universal solvent known. It dissolves gases; for example, oxygen and carbon dioxide. These are among the important constituents of all natural waters. Both are always present in the air, and all rain water contains them. Carbon dioxide is also taken up by the water as it percolates through ground covered with vegetation. The presence of this gas increases the solvent powers of the water, enabling it especially to dissolve limestone and other mineral and organic substances. The presence of oxygen is essential to normal aquatic life.

The mobility of liquid water and water vapor and the ease of conversion from one to the other permit rapid circulation and universal penetration of water. The circulation of water has a great influence on climate and is largely responsible for the wide distribution of vegetable and animal life on the earth.

**The Uses of Water in the Body.** Water enters and leaves the body in greater quantities than does any other substance. Much of it passes through the body unchanged; but it also enters the structural composition of the body, as well as that of all foods, and hence in the broader sense is entitled to rank as a food, although it does not of itself build tissue or produce energy. The uses of water in the body may be summarized as follows: it enters into the chemical composition of the tissues; it forms the chief ingredient of all body fluids, maintaining proper dilution of these fluids; it prevents friction by moistening such body surfaces as the mucous and serous membranes; in the blood and lymph it furnishes a medium for the transmission of food to, and removal of waste from, remote parts of the body; and it serves as a distributor and regulator of body heat through the physical processes of heat transfer and evaporation.

Water constitutes about 70 per cent of the entire body weight; to maintain this level a healthy man will require, on the average, 1,800 to 2,100 ml. of liquid water every 24 hours, in addition to about 600 ml. taken in as a component of solid foods,\* or a total of 2,400 to 2,700 ml. Of this water intake, 28 per cent is lost through the skin, 20 per cent through the lungs, 50 per cent through the kidneys, and 2 per cent in other secretions and in the feces. One of the more frequent metabolic faults is failure to take enough water into the system.

**The Amount of Water Used and Wasted.** From a sanitary standpoint our aim should be to encourage a generous use of water but to discourage waste. The conservation of pure water and the economic use of purified water are pressing problems that a growing and expanding country must meet and solve as a matter of self-interest if not of self-preservation. Many large cities have at times experienced difficulty in meeting their water requirements.

\* Fully five-sixths of the food in an ordinary diet consists of water.

It is possible to get along with a very small amount of water. From 3 to 10 pints a day, depending upon the climate, are needed for drinking, and about 5 pints for cookery. In present-day American communities the problem is often not under-consumption of water, but needless waste.

For general household purposes the rate of consumption of water in round numbers is 25 to 50 gallons per capita per day, the volume varying with the standard of living. Industrial communities use water in much larger quantities. The rates range from about 75 to 275 gallons per capita per day and are seldom much less than 100 gallons. They tend to be lower in cities where the services are metered and also in smaller cities. In the latter, industrial and public uses and waste of water are generally not so great in proportion to population. There is always a difference between the amount of water delivered to a distribution system and that which reaches consumers; this is termed "water unaccounted for" and includes not only leakage, but under-registration of meters and certain municipal uses. In a well-maintained and fully metered system this discrepancy seldom exceeds 15 per cent. Some industries use very large amounts of water; for example, a brewery consumes 470 gallons for every barrel of beer produced, an electric power plant 80 gallons for each kilowatt hour, a paper mill 40,000 gallons per ton of paper made. When such industries are present in a community, the consumption rate will be very high, even when domestic consumption remains comparable with that of other communities.

\* Am. Civil Eng. Handbook, 1930.

**Causes of Water Waste.** In most American cities, from 25 to 50 per cent of water provided can be said to be wasted. Much of this waste is avoidable, and in the face of steady diminution of water resources and rising costs of purification considerable effort and expenditure to avoid waste are justified.

There are three principal causes of water waste: (1) leakage from the mains and service pipes; (2) waste from defective house fittings, and (3) waste resulting from carelessness. The first cause includes all hidden defects in the system.

Table 36-2. Water consumption in foreign cities

City	Year	Consumption (U. S. Gallons) per Capita per Day
London .....	1927	43

Geneva .....	1919	118
Tokyo .....	1931	48

which allow the water to escape unperceived into drains and sewers or into the subsoil. It is possible to locate and check a large part of this waste by means of leak detector or pitometer surveys. These instruments function by measuring, or making audible, abnormal flows in portions of the system isolated for observation, usually at night.

The amount of water wasted by a leaky or improperly closed house tap is larger than one might expect. A one-sixteenth-inch stream under 40 pounds pressure will discharge 630 gallons in a day. In cities having severe winters the water in many houses is allowed to run continuously from the cold water faucet in order to prevent freezing.\* The waste from this cause is enormous and may be eliminated by placing the pipes so as to avoid the danger of freezing.

**WATER METERS.** It has been the universal experience that much water is thoughtlessly wasted where the service is not metered. There is no valid objection to a metered service; the cost of the meters is soon covered by the saving in water. Furthermore, metering defers and decreases future expenditures for water works. All measures for combating water waste by consumer education are temporary unless the effort of the water authorities is continuous; metering makes the consumer permanently conscious of the undesirability of waste.

**Dual Water Supply.** The possibilities of dual supplies of water—one of them expensive and inferior in quality but satisfactory for general garden, street, and industrial purposes, and the other of high quality for personal use—have long engaged the attention of engineers and sanitarians. Ancient Rome had this kind of supply, and Paris and other European as well as some American cities have it at present. The advantages and disadvantages of the dual system are evident. Even when the community served is intelligent and careful, the hazards of dual systems are considerable, because of the ever-present possibility of chance interconnection. They are seldom resorted to except through stress of circumstances.

A number of cities have a separate water distribution system under high pressure for fire fighting. Ordinarily, this system derives its water from the same source as the general supply. Auxiliary water systems are often provided for industries. Some of the older ones are connected with the municipal water mains through

\* In cities where this practice prevails, more water is used in the severely cold months than the summer months.

what is termed an approved cross connection. This contains special check valves and auxiliary testing equipment. There are other means of connection as well. All such arrangements are inherently hazardous, and a number of outbreaks of water-borne disease have been traced to faulty check valves or failure to break connections in such dual systems. Cross connections are prohibited by the rules of many state departments of health. Between 1938 and 1945, nine outbreaks of water-borne disease, comprising a total of 41,540 cases, were caused by cross connections with unsafe water supplies (Eliassen and Cummings, 1948). One of the outstanding instances was that of Rochester, New York, where a cross connection between a polluted high-pressure fire and industrial supply and the city water system was accidentally opened. The result was 35,000 cases of gastroenteritis and 6 of typhoid fever. The polluted supply was abandoned at once.

### SOURCES OF WATER

We may begin the circle by considering that all water comes to us from the aqueous vapor condensed in the form of rain or snow. Of this a certain amount returns to the atmosphere by evaporation; the rest collects upon the surface of the earth or soaks into the ground. Some of it flows off in the direction of surface slope to join the ponds, lakes, rivers, or seas, and some of it may penetrate the earth to varying depths. The sources of our water supply may therefore be classified as (1) rain or snow water, (2) surface water, including ponds, lakes, streams, and rivers, and (3) ground water, including springs and wells. This classification is an arbitrary one, used for convenience. There is no sharp distinction between rain, surface, and ground water. Rain water soon becomes surface water, and surface water may quickly pass into the ground; the ground water frequently reappears to feed streams and lakes and other surface supplies, especially at times of low surface runoff.

Rain water is nominally the purest, but is liable to irregularity of composition. In built-up sections it is difficult to collect it in such a way as to render it free from pollution and fit for drinking. Surface water from inhabited watersheds is, in its raw condition, never entirely safe for drinking purposes. Ground water obtained from the sandy subsoil of a catchment area that is free from sources of pollution is usually of a satisfactory character. Ground water obtained from the deep underlying strata may be so rich in mineral matter that it is unsatisfactory for most uses.

**Rain Water.** Rain water is really "distilled water"; that is, it is water that has been vaporized and then condensed. The process of distillation is one of the best known methods for purifying liquids of all kinds. All of the nonvolatile substances are left behind; theoretically, therefore, rain water should approach nearer to absolute purity than any other kind of natural water. However, it receives impurities from the moment it condenses, for droplets of mist are formed initially about a particle of dust in the air. The raindrop absorbs gases, near the seacoast it dissolves suspended salts, and as it drops through the air it collects some of the "dirt" floating in the lower portions of the atmosphere. Micro-organisms are also included. The impurities collected by the rain before it reaches the surface of the earth, while considerable in amount, are practically negligible from a sanitary

standpoint. After rain touches the earth's surface it becomes a surface water. If collected from a clean, impervious surface in the open country, it is the purest of natural waters. However, rain water for drinking purposes is all too frequently collected and stored in such a careless manner that it is subject to pollution.

The softness of rain water makes it useful in the laundry, and the absence of lime salts renders it desirable for cooking. On the whole, however, it is not considered as practicable as a good ground or surface water for a communal supply.

From Water Supplies and Sewage Systems for Farm Residences, Bd. Health Minn., March, 1925.

Fig. 36-1. Properly constructed cistern with sand filter, located outside the house to protect rain water.

The storage of rain water in cisterns and containers about the house was the principal factor in keeping yellow fever alive in endemic foci. The yellow fever mosquito (*Aedes aegypti*) breeds by preference in artificial containers holding clean water. It is the abolition of these breeding places that has protected cities and towns from the classical yellow fever epidemics.

Rain-water filters, constructed of coarse sand, may be employed to exclude impurities from the storage cistern. The filter medium should be regularly cleaned or replaced. It is desirable to provide means for wasting the first flow from collecting areas.

The gallons of water that may be collected as rain water may be estimated by multiplying the area of the receiving surface in square feet by one half \* of the

\* Six tenths is a more accurate factor, but as about 10 per cent is lost, one half gives more nearly the actual amount recovered.

rainfall in inches, measured by a rain gauge. Thus one inch of rain on a house roof 20 by 20 feet in area would be about 200 gallons. With a rainfall of 40 inches per annum, the yield would amount to 8,000 gallons. Losses by evaporation may be considerable, especially in warm weather.

**COLLECTION AND STORAGE.** Safe collection and storage of rain water for domestic purposes require careful attention to the following: (1) the care of the collecting surface; (2) the separation of the first flow, which contains most of the gross impurities; (3) the location and construction of the storage cistern.

Concrete storage cisterns are usually placed underground. Wooden ones are placed above ground; they must be kept full if they are to remain tight. Rain water attacks iron, lead, zinc, and other metals. Metals used in storing or conveying rain water should, therefore, be coated with a good asphaltum paint. Under no circumstances should lead cisterns or lead service pipes be employed for rain water that is to be used for drinking purposes. Surface drainage should be away from a cistern if pollution is to be avoided. Cisterns should be inspected and cleaned from time to time.

Overflow pipes from rain-water tanks should never be connected to drains carrying sewage, because of the danger of contamination through backing up of the drains.

**Surface Waters.** Surface waters include rivers, creeks, and smaller streams, large and small lakes, ponds, and impounding reservoirs. Their composition is highly variable and depends largely upon the character of the catchment basin. A water flowing over an uninhabited rocky soil or over sand and gravel is freer of organic impurities than one that has run over loam or has stood in swamps.

Surface waters are directly exposed to pollution by surface wash and water-carried wastes. They may be dangerous and are always open to suspicion. Because of the large yield of surface sources most cities depend upon surface waters taken from rivers, lakes, or impounding reservoirs. It is scarcely possible, in a populous country, to obtain a large quantity of surface water entirely free from pollution with human wastes. Sanitary engineers have, therefore, come to the conclusion that while surface waters used for drinking purposes should be protected from contamination as far as possible, they must be subjected at least to disinfection before use, no matter how good the protection.

**RIVERS.** Streams are the natural drainage channels of a region. Except along the seacoast and where sewage is used for the irrigation of crops, water-carried wastes must eventually find their way into them. If they are used as a source of water supply without treatment, they constitute, in a sense, a direct connection between the alimentary canals of the people living upstream and the mouths of those below. Most of our large rivers flow through more than one state; yet only recently have we provided legislation for dealing with stream pollution on a national basis. In some of the older countries of Europe, with more centralized power, laws to prevent the pollution of streams have long been enforced.

**STREAM POLLUTION VERSUS WATER PURIFICATION.** The succession of cities which use the river both as a sewer and as a source of water supply is particularly impressive on such rivers as the Merrimac, Hudson, Delaware, Ohio, Missouri, and Mississippi. The use of the waters of these rivers, raw and unpurified, has in the past caused much unnecessary sickness and has cost thousands of lives.

No stream draining an inhabited region can be considered safe without purification, even though the sewage flowing into the stream is completely treated. Storm overflows and street wash always add pollution which escapes treatment.

Normally it is cheaper to purify the water supplies taken from the rivers than it is to treat the sewage to the degree required for safety. But the cost of water purification increases with the degree of pollution, and a river can become polluted to such a point that no reasonable amount of treatment will produce a palatable and safe drinking water. Hence both water purification and sewage treatment are necessary, and one of the tasks of the sanitary engineer is to strike the proper economic balance between the two.

**COMPOSITION.** The composition of river water varies greatly from source to mouth and often from bank to bank. This complexity is due to the mixture of surface and ground water and to incoming wastes, each of which contributes a variety of impurities. Entering ground water as a rule contributes mineral matter and hardness by virtue of its longer contact with rock materials. Soil, swamps, sewage, and industrial wastes contribute organic matter; also some dissolved mineral substances; suspended particles of clay, soil, and waste; bacteria and other microscopic forms of life. In general, the mineral content of rivers is dependent upon the geological formations, the organic content upon the physiography of the area and the density of population.

Rivers are usually less polluted near their source because they generally originate in relatively uninhabited regions. Such pollution as is found is more apt to originate in swamps and from the erosion of clay banks.

The amounts of impurities increase as we descend the stream. Population centers tend to increase in size and number as the stream grows in its flow seaward and pollution may increase more rapidly than the volume of water and more rapidly than it can be eliminated by the forces of natural purification.

In broad, slow-moving streams, great inequalities in composition may be found through the cross section. These inequalities persist below the points at which tributaries enter or large volumes of waste are discharged.

Sudden and extensive changes in the character of river water occur at times of heavy rainfall. In a clean stream this dilutes the dissolved mineral constituents but it may increase the amount of organic substances, suspended solids, and bacteria. In a stream already heavily polluted a flood may cause dilution and relative decrease of all constituents.

General changes in composition, which come with increasing population and greater pollution, often occur over long periods of time. Such changes are of sanitary significance, for they indicate a retrogression in quality, a trend toward incipient nuisance, and an eventual sanitary menace.

**STREAM FLOW AND WATER-BORNE DISEASE.** Attempts have been made to correlate the flow of streams and the stages of a river with outbreaks of water-borne disease. Water-borne disease may be, and usually is, independent of the stage of the river. Such correlation as appears to exist at high stages is due to the fact that outbreaks are often connected with sudden freshets following a long dry spell. At such times there is much surface wash, the flow is rapid, infective material may be present and is then quickly carried for long distances, while nature's forces have not the time to destroy pathogenic bacteria in water. During the spring and

fall freshets, when the water is cold, this danger is greater, since the survival of pathogens is greater at lower temperatures.

**LAKES AND PONDS.** Fresh water lakes and ponds make admirable sources of water supply if kept free from pollution with human wastes. This is much more practicable than for rivers, on account of the limited area of the catchment basin directly draining into a small lake or pond. In large lakes the dilution of accidental contamination is enormous, and time, storage, sedimentation, and other purifying agencies have a good chance to exert their protecting influence. The sanitary problem in connection with large bodies of fresh water, such as our Great Lakes, is more concerned with mass pollution and is quite different from that of small lakes and ponds.

**THE GREAT LAKES.** The lake cities suffer most from the mingling of their own sewage with their own water supplies. This is avoided in part by building the intake structures far out into the lake and providing them with inlets that will permit drawing fresh, clear water that flows from the body of the lake to the intake. Lake currents are never constant. They are influenced in particular by wind; hence safety cannot always be secured. Almost every lake city has at one time or another suffered from outbreaks of water-borne disease. Improved sewage treatment and water purification have largely eliminated these outbreaks.

Pollution may travel a considerable distance in large lakes. At the mouth of the Detroit River, serious pollution was shown to extend more than 10 miles into the lake before sewage treatment was instituted, and at other places sewage pollution was shown to extend as far as 18 miles from the shore.\* The pollution from boats passing near the water intakes may be a serious menace.

**IMPOUNDING RESERVOIRS.** Impounding reservoirs are artificial ponds or lakes, usually made by throwing a dam across a narrow valley. Most impounding reservoirs are created along the course of a small stream. The principal use of impounding reservoirs is to convert an intermittent or fluctuating stream flow into a continuous water supply. This is done by holding the flood waters of the wet seasons in storage for use during the dry seasons. At the same time, the quality of the water is equalized by a mixture of the wet- and dry-weather flows. Time and relative quiescence permit the sedimentation of suspended particles, the bleaching, coagulation, and precipitation of colloidal coloring matter, and the destruction of objectionable aliens among the bacteria. Advantage is taken of the great sanitary safeguard of storage. Dangerous intestinal micro-organisms tend to die a natural death during the time when the water is stored in a large impounding reservoir. This time may be many months. Furthermore, there is primary protection in the fact that impounded supplies are usually located in sparsely settled or uninhabited districts.

The chief disadvantage of impounding reservoirs as storage basins is that they are liable to heavy growths of algae and other microscopic organisms responsible for objectionable tastes and odors. The stagnation of the lower layers of deep bodies of water also contributes to bad tastes and odors at certain seasons of the year.

**COLLECTION AND STORAGE.** The proper development of a catchment area for collecting and storing water calls for highly specialized engineering skills. The

\* Report of International Joint Commission of the United States and Canada.

amount of water that can be economically obtained is determined by such factors as the total amount of precipitation, its distribution throughout the year, and its occurrence as snow, the mean annual temperature and fluctuations from the mean temperature, the amount of water and swamp surface on the area, the nature of the cover and of the underlying geological structure, and the suitability of the area for dam sites.

In the New England region it is customary to plan for a storage of about half a year's supply in order to provide water at all seasons and to allow for fluctuations in run-off from year to year. In some parts of the West, however, storage may be required to meet not only seasonal deficiencies but also annual deficiencies, and so sufficient water has to be stored to serve over long periods of drought.

Many large impounding reservoirs have been and are being constructed to provide water for the larger cities. Among them may be mentioned the Quabbin Reservoir for the city of Boston, with a capacity of 415 billion gallons, the reservoir at Parker Dam on the Colorado River, serving Los Angeles, and the system of reservoirs on the tributaries of the Delaware River, which are being added to the New York water supply system.

**STAGNATION OF WATER; "OVERTURN."** Because water has a point of maximum density at  $4^{\circ}\text{C}$  and decreases in density on either side of this point, reservoirs, lakes, and ponds over 20 to 40 feet deep are subject to vertical stagnation. In the summer the warmer and lighter water remains at the surface. This upper layer is stirred to a certain depth by wind action and vertical currents caused by diurnal temperature fluctuations. The lower layer remains cool and quiet. There is a zone between the two layers, called the thermocline, where the temperature changes rapidly with depth.

As the air temperature falls with the approach of winter, the surface water cools down and approaches that of the bottom water. Density differences become small, and wind action and vertical currents mix the water from top to bottom. This is called the "fall overturn" and it continues for a few weeks, until the temperature of the surface water falls below  $4^{\circ}\text{C}$ . A period of winter stagnation then sets in, because the top water is lighter than that at the bottom. Preservation of quiescence may be aided at this time by an ice cover which protects the lake from wind action. As spring comes, the surface water again warms up until no density difference exists, and the "spring overturn" is set in motion.

These stratification phenomena have a great influence on the quality of the water. Organic matter accumulated in the bottom water decomposes, and may even deplete the oxygen entirely and produce putrefaction odors. Water drawn from these bottom layers may have an unsatisfactory taste and may contain substances such as iron and manganese in undesirable quantities. The fall and spring overturns bring to the surface a fresh supply of carbon dioxide, nitrogen compounds, and other substances favoring algal growths. The overturns are followed by pulses of algal growths, which create additional taste and odor problems. Departures from these occurrences are observed in the tropics and the Arctic.

**Ground Water.** Water that is taken from the ground by means of wells or that flows naturally from springs is often of better quality than surface water in the same area. The surface water is greatly improved as it percolates through the sandy soil. This is nature's process of filtration; the organic matter is oxidized.

the bacteria are largely strained out. The soil can take care of a large amount of pollution and will often yield ground water free of undesirable substances and bacteria. However, this is true only if the soil or rock is fine-grained and does not have cracks, crevices and bedding planes that permit free passage of polluted water. In passing through soil that is rich in decomposing organic matter, the water takes up a rather large amount of carbon dioxide. The water, thus acidulated, has a greater solvent action for lime and other mineral constituents, so that ground water is likely to be harder than surface water and to contain a larger amount of dissolved mineral matter. In deeper waters the solvent action is favored by longer contact with geological formations.

The water that soaks into the soil is finally supported upon an impervious stratum. As a rule, such water does not exist in the ground as a river or lake, but rather occupies the spaces between the sandy particles, except in limestone formations. Sandy, gravelly, or sandstone formations are good aquifers.

It is only in the crevices of limestone regions that ground water exists as flowing rivers or in large bodies. The sanitary hazard of water from limestone crevices or from shale and slate is always great.

Ground water finally reaches an impervious stratum. It then ceases to pass vertically downward and passes more horizontally through the porous stratum in which it is found. The surface of the ground water is known as the *ground-water table*. It is tapped when wells are sunk, and forms springs, lakes, and marshes where it crops out on the surface. It also contributes to the flow of streams during dry weather.

The surface of the ground-water table conforms, in general, to the surface of the land, but may depart from it. The ground-water table rises and falls to a certain extent with the rainfall. The rate of flow is of the order of miles per month whereas that of streams is miles per day.

**AMOUNT.** The amount of water that may be obtained from the ground can be determined only by means of actual pumping tests carried on for a sufficient length of time to bring about an approximate state of equilibrium between the supply and the draft as determined by the level of the ground water. Pumping tests of short duration are likely to be deceptive, as they may give copious quantities of water during the period of pumping; but this water may not be replaced quickly. For example, ground water may exist as a reservoir with little movement, corresponding to a surface pond with a small watershed. When the water is taken out, it may not be replaced for a long time. Ground water supplies are more generally available for, and better adapted to, the needs of small places than of large cities. In the United States there are more than twice as many communities that are supplied with ground water than with surface water. However, the total quantity of ground water delivered is far less.

In Europe ground water supplies have been provided for many large cities; corresponding large developments in America are rare, but industrial ground water supplies may be quite large. In many regions the yield has been depleted in the course of years, or population growth has raised the demand above the amount that can be safely provided.

Most ground water supplies are obtained from (1) sand and gravel deposits, (2) sandstone, (3) limestone formations. Some water may be drawn from the

cracks and crevices of granite and similar impervious rocks especially if they have an overburden of sand or gravel.

**GROUND WATER FROM SAND AND GRAVEL DEPOSITS.** Water flows through sand with some difficulty because of the frictional resistance to flow. A well draws water only from a limited portion of the surrounding area. This area of draft depends upon the depth and coarseness of the sand. Therefore, the way to secure a large quantity of water from such formations is by the use of a series of wells spaced so as not to interfere with one another or by the construction of a horizontal collection gallery, or gravel-filled area surrounding the well.

The amount of water that can be secured from a given area depends upon the rainfall, upon the evaporation from the surface of the ground, either directly or by the transpiration of vegetation, and upon the amount of storage in the pores of the soil. Ground water obtained from sand and gravel deposits is usually clear and free from unwholesome impurities.

Filter galleries near river banks that draw water from the stream through the ground are apt to furnish a diminishing supply, because the pores of the filtering material become filled with the sediment of the river water.

**GROUND WATER FROM SANDSTONE.** The method of driving wells in sandstone differs from that of driving wells in sand or gravel, but the collection, storage, and flow of water are precisely the same.

Aside from cementing material that binds what otherwise would be loose sand into a solid rock, sandstone acts substantially as so much sand would.

Water drawn from sandstone is well filtered unless the rock has been fractured by explosives. The Marshall and Potsdam sandstones underlying parts of Michigan, Illinois, Wisconsin, and Minnesota are used extensively for supplying towns and small cities.

**GROUND WATER FROM LIMESTONE FORMATIONS.** In limestone formations the water travels through fissures or passages. When these are large they are called caverns or caves, which are natural seams or cracks enlarged by the gradual solution and removal of the limestone by the passing water. Limestone and dolomite are the only common rocks that are soluble in this way and, for water supply purposes, these formations must be distinguished from all others.

The crevices may be, and often are, continuous for many miles. The direction and flow of the water may bear no relation whatever to the surface drainage. Pollution at one point may therefore endanger those using the water at a far-distant place.

A limestone formation has little ability to hold the abundant winter flows and to maintain a supply through droughts. The difference between limestone and sand in this respect is striking. While much water may be available, the amount is subject to great fluctuations, and the supply may fall short when most needed. From a sanitary standpoint, the fact is significant that water flowing through sand is filtered and purified, whereas no such action takes place in limestone fissures.

That contamination at one point may soon reappear at a far-distant point may be demonstrated by the use of fluorescent dyes, or by the use of massive cultures of some harmless micro-organism, such as yeast or *Serratia marcescens*.

Water-borne disease has been caused frequently by the use of ground water from limestone formations. A typical example is the Lausen epidemic (see Chap-

ter 3). *All water supplies from limestone formations must be regarded with suspicion unless properly safeguarded by appropriate treatment.*

**WELLS.** A well is a hole sunk into the earth to reach a supply of water and provided with some means for lifting the water to the surface. Wells may be either shallow or deep, and dug, drilled, or driven. The type depends largely upon the nature of the material through which the well is to be sunk. Shallow wells are usually dug and lined with stone or brickwork. Their diameter is usually five or six feet, but they may be much larger. They are rarely over 30 feet deep. Driven wells are made by driving wrought-iron pipes into sandy or gravelly soil. The pipe is fitted with a perforated strainer pointed at the end and covered with screening so as to allow entrance of the water and to exclude the sand and gravel. Deep wells are usually drilled. They consist of iron pipes or tubes, six to eight inches in diameter, and may extend many hundred feet into the earth. If the water is drawn from a depth of 100 feet or more, it is usually called a deep well. If the well passes through an impervious stratum into a pervious one beneath, it is spoken of as an artesian well.\* Water is usually drawn from wells by means of pumps or compressed air.

Except in limestone, wells are usually polluted from the surface. The filtering power of sandy soil or sandstone is usually sufficient to protect the water drawn from a well, unless a cesspool, broken sewer, or other gross source of pollution is close by. If channels, fissures, or crevices exist in sandstone or limestone, impurities may reach the well without undergoing filtration.

In locating a well, therefore, much depends upon the surface configuration of the ground, the character of the soil, and the proximity of possible sources of pollution. The casing of a dug well should be sound and tight, preferably of concrete of good quality. This impervious casing should extend 6 to 10 feet into the well. After it is laid, the outer space between the casing and the earth should be filled in with well-tamped clay soil or concrete. The casing should be extended 12 to 18 inches above the surface of the ground. The cover of the well should rest upon the top of the casing, so that no space is left for seepage water or vermin to enter. The cover is best made of reinforced concrete. It should slope away from the pump base and extend beyond the edges of the casing. Wooden covers are not satisfactory. The pump should be firmly fastened to the cover and surrounded with a flashing of tin to prevent water from washing back into the well.

The widely prevalent idea that some form of ventilation must be provided for a well is entirely erroneous. Well water keeps better in the dark and protected from the outer air and dust.

The tops of driven wells should be as carefully protected as those of dug wells, since otherwise polluted surface water may work down the sides of the pipe. Care should be taken that the pipes of a driven well near the surface of the ground do not rust and become leaky. Such wells should be provided with a heavy top, to which the pump frame should be tightly bolted in order to prevent loosening of the joints in the pipe by the vibration of pumping. The space between the base and the well casing of driven wells should be filled with grouting and overlaid with cement near the top. The ground about all wells should slope away and be kept clean, and

\* The word "artesian" is derived from Artois, an ancient province in France which was supplied with flowing wells. Artesian water may or may not rise to the surface of the ground.

From Water Supplies and Sewage Systems for Farm Residences, Bd. Health Minn., August 1921.

Fig. 36-2. Diagram showing how a dug well can be protected against pollution.

where possible, should be turfed. The waste water should be carried by pipes to a considerable distance from the well (Minnesota State Board of Health, 1921, 1923; New York State Department of Health, 1940).

Deep well waters in sand or sandstone furnish the safest and often one of the most satisfactory sources of supply. Such waters are usually clear and of high sanitary quality, but they sometimes contain a large amount of mineral matter, which renders them unfit for domestic purposes. They may contain iron or manganese, which soon oxidizes upon contact with the air and is thrown out as an insoluble compound, rendering the water yellowish or brownish. Deep well waters may contain an excess of lime and magnesium salts, common salt, hydrogen sulfide, carbon dioxide, etc.

*Location of Wells.* It is evident that in densely inhabited cities, with miles of sewers, some of them doubtless broken or leaky, the soil may be sewage-polluted and capable of contaminating shallow wells. Shallow wells, on general principles,

have been gradually eliminated from all large cities. The wisdom of this policy was shown by studies on typhoid fever in the District of Columbia, in which many of the shallow wells within the city limits were shown, by chemical and bacteriological analyses, to be polluted.

*Disinfection of Wells.* Temporary pollution of wells can be overcome by the addition to the water in the well of bleaching powder or calcium hypochlorite to provide a substantial chlorine residual. There is no remedy for continued pollution; the well must be abandoned, the source of pollution must be removed, or the water must be purified, boiled before use or otherwise disinfected. It is inadvisable for untrained persons to attempt chemical disinfection of the water.

**SPRINGS.** A spring is a stream of water flowing naturally from the ground. Spring water does not differ in any way from the ground water obtained from shallow wells. Spring water is subject to pollution from the same sources as well water and should not be regarded as safer than other ground waters. Spring waters differ greatly in character, especially as to their temperatures and the inorganic constituents which they contain. Springs may be perennial, the flow being constant, or they may be intermittent.

Springs may be contaminated from various sources and in much the same way as wells. The overlying porous layer of soil may be too thin to remove the contamination of surface washings from privies, stables, hog pens, and other places. Springs may be directly contaminated from surface washings; that is, the material may be washed down and into the spring by heavy rains, and unless the spring has a heavy flow, the material may remain in it for some time. The greatest hazards are found in spring water from limestone formations. A limestone spring that becomes muddy soon after a rain should be regarded as particularly suspicious.

## POLLUTION AND CONTAMINATION

**Sources and Nature.** Pollution refers to the entrance into water of substances, of any nature whatsoever, which impair its physical qualities. Vegetable matter from swamps and certain manufacturing wastes come in this category and have little influence upon health. Sewage may cause not only *pollution* but also *contamination* and is a direct menace to health. Contamination is a specific kind of pollution. These terms as used in connection with water are defined on page 1134.

Direct evidence of infection in water has rarely been demonstrated except in the case of cholera. Typhoid bacilli have occasionally been isolated from drinking water, but the technics are too laborious for general use. The evidence of water-borne infection is practically always epidemiological and is gathered after cases of disease have occurred. Contamination, however, can easily be established on the basis of field or laboratory findings, which show that wastes from man or animal have defiled the water. *Contamination is an index of potential infection.*

**Danger of Contamination.** The greatest hazard to man is found in a water contaminated with the alvine discharges from the human body. There is comparatively little danger from water containing the wastes of other animal life, for the reason that few of the infections of the lower animals are thus transmissible to man. There is practically no danger from water polluted with organic matter of plant origin.

**Prevention of Contamination.** The prevention of the contamination of surface waters is an important sanitary problem; the extent to which prevention is possible is determined largely by economic considerations. The most dangerous contamination is that which is recent in point of time, that is, that which is quickly transferred in a fresh and virulent form. It has become nearly impossible to maintain large streams and lakes entirely free from contamination. Substantial protection may be accomplished by installing sewage disposal works for all upstream towns and settlements and abolishing all overhanging privies upon the river and its tributaries. This requirement needs to be supplemented by continuous sanitary inspection. However, when a stream has a considerable population along its course, none of these measures affords complete protection. They help, but purification of the water must furnish the final safeguard. It is comparatively easier to guard small lakes, ponds, and impounding reservoirs than large streams and lakes.

**Legal Control of Stream Pollution.** The development and enforcement of laws for the prevention of stream pollution have lagged behind the scientific and technological means available for prevention. For many years enforcement was left up to the injured party, who had to resort to a damage suit under the common law doctrine that riparian owners were entitled to have the streams flowing past their property "undiminished and unimpaired, subject to a reasonable use" by the owners upstream. Many court battles were fought over what constituted "reasonable use," but the courts in general decided that pollution was not "reasonable." England was the first to adopt a comprehensive plan, backed by legislation, for country-wide abatement of pollution. This began with the Rivers Pollution Commission of 1855.

In the United States, until 1948, the regulation of pollution was left entirely to the separate states, with the Federal Government having jurisdiction only over navigable waters. All states have passed laws dealing with the subject; these vary greatly in effectiveness and enforceability. No two of them are alike but, in general, the control is vested in the state health department or in a separate water pollution control board. In some cases control is divided between two agencies. The penalties for violations vary from nominal to severe, and the powers of the agencies to make rules and regulations having the force of law may be extensive or negligible. The trend is to increase the authority of these agencies. Individual state laws do not deal with pollution which crosses state lines; such cases, where they have been dealt with at all, have been handled by interstate compacts and agreements.

In 1948 Congress passed a Federal Water Pollution Control Act. This provides that The Surgeon General of the U. S. Public Health Service shall have general supervision of stream pollution control activities. Initial enforcement of pollution abatement is left to the states, but The Surgeon General has power to enforce abatement if the states fail. The Public Health Service is empowered to establish a water pollution control advisory board and to assist states or interstate agencies with loans for construction of treatment works and funds for investigation and research. Pollution abatement activities under this new law are now in progress.

**Pollution of International Boundary Waters.** Under terms of Article IX of a treaty of January 11, 1909, between the United States and Great Britain, the questions of extension of pollution of boundary waters and remedies were referred to

the International Joint Commission under date of August 1, 1912. A sanitary survey was made of the Great Lakes District, particular emphasis being laid on sewage pollution from cities and towns, sewage from vessels, sawmill and other industrial and household wastes, and existing methods for their control. In general, the conclusions embodied in their report, 1919, are that it is "feasible and practicable without imposing an unreasonable burden on the offending communities to prevent or remedy pollution, both in the case of boundary waters and waters crossing the boundary. In case of city sewage, this can best be accomplished by installing collection and treatment works having special reference to the removal of bacteria and matters in suspension." The conclusion is made that vessels should treat their sewage before discharge, as for instance with live steam; also that water ballast discharge should be regulated with due regard for drinking water intakes for any neighboring community; further, that restriction should be placed on disposals of garbage and carcasses in boundary waters. The International Joint Commission has continued to regulate the pollution of boundary waters.

**The Care of Catchment Areas.** "Catchment area," "watershed," "drainage area," and "catchment basin" are terms used to include the area that contributes, by drainage to a particular stream, lake, or reservoir, the water that falls upon it. The ideal catchment area is free from human habitation and is covered with forests. The catchment areas supplying impounding reservoirs and the natural ponds and lakes used as reservoirs are limited in area when compared, for example, with the catchment areas of the great rivers, from which many public water supplies are drawn. It is, therefore, possible to inspect and control the former more readily than the latter.

It is often impossible to remove population from a catchment area. If the population is limited, proper precautions will ensure good water from the catchment area; but as population grows, the effectiveness of such precautions decreases. For example, population growth on the catchment area of the Sudbury Reservoir of the Boston water supply eventually forced the abandonment of this reservoir as a part of the regular supply. Similar changes have been forced on other cities, and treatment of waters once used without any purification has had to be instituted. The use of the automobile has greatly increased the hazard upon all such watersheds, for it is not possible to control effectively the habits of an itinerant population.

The prolonged storage of the water in large protected reservoirs is a sanitary safeguard and makes the Boston and New York supplies safer than they otherwise would be. The greatest danger lies in the fact that contaminated water may sometimes pass through a reservoir by short circuit, because of surface currents or unusual draft, and so reach the consumer before it has enjoyed the full benefits of purification by storage. Also the length of storage may be greatly decreased in times of drought. All such waters are now chlorinated.

The proper sanitary care of a catchment area requires, first of all, sufficient laws granting suitable authority, especially concerning the disposal of human wastes.

Care must also be exercised to keep out manufacturing wastes and the surface washings that may carry contamination from human sources or undesirable pollution. This object may be accomplished in various ways. The city should own the shores of the reservoir and also much of the land along the important streams. Old

sources of pollution must be removed and new sources prevented. Where the danger from human contamination is especially great, as around the impounding reservoir itself or at nearby suburban settlements, engineering projects, sometimes of considerable magnitude, are necessary to carry away the sewage and the surface drainage. A strict patrol of the catchment area and supervision of picnic and camping grounds and camps of construction gangs must be exercised.

In the investigation of a stream and its watershed, the chief points requiring attention are the relative proportions of polluting matter and the flow of the stream when at its minimum, the general character of the stream, the rate of flow, and the distance between the source of pollution and the water intake.

Water boards should plant their catchment areas with trees. Trees add to the retention of water and reduce erosion.

## SANITARY ANALYSIS OF WATER

EDWARD W. MOORE, M.A.

Judgment as to the sanitary quality of an actual or a potential water supply is based on information obtained from two sources: field surveys of the water source and laboratory examinations of collected samples. Field or sanitary surveys determine the presence or absence of possible sources of pollution. Laboratory examinations indicate whether or not the collected samples of water contain substances that are indicative of pollution or that are themselves harmful or undesirable. The fact that a water supply has been used for many years without causing recognized cases of disease can be relied on as evidence of present and future fitness only if conditions surrounding the supply have remained unchanged. This is seldom true, and the adoption of a *laissez faire* policy should be guarded against. Repeated field surveys and routine laboratory analyses of collected samples are the only real safeguard.

**The Field Survey.** The field survey is of surpassing importance in judging the fitness of a water supply. It calls for a consideration of a great many items and should be entrusted only to persons who have by training and experience acquired a broad knowledge of those matters which are pertinent to the sanitation of water sources, to their physical development, and to the purification of water. The survey should deal with the following features, a complete discussion of which is given in the Manual of Recommended Water Sanitation Practice (U. S. Public Health Service, 1946a):

## A. GROUND WATER SUPPLIES

1. Character of local geology; size and topography of catchment area; slope of ground surface.

2. Nature of soil and underlying porous strata, whether clay, sand, gravel, rock (especially porous limestone); coarseness of sand or gravel; thickness of water-bearing stratum; depth to water table; location and log of wells in vicinity in use or abandoned.

3. Slope of water table, preferably as determined from observational wells or as indicated presumptively but not certainly, by slope of ground surface.

4. Extent of drainage area likely to contribute water to the supply, population on the drainage area.

5. Nature, distance, and direction of local sources of pollution.

6. Possibility of surface-drainage water entering the supply, and of wells becoming flooded; methods of protection.

7. Methods used for protecting the supply against pollution, by means of sewage treatment, waste disposal, and the like.
8. Well construction: material, diameter, depth of casing; depth to strainers or perforations; length of strainers or perforations.
9. Protection of collecting well at top and on sides; protection other than check valve, or gate valve, against backflow of drain; protection of collector lines, etc.
10. Pumphouse construction (floors, drains, etc.); capacity of pumps; draw-down when pumps are in operation.
11. Availability of an impure supply, usable in place of normal supply, hence involving danger to the public health.
12. Disinfection; equipment; supervision; laboratory control.

*Examples of Sanitary Defects in Ground Water Supplies:*

1. Caves, sink holes, or abandoned borings, used for surface drainage, or sewage disposal, in vicinity of the source; fissures or open faults in strata overlying water-bearing formations.
2. Casing of tubular wells leaky, or not extended to sufficient depth, or not extended above ground or floor of pump room, or not closed at top; or casing improperly used as a suction pipe.
3. Collecting well, or reservoir, subject to contamination by backflow of polluted water through improper drain or by entry of surface drainage. Lack of covers, improperly designed manholes, vent openings, etc., which may permit contamination.
4. Source of supply or structures subject to flooding.
5. Use of tile pipes, or other conduits, that are not tight where the ground water may be contaminated.
6. Leak in systems under vacuum.
7. Air-lift line, or lines, cross-connected to a sewer or secondary water supply.
8. Wells located near sewers; pit privies; cesspools; septic tanks; subsurface tile systems; drains; barnyards; pits below ground surface; or other sources of contamination.
9. Wellheads, well casings, pumps, pumping machinery, exposed suction pipes, or valve boxes connected with suction pipes, located in pits extending below the ground surface.
10. Manufacturing and industrial plant wastes discharged on watersheds, or to underground strata causing contamination of ground-water supplies.

**SURFACE WATER SUPPLIES, UNFILTERED**

1. Nature of surface geology; character of soils and rocks.
2. Character of vegetation; forests; cultivated and irrigated land, including fertility, effect of irrigation water, etc.
3. Population and sewered population per square mile of catchment area.
4. Methods of sewage disposal, whether by diversion from watershed or by treatment.
5. Character and efficiency of sewage-treatment works on watershed.
6. Proximity of sources of fecal pollution to intake of water supply.

7. Proximity, sources and character of industrial wastes, oilfield brines, acid mine waters, etc.

8. Adequacy of supply as to quantity.

9. For lake or reservoir supplies: wind-direction and velocity data; drift of pollution; sunshine data (algae).

10. Character and quality of raw water: coliform organisms (most probable number); algae; turbidity; color; objectionable mineral constituents.

11. Nominal period of detention in reservoir, or storage basin.

12. Probable minimum time required for water to flow from sources of pollution to reservoir, and through reservoir to intake.

13. Shape of reservoir, with reference to possible currents of water, induced by wind or reservoir discharge, from inlet to water-supply intake.

14. Measures taken to prevent fishing; boating; landing of airplanes; swimming; wading; ice cutting; permitting animals on marginal shore areas, and in or upon the water, etc.

15. Efficiency and constancy of policing.

16. Disinfection of water: kind and adequacy of equipment; duplication of parts; effectiveness of treatment; adequacy of supervision and laboratory control; contact period after disinfection; whether residual-free chlorine or chloramines used in chlorinated water; residuals carried.

17. Pumping facilities: pumphouse; pump capacity and standby units; storage facilities.

#### *Examples of Sanitary Defects:*

1. Absence, or inadequacy, of chlorination, or lack of proper control of chlorination; insufficient contact period when chloramines only are present in treated water.

2. No restrictions on recreational use of streams and reservoirs, together with their marginal lands, in the local catchment area.

3. Existence of sources of pollution, such as population on watershed, lumbering, hunting, grazing, and other activities; leaching cesspools, or sewers draining into streams or lakes of the catchment area, or into the marginal lands adjacent to them.

4. Improper location of intake with respect to bottom of reservoir and current, or to surface-drainage-water inlets.

5. Intake exposed and accessible to trespassers.

6. For lake supplies: vessels passing near intakes; drift of ice fields; dumping of dredging, garbage, etc., into lake near intakes; inadequate toilet facilities on cribs.

#### **C. SURFACE WATER SUPPLIES, FILTERED**

1. Catchment area: size, topography; population density, sewered and unsewered; surface geology; reservoirs, their capacity and location.

2. Sources of pollution: nature; distance from intake, including miles and rate of flow; amounts and distances of sewered population.

3. Sewage treatment on watershed: extent; methods; population served; effectiveness and uniformity of results.

4. Raw-water characteristics: turbidity, color, alkalinity, hardness, iron, etc.

bacterial quality, average and ranges, variations in quality, especially after heavy rainfall or at times of high run-off.

5. Capacity of filter plant (million gallons per day); rated output, average and maximum daily; maximum capacity of raw-water pumps; standby equipment.

6. Coagulant system: type, as solution or dry feeding; chemicals used; dosage rates, average, maximum, and minimum; number and capacity of units; reserve units.

7. Mixing and flocculation basins: type, flash mixing, average and minimum times; flocculation, average and minimum times; number, size and arrangement of units; provisions for cleaning.

8. Sedimentation basins, number, size and retention capacity; plain sedimentation; postcoagulation sedimentation; methods of cleaning; flexibility of operations; efficiency of turbidity and bacterial removal.

9. Filters: pressure or gravity type; number; sizes and rated capacity, net filtering area; effective size and uniformity coefficient of sand; washing system, direct or from storage, rates of washwater application; loss-of-head gauges; rate controllers, average and maximum rates of filtration.

10. Filtered-water storage: capacity; location; arrangement; covered or uncovered; protection against contamination; methods of cleaning; added storage in distribution system.

11. Aeration: purpose; kind; capacity; location in purification system; efficiency.

12. Disinfection: kind; stages, if more than one; location in purification system; capacity; method of operation; operation control; average, maximum and minimum dosage; chlorine—ammonia ratios, if ammonia is used; simple or “break-point” chlorination, if used; efficiency of each stage; period of chlorine or chloramine contact before delivery.

13. Plant operation and control: technical supervision, trained or untrained, full-time or part-time; number of operators; laboratory control, kind and frequency of tests; plant and laboratory records, kind, extent, use, etc.; meteorological records.

#### *Examples of Sanitary Defects:*

1. Excessive raw-water pollution in relation to extent of treatment provided; existence of nearby uncontrolled sources of raw water pollution.

2. Bypass connections for raw water, or partially treated water, whereby such waters may be discharged into the distribution system.

3. Existence of cross connections, bypasses, or concrete channel walls within plant, such as between conduits or basins carrying untreated or partly treated water, and those containing completely treated water.

4. Lack of reserve capacity of treatment works, necessitating excessive overloading, or occasional bypassing of units.

5. Lack of competent supervision and operation, or of adequate laboratory control.

6. Deficient or inaccurate operation or laboratory records.

7. Lack of suitable devices for measuring and recording volumes of water treated; for maintaining continuity of coagulant and chlorine dosage; deficient retention periods in settling basins; or areas, depths, sizes of sand and washing facilities in filters.

8. Lack of, or deficiency in, proper chlorination equipment and control, or failure to maintain proper chlorine residuals in the treated effluent at all times.
9. Lack of suitable protection for purified water; storage capacity less than requirements for safety.
10. Improper location of water-treatment plant or inadequate protection with respect to flood waters.

#### D. PUMPING STATION AND COLLECTING SYSTEM

1. Location and protection with reference to flooding.
2. Number, type and capacity of pumps, including reserve; condition of equipment and method of operation; condition of suction pipes.
3. Location of suction pipes relative to sources of pollution.
4. Emergency intakes.
5. Emergency supply of power; record of power shut-down; effect of shut-down on surges through conduits, etc.
6. Recording apparatus on suction-well elevation; rise and fall of suction-well elevation.
7. Screens for fish and debris.
8. All sewers cast iron, or otherwise.
9. Curb walls around suction wells to protect against surface drainage.
10. Continuous or intermittent operation.

#### *Examples of Sanitary Defects:*

1. Leaky suction pipes.
2. Pump not self-priming; unsafe water used for priming.
3. Suction well subject to pollution through backflow of polluted water through drain.
4. Suction well or suction pipes unprotected from surface or subsurface pollution.
5. Improper location or inadequate protection with reference to flood waters.
6. Lack of suitable provision for ensuring continuity of pumping service under all possible conditions.

#### E. DISTRIBUTION SYSTEM (EXCLUSIVE OF RESERVOIRS OR STANDPIPES)

1. Area and population supplied, proportion to total within corporate limits.
2. Adequacy of distribution system with respect to area served; sizes of mains and laterals, circulation of water; storage provided.
3. Type of distribution system: whether gravity, direct pumping, indirect pumping, including capacity of pumps, etc.
4. For above-water crossings: flexibility of pipe joints for maintaining tightness under forces due to vibration and temperature changes including freedom of protection of pipe from impact of runaway vehicles, flood waters, and objects carried by flood waters.
5. For underwater crossings: use of flexible watertight joints, provision of valves located above flood level at each end of crossing, duplicate lines, etc.

ment installed for making pressure tests to detect leakage; sampling taps at each end of crossing; provision for blowing off such sections of pipe to waste above ground level; distance pipe is laid below bottom of stream bed.

6. Use of common, or separate, trenches for laying water mains and sewers; practice concerning crossings of water and sewer lines.

7. Disinfection procedure followed in laying new mains, or repairing existing mains.

8. Method of draining hydrants: sewers, dry wells, ground surface, other.

9. Elevation of booster-station floor level with regard to ground level; location of booster-pump suction lines relative to sources of pollution; possibility of developing negative heads in booster-pump installations drawing directly from the distribution system.

10. Method of delivery of water from public supply to some other water system which uses unsafe water.

11. Adequacy of piping system for maintenance of positive pressure in all parts of the distribution system, under normal usage, at all times.

#### *Examples of Sanitary Defects:*

1. Existence of cross connections between primary supply and secondary supply of questionable safety at any point in the distribution system.

2. Return to the system of any water used for cooling; hydraulic operations, etc. (This is not intended to rule out the use of the barometric-type condenser, or an entirely closed cooling circuit, at the water-supply plant.)

3. Absence, or inadequacy of, protection; lack of covers, improper location of distribution reservoirs, standpipes, or elevated pressure tanks.

4. Intermittent service, resulting in reduced or negative pressures in distribution system; sizes of mains and laterals inadequate for preventing negative pressures; presence of dead ends permitting reduced or negative pressures.

5. Connections to sprinkler systems using toxic solutions, such as antifreeze.

6. Repumping on consumer premises when pressure is low, causing negative head.

7. Connection to sewers and sewer-flushing chambers, and improperly located blow-offs in distribution system.

8. Existence of hydrant drain lines connected to sewer.

9. Presence of a secondary nonpotable water system on premises where a public system exists, unless adequate regulations and enforcement are provided to prevent the occurrence of cross connections.

10. Lack or inadequacy of enforcement of plumbing regulations and/or ordinances designed to protect the water supply against the possibility of backflow from plumbing fixtures or from mechanical equipment supplied with water from public water supply.

11. Connection of new pipe lines to the system without prior disinfection of pipes.

12. Existence of tile, or other leaky pipes, in distribution system.

13. Improper location of water pipes in relation to sewers and storm-water mains.

## F. STORAGE (RESERVOIRS ON DISTRIBUTION SYSTEM)

1. Use, location, and capacity of reservoirs and standpipes.
2. Reservoir sites, protection from trespassers; location with respect to sources of pollution; character of local geology.
3. Hazard of entry of flood and drainage waters; elevation of top of storage units with respect to highest known water level of any lake, pond or stream, the waters of which might approach storage units; precautions taken to divert surface drainage from the storage units; water tightness of reservoir or storage unit.
4. Point of discharge, as sewers, ground surface, etc., of overflows, blow-offs, clean-outs, and drains from roof or bottom of water-storage units.
5. Elevation above ground level of walls of surface storage units.
6. Protection of valve pits for storage units against flooding and surface drainage, and point of discharge of drains therefrom.
7. Type of cover or roof, manholes, vents, overflows, control gauges, and character of pipe connections to reservoir with regard to danger of leakage at points of entry.
8. Disinfection practice for new reservoirs or after cleaning and repairs on existing units.

*Examples of Sanitary Defects:*

1. Presence of earth formations at the reservoir site such as limestone, broken lava rock, coarse gravel, etc., whose interstices are in the form of channels, joints, or fissures and hence provide too little filtering action to prevent contamination from reaching the reservoir; poor surface-drainage conditions; insufficient distance from bodies of surface water or sources of contamination; top of reservoir not above ground or above level of flood waters.
2. Unsatisfactory materials, poor state of repair, cracks, lack of proper covers, vents and overflows that do not exclude birds, dust, rain, insects, etc.
3. Water-level indicators and control gauges that permit entrance of contamination into stored water.
4. Curbing or roof coping interfering with roof drainage.
5. Manholes and covers of flush type, and covers or manholes which permit leakage of drainage into the reservoir or storage unit.
6. Drains from reservoirs to sewers or surface waters when backflow therefrom can reach reservoir.
7. Valve stems projecting through reservoir covers not protected.

The field examination, when properly made and repeated at intervals, furnishes information of the sanitary and hygienic aspects of a water supply of greater significance than that obtained in any other way. It secures not only collateral evidence to be used in the interpretation of laboratory findings and morbidity statistics but also brings together facts which indicate the hazards under which the supply is operating. Further, these facts form a basis for prediction of changes to come. They show the trend of conditions and are a guide in shaping plans to meet future contingencies.

**Laboratory Examination.** A sanitary analysis is intended to furnish evidence of the wholesomeness of water and its general fitness for domestic and permitted industrial uses. The analysis of water is unlike that of most other substances in

that many of its constituents have no great significance of themselves but acquire significance only in relation to other information. It is also a fact that waters of acceptable quality differ greatly from each other and that the same water supply may show wide fluctuations in quality from season to season. This is particularly true of surface supplies. The interpretation of laboratory findings needs to be made in the light of all the analytical data obtainable and with the guidance of supplementary information from every possible source. When this is done the laboratory becomes an invaluable adjunct for estimation of sanitary quality.

Great stress should be laid upon the frequency of analysis. A single examination gives but little information, since it provides no indication as to whether or not the sample is truly representative. Only when examinations are made at regular and frequent intervals can well-founded conclusions be drawn. Frequency of analysis is a matter of judgment, and depends on the purpose of the analysis, the observed fluctuations in water quality, and the nature and magnitude of possible health hazards present. The report on drinking water standards of the U. S. Public Health Service (1946) contains suggestions as to the frequency of sampling for bacteriological analyses.

Laboratory examination is indispensable to the design and operation of water purification plants. It is the only means by which the performance of the purification processes can be evaluated and controlled. The degree of contamination in the raw water and the extent to which it is removed by purification processes can best be judged by tests in the laboratory. Laboratory analyses also indicate trends and changes, and are useful in forecasting future conditions which purification processes will have to meet.

Thus, although sanitary analysis is second in importance to the field survey, it is an indispensable part of the work of establishing and maintaining a safe water supply. It corroborates or modifies estimates of quality made in the field and indicates, within the bounds of present knowledge, the probable results of use of the water.

## STANDARD METHODS

If the results obtained from analyses of collected samples by different analysts are to be comparable, and subject to uniform interpretation, the procedures used must be standardized. A standing committee on Standard Methods of Water and Sewage Analysis is maintained by the American Public Health Association, with the cooperation of the American Water Works Association and the Federation of Sewage Works Associations. This committee produces, at suitable intervals, a revised edition of *Standard Methods of Water Analysis*,\* which contains the accepted methods for chemical and bacteriological analyses of water. These methods are periodically checked by the committee, and improvements and alterations are made as experimental work confirms their desirability. Analyses made by the procedures described in *Standard Methods* are recognized by the courts and are universally used by analysts responsible for the control of public water supplies. Such standardization does not preclude the development of new and improved methods, or the use of special technics for special investigations. Its purpose is to establish a

\* The full title of the tenth edition (1955) is: *Standard Methods for the Examination of Water, Sewage, and Industrial Wastes*.

recognized norm of procedure which conforms to the best in current analytical practice.

**The Parts of a Sanitary Analysis.** A sanitary analysis of water resolves itself into four component parts: (1) physical, (2) chemical, (3) microscopic, and (4) bacteriological examinations.

**PHYSICAL TESTS.** Physical tests have to do with the determination of substances which affect the physical or esthetic quality of water, such as taste, odor, color, and turbidity. These tests are likely to be empirical and arbitrary in method and form of expression. It is difficult to express the results in terms of the amounts of specific compounds present, for any of the above-mentioned qualities may be due to a variety of compounds, many of which are of complex, organic structure and some incapable of detection by present laboratory methods. The technics employed for the physical examination attempt to evaluate the total effect of all compounds present which can be measured by the sense of taste, smell, or vision.

**CHEMICAL EXAMINATION.** The chemical examination is made by special technics of analytical chemistry adapted to measure the relatively small quantities of substances present in water. Some of these technics directly determine specific substances, others are indirect, and measure the total effect of a complex of ingredients. The chemical examination is of some value in detecting pollution, but its principal contributions are data concerning the chemical quality of the water, the effectiveness of purification processes, and the previous history of the water.

**MICROSCOPIC EXAMINATION.** The microscopic examination is designed to detect and measure the quantities of algae, protozoa and related organisms of the same order of magnitude. These organisms are of importance to the analyst as frequent sources of odors and tastes as well as of scums and water blooms. Dead organisms and amorphous matter may also be included.

**BACTERIOLOGICAL EXAMINATION.** The bacteriological examination deals with the numbers and kinds of bacteria present. From its findings a better appraisal of hygienic quality can be made than from any other part of a sanitary analysis. It has been possible from experience to define more closely limiting values for bacteria, particularly the coliform group, than for other constituents of water.

**CORRELATION.** From the foregoing it will be noted that each of the four parts of a complete sanitary analysis deals with different, although often complementary, qualities of the sample. It is, therefore, of prime importance that any estimate of character and quality which is based upon laboratory findings should be made in the light of all the tests assembled and correlated.

**Collection of the Sample.** For a complete physical, chemical and microscopical analysis of water one gallon is necessary. If the sample has been collected in a sterile container with precautions to prevent contamination the same sample may serve for the bacteriological examination. Usually the bacteriological samples are collected separately in special bottles holding at least 100 ml., but not completely filled.

The bottles for bacteriological samples should be of hard, clear white glass and have a glass stopper or other closure which will resist the high temperature necessary for sterilization. Cork stoppers are not satisfactory. The bottles should be chemically clean and sterilized in an oven at 170° C for one hour, or in an autoclave at a steam pressure of 15 pounds for 15 minutes. For transportation the neck

may be covered with tinfoil, cloth, or heavy paper before sterilization and the bottle placed in a tin box. Earthen jugs and metal containers are entirely unsuited.

Samples for physical, chemical and microscopic analyses should also preferably be collected in bottles of good glass with glass stoppers or plastic closures. Cork stoppers covered with tinfoil or paraffin may be substituted when only mineral analyses and physical examinations are to be made.

Generally speaking, the shorter the time elapsing between collection and analysis, the more reliable will be the analytical results. The bacteriological results are especially sensitive to delay, since bacteria may multiply or diminish in the bottle. Best results are secured if the bacteriological samples are transported and stored at refrigeration temperatures. The oxygen consumed, the oxygen demand, the pH value, and the nitrogen determinations are also materially affected by comparatively short delay. The dissolved gases should be determined at the source. The following are the maximum times which may elapse between sampling and analysis (American Public Health Association, Standard Methods for the Examination of Water and Sewage, Tenth Edition):

#### PHYSICAL AND CHEMICAL ANALYSIS

Unpolluted water . . . . .	72 hours
Fairly pure waters . . . . .	48 hours
Polluted waters . . . . .	12 hours
Sewage and sewage effluents . . . . .	As soon as possible
	Store at 3° to 4° C

Preservation by sterilization with acid or a germicide will permit longer delays. Procedures depend on the determination to be made.

#### BACTERIOLOGICAL ANALYSIS

Pure waters . . . . .	12 hours
Impure waters . . . . .	6 hours
Samples to be kept between 0° C and 10° C	

Samples for microscopic analysis are preferably examined in the field, especially if fragile organisms are present. Under no circumstances should the elapsed time be more than 12 to 24 hours of refrigerated storage.

**Technic of Sampling.** Care should be taken to secure a sample thoroughly representative of the water to be analyzed. A pump should be operated five minutes, a water faucet allowed to run several minutes, before the bottle is filled. In collecting samples of surface waters the specimens should not be obtained too near the bank of the stream or pond and surface pollution should be avoided. If the sample is not collected from the surface, a note should be made of the depth at which it is taken. It is always advisable to take the temperature of the water at the time of collection.

**Expression of Chemical Results.** Use of a measured volume of water underlies most analytical procedure. Results are expressed in milligrams per liter (mg./l.) or in parts per million (p.p.m.); these are substantially identical since a liter of water weighs very nearly 1,000 gm.

When water is highly mineralized analytical procedures may be based on a

known weight of water, or the weight may be estimated from the known specific gravity and volume.

The concentration of chemicals, such as alum and lime, that are added to water for treatment purposes, is commonly expressed in grains per gallon. One grain per U. S. gallon is equivalent to 17.1 parts per million, and, since the Imperial gallon is 1.2 U. S. gallons, one grain per Imperial gallon corresponds to 14.25 parts per million.

### PHYSICAL TESTS

**Odors and Tastes.** Although the taste of a water seldom bears any relation to its safety, to the ordinary consumer it is probably the most important property of a water supply. No amount of scientific evidence that the water is free from anything injurious to health will suffice to allay the suspicion aroused by unpleasant or unusual flavors. It has been demonstrated many times that a safe but unpalatable supply will be abandoned by many in favor of a palatable water of dubious sanitary quality.

The sources of the odors and tastes which occur in potable waters are numerous; some of them are as yet imperfectly understood, but most of them can be controlled or at least mitigated. The true tastes, namely, the salty, sour, sweet, and bitter flavors, are comparatively rare in water supplies. Where they occur, they are generally due to excessive amounts of dissolved salts, acid or alkaline substances, iron compounds, and a few other less well identified agents. Tastes are sometimes produced as a result of improper or excessive chemical treatment of water. Most of what are called "tastes" in water are in reality odors; they represent the response of the olfactory centers to substances volatilized from the water in the course of ingestion.

The most common cause of objectionable odors in water supplies is the presence of microscopic organisms. The principal offenders are members of the following groups: green and blue-green algae, diatoms and protozoa. Recently, suspicion has also been directed toward the actinomycetes. Odors may also develop from the decay of organic matter in the absence of oxygen as, for example, in the lower depths of impounded reservoirs. Well waters in certain regions may contain hydrogen sulphide; the resulting odor is highly objectionable. Industrial wastes are often responsible for odors. For example, certain wastes from the beet-sugar industry produce objectionable flavors in water even when present in very small amounts.

Chemical treatment of water often produces objectionable flavors. The single outstanding defect of chlorine as a disinfecting agent is its tendency to alter the flavor of the water for the worse. Excessive chlorination results in a product in which the odor of chlorine itself is objectionable to many consumers. More frequently, however, the chlorine reacts with substances present in the water to produce odors of other types; a notable example is the iodoform or medicinal taste produced by the action of chlorine on water containing even a few parts per billion of phenolic substances. Other chlorine reaction products result in tastes often described as "woody." Used judiciously, in accordance with modern practice, chlorine does not necessarily produce such taste and odor problems, and may even eliminate many tastes and odors from other sources, but careful control of chlorination is an absolute necessity if a palatable water is to be secured.

**DETERMINATION OF ODOR.** The odor of a water should be observed both at room temperature and at 50° to 65° C. The kind of odor observed may be described as vegetable, aromatic, grassy, fishy, earthy, moldy, musty, disagreeable, peaty, sweetish, etc. The intensity may be estimated, or it may be determined semiquantitatively by serial dilution with odor-free water—the so-called threshold odor test.

**ODORS DUE TO MICROSCOPIC ORGANISMS.** The odors and tastes in water caused by microscopic organisms deserve special consideration, because they are common faults in water stored in open reservoirs of all kinds. Certain organisms can be distinguished by their odor, as, for example, the “fishy” odor of *Uroglenopsis*, a member of a group of motile, chlorophyll-bearing organisms (Chrysophyceae) often included in the protozoa; the “aromatic” or “rose-geranium” odor of *Asterioella*, which belongs to the Bacillarieae; and the “pig-pen” odor of *Anabaena*, which is one of the blue-green algae (Whipple, 1927). Most of these microscopic organisms grow near the surface and require sunlight for their development; hence, they do not grow in covered reservoirs or in waters kept in the dark.

Calkins has shown that the odors caused by the undecomposed microscopic organisms are due to compounds of the nature of essential oils, and Whipple points out that the amount of such oil produced by an abundant growth of the organisms is quite sufficient to account for the effect observed. Whipple further suggests that the flow of water through pipes may cause disintegration of organisms with liberation of the odor-producing oil, hence the odor at the tap may be greater than at the intake.

The micro-organisms causing bad tastes and odors in water are mostly chlorophyll-bearing forms, which do not depend upon organic matter or the bodies of other organisms for their food supply. They require only sunshine, carbonic acid and the nitrates and minerals always present in the water and in the air. In other words, they have properties comparable to the higher orders of chlorophyll-containing vegetation. Many of them, however, resemble animals insofar as they possess a high degree of motility.

There are many kinds of algae, and they differ greatly in their odor-producing powers. Most American impounded reservoir waters suffer from them.

A certain degree of quiet and repose is necessary for the development of a large growth of algae; that is why they rarely develop significantly in rivers and flowing water. Wave action also prevents growth, and this seems to be the reason why large lakes and reservoirs are less troubled by them than smaller ones.

In most American impounded reservoirs the water is drawn from near the surface layer, so as to avoid the odors and tastes of putrefaction in the bottom water, but it sometimes happens that the surface is the more objectionable because algae grow there. For this reason a water-intake should preferably permit shifting depth from which water is drawn.

**PREVENTION AND REMOVAL OF TASTES AND ODORS.** Odors can be reduced, but almost removed, by aeration. Natural aeration takes place during turbulent flow over stones and ledges. Aeration may also be accomplished in water treatment plants by devices such as nozzle fountains and cascades. The reduction in odor accomplished by such devices depends on the type of odor present; for algal odors the expense of aeration is rarely justified. The degree of removal also depends upon

the thickness of the water films brought into contact with the air and upon the time allowed for contact.

Some reduction of odor is accomplished by filtration. Chlorination for disinfection often intensifies odors, either by destruction of algae and release of their odor-producing substances, or by reaction with organic substances to produce compounds of greater odor intensity. Such intensification can be avoided by the use of ammonia along with the chlorine, to reduce the reactivity of the latter. Complete destruction of odor can often be accomplished by a very heavy dose of chlorine which completely oxidizes odoriferous organic substances, and is itself partly destroyed in the process. The surplus of chlorine can be eliminated by dechlorinating agents, such as sulfur dioxide, or the chlorine dose can be adjusted to leave a slight residual, the so-called "break-point." The use of chlorine dioxide in place of, or in conjunction with, chlorine shows promise as a means of destroying tastes and odors.

One of the most effective methods of removing tastes and odors makes use of activated carbon, a charcoal prepared from various materials and subjected to special treatment to enhance its adsorbing power. The water may be filtered through beds of granular activated carbon, but the usual and more effective practice is to add powdered activated carbon to the water in the course of the rapid sand process of filtration. The carbon is removed as the water passes through the coagulation basins or filters. It adsorbs organic substances and the odoriferous oils of the algae. It is highly efficient as a taste or odor *remover*, as well as being a *preventive* of these qualities by reason of its ability to take out foreign substances which might react with chlorine when the latter is applied for final disinfection. For further information on the ammonia-chlorine, break-point, chlorine dioxide, and activated carbon treatments see Chapter 39.

It is practically impossible to prevent the seeding of reservoirs and ponds with algae and other organisms responsible for the objectionable odors. The growth may be checked and the odors temporarily controlled by the use of copper sulfate (see Chapter 39).

If a well develops odors from putrefying organic matter collected on the bottom, the trouble may be corrected by cleaning out the well thoroughly, or by filling up all unnecessary space below the suction pipe with clean gravel and sand.

**Color.** Pure water, such as distilled water, when viewed in shallow depths appears to be perfectly colorless, but, when viewed in bulk, it is seen to possess a beautiful greenish-blue tint. A small amount of suspended or dissolved impurity is sufficient to modify or obscure this color.

Most surface waters exhibit a color varying from green to yellow and brown when examined through a depth of several inches in clear glass tubes.

Color in surface water is usually of vegetable origin; animal matter contributes but little color. The coloring matter is extracted from dead leaves, bark, and roots, from soil and from peat. It is similar to the coloring matter of tea. It is certainly harmless, but makes water less pleasing in appearance, and great efforts are made to prevent and remove it. Water from swamps is usually brown-colored. Colors may also be due to the presence of industrial waste, unlike natural colors which tend to be of approximately the same hue, the colors due to industrial

waste vary greatly in hue and intensity and no standard method for their measurement is available.

Ground waters are usually colorless. If the water contains iron it will be perfectly clear on coming from the ground, but will soon turn a rusty yellow color. This is caused by the oxidation of the soluble ferrous salts to insoluble ferric salts.

**DETERMINATION.** The natural color of water is determined by matching a 50- or 100-ml. sample in a Nessler tube with a standard solution of platinum and cobalt salts. The primary standard, containing 1.425 gm. potassium chloroplatinate and 0.1 gm. cobaltous chloride per liter, is assigned a color value of 500 p.p.m. This standard is diluted to give subsidiary standards of suitable range for comparison with the sample. The comparison is made by looking vertically downward through the tubes upon a white surface placed at such an angle that light is reflected upward through the column of liquid.

**PREVENTION AND REMOVAL.** Excessive color in surface water can be partially controlled by preventive measures on the watershed. These consist of the drainage of swamps and the stripping of the shore line. In the construction of impounding reservoirs heavy deposits of muck and organic matter are removed or covered with gravel and sand before the reservoir site is flooded.

Color is reduced by storage in reservoirs. The action is the result of several forces. To some extent there is a bleaching action and oxidation due to exposure to sunlight and air, but it is probable that physical forces play the major role and operate to bring about a coagulation of colloidal color particles which gradually precipitate.

Color is removed from water by coagulation with aluminum sulphate or occasionally with iron salts, followed by sedimentation and rapid sand filtration. At many plants nearly complete removal is obtained. Other methods for removing color, such as oxidation by chlorine, are possible, but their cost is greater than that of coagulation and filtration, so that they are not in use. The drinking water standards of the U. S. Public Health Service (1946b) limit color in filtered waters to 20 parts per million.

**Turbidity.** Practically, turbidity is synonymous with muddiness. It is that property which interferes with the distinctness with which the outline of objects is seen through water. The turbidity of surface waters is usually due to mud, clay or silt, but it may also be due to a variety of other substances, such as finely divided organic matter or microscopic organisms. Many industrial wastes contribute large amounts of turbidity. Turbidity measures the amount of foreign substances in suspension. Turbidity and color do not generally occur together in large amounts; the former presents the washings of a readily eroded drainage basin, the latter is mostly extracted from the decaying vegetation of swamps.

Clean water is clear and sparkling, but brilliancy and clearness do not guarantee freedom from contamination, nor, on the other hand, does turbidity necessarily indicate danger. The turbidity problem is practically limited to river waters. Ground waters should seldom be turbid and, if so, should at once excite suspicion. Some ground waters become more or less turbid through the precipitation of iron through the failure of supporting strata which allows entrance of clay or soft rock material to the water.

All river waters are more or less turbid, but the differences are great indeed.

The amount of turbidity depends largely upon the character of the catchment areas. In general, rivers draining the large areas of our North and East which are covered with glacial drift of a sandy character, carry less than 10 p.p.m. of turbidity, unless they are polluted by sewage and industrial waste. In that part of our country which is not glaciated—for example, the lower Susquehanna basin, much of the Ohio basin, and the Missouri basin—turbidity is often present in large amounts, and consists largely of finely divided clay. The Missouri River carries an annual average of 1,200 or 1,500 parts per million of suspended matter. In winter it falls to 200 parts or less, while in midsummer it rises for weeks and even months to 5,000 parts or more.

Turbidity is ordinarily removed by coagulation, sedimentation, and rapid sand filtration. The coagulants and procedures are substantially the same as those used to remove color, but the required dosages and the optimum pH range for coagulation are often different. One of the principal factors contributing to the obsolescence of the slow sand filter is its inability to handle waters containing any substantial amount of turbidity. Occasionally, very turbid waters may be given a preliminary period of sedimentation, to reduce the load on the coagulation and filtration process. This procedure succeeds only if a fair proportion of the turbidity is comparatively coarse, and is becoming rare in practice. Even less common is the use of preliminary rapid filters, or scrubbers, used without coagulant to protect slow sand filters, as, for example, in the purification plants of the London Metropolitan Water Board. The turbidity in the London supply is due primarily to algae. Even here the use of scrubbers is conceded to be obsolete, and other methods, such as fine screening, are being investigated.

There is no evidence that natural turbidity is harmful in any way, although this may not necessarily be true of turbidities caused by industrial wastes. For filtered waters the U. S. Public Health Service (1946b) drinking water standards specify a limiting turbidity of 10 parts per million, but for unfiltered waters the limit is a matter for judgment based on local conditions. Obviously, the reasons for setting a low limit for filtered water relate to esthetic considerations, and to the effectiveness of the filtration plant in removing truly harmful substances.

Low degrees of turbidity may be accurately determined by the comparison of a sample with standards in clear glass bottles or long glass tubes, prepared by dilution of a standardized suspension of fuller's earth with distilled water. For high turbidities a turbidimeter gives satisfactory results. Jackson's turbidimeter employs a calibrated glass tube, into which the sample is poured until the image of a standard candle flame below the base of the tube is obscured.

#### CHEMICAL EXAMINATION

**Total Solids.** The concentration of total solids or residue on evaporation is obtained by evaporating a given quantity of water to dryness, whereupon a grayish-white residue, composed of the mineral and organic matter which has been held in the water in suspension and in solution, will be obtained. The amount of this residue varies with the character of the water. If the total residue is ignited, the "loss on ignition" is a rough index of the total amount of organic substances present. The residue remaining after ignition consists of mineral matter and is an index of the inorganic matter in the water.

The amount of total solids in a water depends upon the character of the soil and rocks with which the water has been in contact, the length of exposure, and the amount of carbon dioxide in the water to favor the solution of inorganic salts. Some mineral springs contain very large amounts of total solids, derived from deeply situated natural deposits. The springs at Saratoga are an example.

The permissible amounts of total solids cannot be arbitrarily stated, but the drinking water standards of the U. S. Public Health Service (1946b) recommend that they should not exceed 1,000 parts per million and should preferably not be over 500. From a sanitary standpoint the problem is not alone quantitative, but also qualitative.

**Hardness.** Hard water is objectionable because it wastes soap and affects the skin unpleasantly; it is less satisfactory than soft water for cooking and washing; it produces scale in boilers and is objectionable in many industries, such as textile and paper mills. However, with the advent of synthetic detergents, some of the objection to hard waters for domestic use has been eliminated. There is a general belief that abrupt change from soft to hard water, or vice versa, will cause temporary gastrointestinal disturbances, but no clinical evidence exists. There is likewise no evidence that hard water as such, has any other influence on health, either favorable or adverse. However, it is true that waters containing substantial amounts of magnesium ions associated with sulphate ions will produce laxative effects in persons unaccustomed to them. Hardness in water is, therefore, primarily an economic question.

Hardness in water is due to the presence of the soluble salts of the alkaline earths, especially calcium and magnesium. These salts form a curd with soap, hence soap must be consumed in precipitating the calcium and magnesium ions before lather will form. In this way hard water causes an enormous waste of soap. In this country hardness is expressed in parts per million of calcium carbonate, or in grains per gallon of calcium carbonate. In Europe, hardness is usually expressed in degrees. One English degree of hardness corresponds to one grain of carbonate lime in an Imperial gallon of water.

The hardness of water is of two kinds, "carbonate" and "noncarbonate." Either both may be present. *Carbonate hardness* is that portion of the calcium and magnesium ions which is chemically equivalent to the carbonate and bicarbonate ions present in the water. This is sometimes more simply expressed by saying that it consists of carbonates and bicarbonates of calcium and magnesium; but the statement, although convenient in practice, is scientifically inaccurate. Most natural waters contain dissolved  $\text{CO}_2$ , in the presence of which carbonates become bicarbonates, so that carbonate hardness is usually due to bicarbonates. This form of hardness is sometimes called "temporary" because boiling will drive off  $\text{CO}_2$  from causing most of the bicarbonate ion to be converted to normal carbonate ion. As soon as the product of the calcium and normal carbonate ions exceeds a fixed value, solid calcium carbonate is formed. The reactions are shown below; they are reversible:

*Noncarbonate hardness*, on the other hand, is that portion of the total calcium and magnesium ions in excess of the equivalent amounts of carbonate and bicarbonate. It is frequently but inaccurately referred to as calcium and magnesium sulphate, chloride, etc. It is sometimes called "permanent hardness" because it does not precipitate on boiling. Both carbonate and noncarbonate hardness contribute to scale in steam boilers.

Waters containing less than 50 parts per million of hardness may be considered soft; those containing more than 150 parts, hard. Usage largely determines the degree of satisfaction with which waters of different amounts of hardness are received, although standards are rapidly changing and there is a popular demand that very hard waters be softened. In the lake cities, 100 parts per million is considered satisfactory, yet such a hardness in eastern cities, where values are generally under 50 parts per million, would be a cause of complaint.

Rain water is always soft; surface waters vary, but are usually not very hard; ground waters are more apt to be hard.

Two conditions must be present to make a ground water hard: first, the material through which the water passes must contain calcium or magnesium salts; and, second, the conditions must be favorable for dissolving them. If the calcium and magnesium are present in the soil as the carbonates, any carbon dioxide present in the water will dissolve them, by reversing the reactions given under the discussion of temporary hardness.

As a result, waters drawn from limestone regions vary greatly in hardness. Rain water contains but little carbonic acid and, therefore, has little power of dissolving limestone. The principal source of the carbonic acid in ground water is from the decomposition of organic matter in the soil. The hardness of water, therefore, depends more upon the nature of the catchment area than upon the amount of lime in the various materials over which the water flows.

**SOFTENING OF WATER.** There are two methods of softening water in general use, the lime-soda or Clark-Porter process, and the ion-exchange or Zeolite process.

In the lime-soda process, hydrated lime and soda ash (sodium carbonate) are added to the water to precipitate, respectively, the carbonate hardness and the magnesium, and the remaining noncarbonate hardness. The precipitate is settled out, and the water is then filtered. The basic equations are as follows:

where X represents any ion other than carbonate or bicarbonate. Given the calcium (Ca), magnesium (Mg), and bicarbonate content (alkalinity) of the water all expressed as calcium carbonate, the chemical dosages required to soften a water can be computed from the following equations, derived from the chemical expressions above:

Lb. lime as CaO per million gallons =  $4.66 (\text{Mg} + \text{alkalinity})$

Lb. soda ash as  $\text{Na}_2\text{CO}_3$  per million gallons =  $8.83 (\text{Ca} + \text{Mg} - \text{alkalinity})$

In these equations the terms Ca, Mg, and alkalinity are all expressed as parts per million of calcium carbonate.

As carried out in municipal water softening, the lime-soda process can reduce the hardness of a water to about 75 parts per million; special variations of it, such as excess treatment, or softening the water after heating, are used in industrial practice, and permit reduction of hardness to about 30 parts per million.

The ion-exchange process is based on the ability of certain natural and synthetic materials to remove from water the objectionable calcium and magnesium ions, and substitute for these, less objectionable ions, such as sodium. The exchange materials then can be regenerated for further use by treatment with a strong solution of sodium chloride. The reactions are as follows:

In operation, the water to be softened is passed through a bed of the exchange material in granular form, which removes the hardness. When the bed is exhausted, it is treated with a 5 to 10 per cent solution of salt to regenerate it, rinsed to free it from the salt, and is then ready to soften more water. The operation can be made completely automatic. The ion-exchange method can reduce the hardness of the treated water substantially to zero, but this is undesirable in practice, since such water is highly corrosive; it is usual to by-pass a portion of the water around the softener, producing a blended water containing some residual hardness.

There are three general types of ion-exchange materials. The first ones used were naturally-occurring silicate minerals, variously called greensands, glauconites or zeolites; they are still valuable because of their high durability, although their capacities are relatively low. Synthetic siliceous materials, called gel zeolites, have high capacities but are less resistant to attack by chemical substances in the water. The comparatively new organic ion exchangers are made from carbonaceous materials treated with fuming sulphuric acid, or from synthetic resin-like polymers. These organic exchangers combine high capacity and resistance to chemical attack and are tending to replace the other two types.

The organic ion-exchange materials are capable of replacing all positive ions in the water by hydrogen ions if they are regenerated with acid rather than with alkali. This makes possible the complete demineralization of water; a second bed of exchange material, called an anion exchanger, removes the hydrogen ions, and also takes out nearly all the negative ions, such as chloride, sulphate, etc. The anion exchanger is regenerated with soda ash or caustic soda. Water treated by this two-stage exchange process is substantially equivalent to distilled water; the process has considerable application in industrial water supply, and is beginning to be used to produce potable water from waters containing excessive salinity.

**Alkalinity and Acidity; pH Value.** Most natural waters contain bicarbonate ions; occasionally normal carbonate ions are present. All waters contain the hydroxyl ion, but the amounts are negligible except in waters which have received strongly alkaline wastes, and in waters which have undergone certain types of treatment. The presence of these ions causes the water to have an alkaline reaction with respect to methyl orange indicator, and occasionally to phenolphthalein indicator. The quantity of standard acid required to render the water neutral to these

indicators is a measure of the quantity of the ions mentioned above present in the water; this quantity is called the alkalinity of the water, and is expressed in terms of equivalent calcium carbonate. The alkalinity of a water, in relation to its hardness, determines the proportions of "temporary" and "permanent" hardness, and also determines the amounts and kinds of chemicals necessary for softening. It has an important bearing on the corrosiveness of the water; a water having a high alkalinity is generally less corrosive than one of low alkalinity. It is of significance in determining the method used for coagulation of the water prior to rapid sand filtration.

Waters from mining regions, and rain waters collected in the vicinity of cities may sometimes contain little or none of the ions comprising alkalinity, but instead may have considerable quantities of acids, principally sulphuric. The measurement of acidity is analogous to that of alkalinity; methyl orange indicator is used, and a standard base is substituted for the standard acid. Acid waters are difficult to handle; they are highly corrosive, and the acid must be neutralized by the addition of lime or other alkali before they can be used in water supplies.

The alkalinity and acidity of waters are measures of the total quantities of substances capable of reacting with acid or alkali. The intensity factor, which corresponds to these quantity factors, and which determines the behavior of the water, is called the pH value. It is a measure of the hydrogen ion activity in the water, but since the actual quantity is small, it is more conveniently expressed as the logarithm of the reciprocal of this activity. The scale runs from zero, representing a highly acid solution (one normal acid) to 14, representing a highly alkaline solution (one normal base). A completely neutral solution has a pH value of 7.0; a water having this pH value has neither an acid nor an alkaline reaction, although it may contain considerable amounts of "alkalinity." Most natural waters have pH values which range around 7.0; the usual limits are about 5.5 to 8.5, although exceptions can be found. Treated waters may have values outside this range; the U. S. Public Health Service drinking water standards permit pH values as high as 10.6.

The pH value of a water is determined by the chemical equilibria which are set up between hydrogen ions and the various acid and alkaline substances present in the water; in most waters, the principal determinants are the proportions of carbon dioxide (carbonic acid), bicarbonate, normal carbonate, and hydroxyl ions. The relationships between pH value and these components may be computed by solving the equations which govern these equilibria (Moore, 1939).

The pH value of a water is one of its most important properties. Taken together with the alkalinity and hardness, it determines the corrosiveness of the water, it is probably the most important factor in the behavior of the water toward coagulants, and it has great influence on the effectiveness of the disinfection procedures applied to the water, especially on chlorine disinfection. Although it has no direct sanitary significance, its marked effect on all phases of water supply and treatment makes it an essential part of a sanitary water analysis.

**Chlorides.** Chlorine in the form of chloride ion is a normal constituent of all waters. Traces taken up from the air are found in rain water, especially near the sea-coast. The chloride in surface and ground waters comes from the mineral deposits of the earth, from the ocean vapors and spray carried inland by the wind, and also from polluting materials like sewage and trade waste, both of which are likely to contain

the common salt used in the household and in manufacturing. The chloride content of urine is high. A comparison of the chloride content of a water with that of other waters in the general vicinity known to be unpolluted may afford useful information.

The amount of chloride in water is determined by titration with standard silver nitrate, using potassium chromate as an indicator for the end point.

Before the water analyst is able properly to interpret the significance of the chloride content of a water it is necessary to know the normal amount of chloride present in the waters of that locality. The amount of chloride in a water of a district varies with several factors, such as the distance from the sea, the amount of rainfall, the amount of evaporation, and the direction of the winds. An increase over the normal is an indication of pollution. While the ammonia and the nitrites may have disappeared and the nitrates may have been largely taken up by growing vegetation, the chloride, which is exceedingly stable, will be left to indicate remote or past pollution.

The admixture of even a small proportion of sea water renders water hard and salty and undesirable for domestic use. It also renders water unsuitable for use in boilers. Wells driven near the sea frequently become contaminated with sea water, particularly if sufficient water is withdrawn to allow sea water to work back into the wells as an undercurrent. It then gradually mixes with the fresh water above and sooner or later appears in the well water. When this happens it may be a difficult matter to operate the well so as to avoid drawing sea water. In wells near the sea it is important to draw no more fresh water than would otherwise flow to the ocean. The yield of such wells is therefore limited.

With regard to the consumption of waters made saline by admixture of sea water or by contact with underground salt deposits, there is no present evidence that such waters are injurious to the health of normal persons, at least up to a salt concentration of 4,000 p.p.m. However, such waters possess a taste objectionable to most consumers at levels of 500 to 1,000 p.p.m. of salt, and if neutral salts other than sodium chloride, such as sodium sulphate or magnesium sulphate are present in appreciable amounts, they may have a laxative effect on new consumers. They are also corrosive and unsatisfactory for industrial uses. Because of the difficulty and expense of removing these neutral salts from water, it is better to avoid them if nonsaline sources are available. The removal of salts from water by distillation is discussed in the section on water purification. As previously noted, the use of ion exchange is a possibility. However, the costs of both processes are very high, and they are employed only where saline waters are the only ones available.

**Iron.** The iron content of water, although it has no bearing on health, is of great importance with respect to its appearance, palatability, and suitability for domestic and industrial uses. All natural waters contain a certain amount of iron, and ground waters are likely to contain it in objectionable quantities. No water can be considered entirely satisfactory that contains more than 0.3 part per million parts of iron. More than this renders water unsuitable for domestic and technical purposes; it stains clothes in the laundry, clogs pipes, interferes with industrial processes and forms sludge in boilers.

When iron is present in water it may support filamentous bacteria such as *Sphaerotilus*. This organism may grow in pipes in sufficient amounts to obstruct the flow of water or even completely choke them. This sometimes occurs in the

pipes of driven wells. It is chiefly troublesome in ground waters containing organic matter and iron.

Iron is widely distributed and exists in practically all sands, gravels, soils and rocks with which water comes in contact. The solution of the iron is partially brought about by the organic matter. The iron exists in the soil both as ferrous and as ferric compounds. The latter are reduced by the organic matter to ferrous salts, which are soluble in water containing carbonic acid. The iron is dissolved as ferrous ion, usually in association with bicarbonate ion. Iron is also a constituent of plant material and will be found in surface waters in organic combination. Trouble from iron is always to be expected when there is an excess of organic matter in the material through which the water passes. When ground waters containing iron are first drawn they look clear, but the ferrous iron ( $\text{Fe}^{++}$ ) in solution is soon oxidized to ferric iron ( $\text{Fe}^{+++}$ ). The ferric ion is then precipitated as red flocculent ferric hydrate.

**REMOVAL OF IRON.** There are a number of methods for removing iron from water. The one most commonly used is aeration to oxidize the iron to the ferric state, followed by filtration. Zeolite will also remove iron. A special zeolite regenerated with sodium permanganate is often employed. Lime alone, or lime and chlorine, followed by filtration have been successfully used in a few instances.

Manganese also occurs in ground and surface waters, usually along with iron. It also precipitates on exposure of the water to air. The total content of iron and manganese in potable waters should not be over 0.3 part per million. Manganese is removed by the same methods as those used for iron but with somewhat greater difficulty.

**IRON PIPES.** Nearly all waters attack iron pipes, corroding them and forming tubercles on the inner surface. This is objectionable because it reduces the carrying capacity of the pipe and also influences the quality of the water. The process is continuous, though slow. Many years may elapse before the tubercle reaches the height of an inch. Tuberculation may be prevented by applying certain chemical treatments to the water, or by thoroughly coating the inside of the pipes with specially prepared bitumastic compounds. Cement-lined pipes are also not subject to tuberculation. When the process of tuberculation has advanced far it may be corrected by cleaning the pipe with special scraping tools. These are driven by the water pressure through the pipes. Their whirling blades scrape off the tubercles. Scraped pipes may be relined in place in order to preserve their capacity.

Hot water systems containing iron pipes or tanks are particularly likely to accumulate large quantities of iron, and thus deliver red water, which is objectionable in laundering.

**Lead and Other Heavy Metals.** The presence of lead in water may be discovered by chemical tests; where lead piping or service connections are used in the water system, these tests should be made frequently since dangerous amounts of lead go unnoticed because they have no effect on the appearance or taste of the water. Lead is a cumulative poison.

The sample of water used for a test for lead should be the *first portion* (a pint or less) drawn after the water has stood at least one hour in the pipes. Often the sample examined will not represent the daily maximum.

With the decreased use of lead piping, poisoning from this source is becoming

less frequent. The 1946 Drinking Water Standards of the U. S. Public Health Service state that the presence of more than 0.1 part per million of lead shall constitute ground for rejection of a supply. The question of lead poisoning and its relation to water is discussed in Chapter 40. The standards also limit copper to 3.0 parts per million and zinc to 15.0 parts per million. Arsenic, selenium and hexavalent chromium are limited to 0.05 part per million. The limits prescribed are based on present knowledge of the toxicity of these metals.

**Organic Matter and Nitrogen.** Organic matter in water originates from both plant and animal sources and appears in a great variety of compounds, most of them too complex or too small in quantity to allow of direct determination. There is only one direct determination of organic constituents which is ordinarily made. That is the "loss on ignition" of total solids, which gives the weight of volatile and combustible organic constituents. Ignition is subject to the error of recording unavoidable loss of some mineral compounds. Nevertheless, a fair measure is obtained of the total weight of organic substances as indicated by the loss of combustible material.

**THE NITROGEN CYCLE.** Organic matter in soil or in water undergoes a complex cycle of decomposition and resynthesis in which all types of living organisms have part. The carbon, hydrogen, oxygen, nitrogen, sulfur, and other elements making up organic compounds appear in specific combinations at each stage of this cycle. Figures 37-1 and 37-2 illustrate the nature of the cyclic changes for carbon, nitrogen and sulphur in the decomposition and resynthesis of organic matter; the diagrams are specifically related to organic matter of sewage, but would hold without substantial change for any other forms of organic matter. The course of the cycle is dictated in part by whether or not a sufficient supply of oxygen is present; under anaerobic conditions (absence of oxygen) the end products of decomposition are unoxidized compounds such as ammonia and sulfides, whereas under aerobic conditions, the end products are highly oxidized compounds such as nitrates and sulfates.

The cyclic changes of nitrogen are of particular interest with respect to the elimination of pollution in water by natural forces. Nitrogen exists in living organisms primarily in the form of proteins, which are large and complex molecules in which nitrogen, sulfur, and phosphorus are linked to carbon-hydrogen chains. As soon as the organism dies, the proteins are attacked by saprophytic bacteria, which break them down to smaller fragments. The steps in the decomposition are numerous, passing through peptides (smaller protein-like molecules) and amino acids or amines, to ammonia, the final product of this phase of decomposition. The process is mainly one of hydrolysis. A large variety of bacteria, both aerobic and anaerobic, can carry out this stage of the cycle. The *Bacillus* group is an example of the strictly aerobic types; the *Coli-aerogenes*, *Pseudomonas*, and *Proteus* groups can function under either condition; the *Clostridia* require strictly anaerobic conditions. The result is a decrease in organic nitrogen, and an increase in ammonia ( $\text{NH}_3$ ). In the absence of oxygen, ammonia is the final product, and the organisms using the decomposed material for food must be able to assimilate nitrogen in the form of ammonia, an ability possessed by few organisms except the bacteria.

In the presence of oxygen, the ammonia undergoes further changes; these are

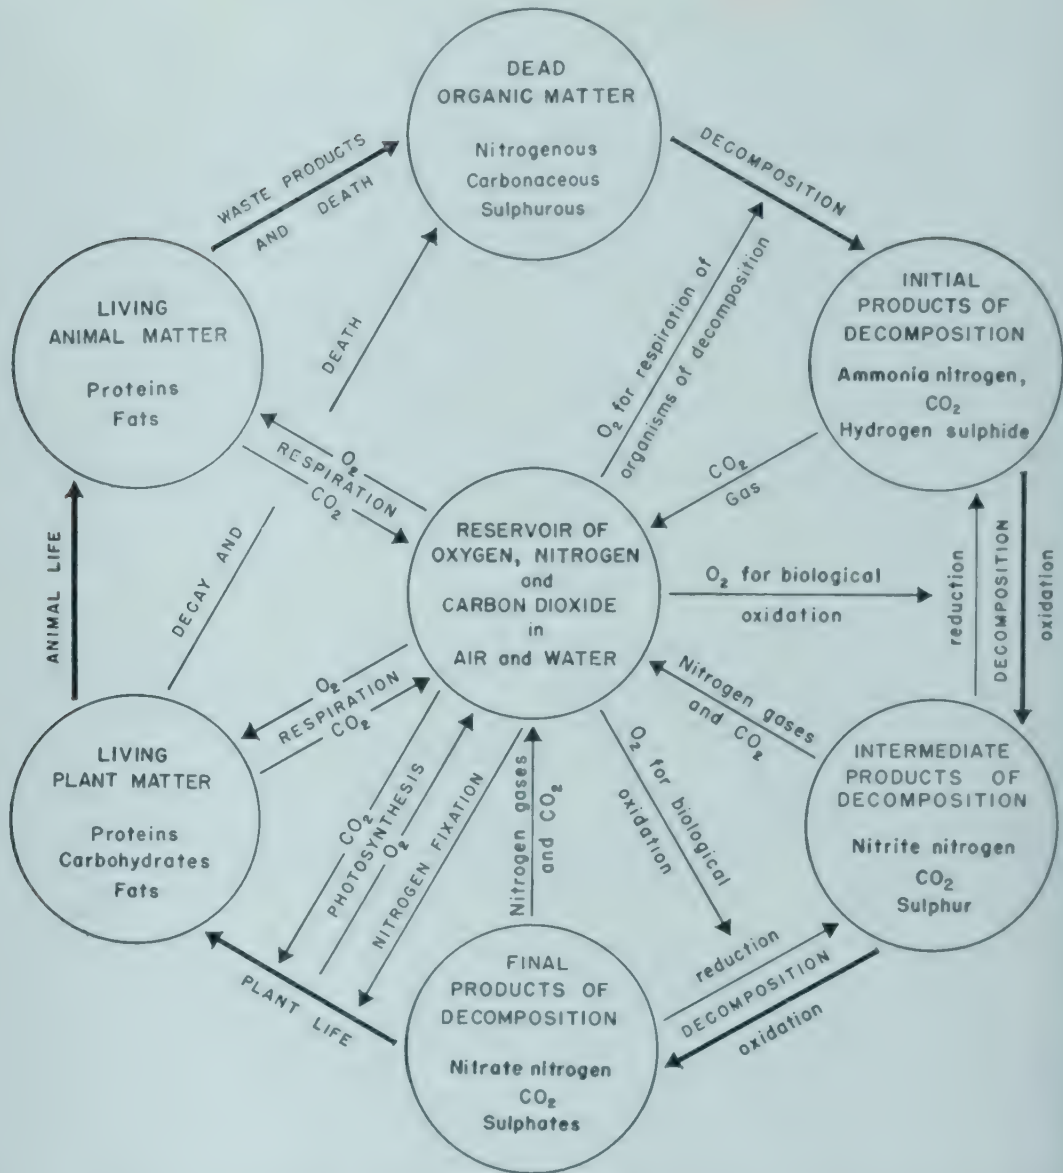

Fig. 37-1. The cycle of nitrogen, carbon and sulphur in its relation to the aerobic decomposition of sewage.

induced by specific organisms, and are reactions of oxidation. The first stage of oxidation, from ammonia ( $\text{NH}_3$ ) to nitrite ( $\text{NO}_2$ ) is carried on by two groups of organisms, *Nitrosomonas* and *Nitrosococcus*. They are so-called autotrophic bacteria, meaning that they derive their energy from the oxidation of an inorganic compound (in this case ammonia) rather than from the oxidation of organic matter. They are strictly aerobic and grow best in media containing but little organic matter; the material which forms the bacterial cell is directly synthesized from carbon dioxide, water, and other mineral compounds.

The second stage of oxidation is from nitrite to nitrate ( $\text{NO}_3$ ). This represents the highest stage of oxidation of nitrogen, and signifies the final "mineralization" of the organic nitrogen. The reaction is carried on by *Nitrobacter*, another aerobic autotrophic organism, which derives its energy solely from this particular oxidation reaction.

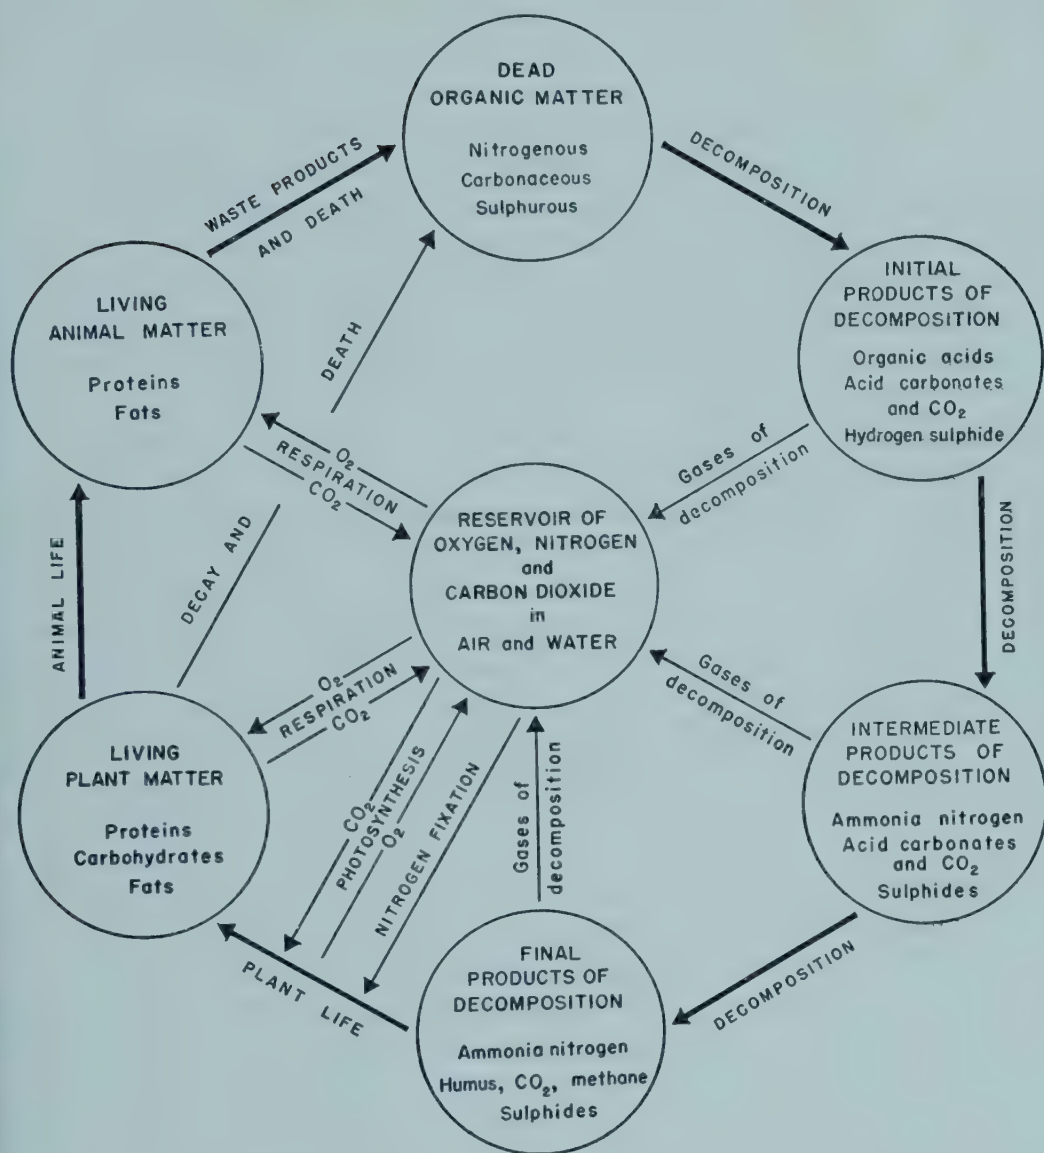

fig. 37-2. The cycle of nitrogen, carbon and sulphur in its relation to the anaerobic decomposition of sewage.

The nitrates form the principal source of nitrogen for algae and plants; the nitrates are taken in by these organisms and utilized to build plant proteins. Plant proteins are in turn utilized by animals to build animal protein. When either plant or animal dies, the cycle of decomposition begins anew.

Certain side reactions may modify the main cyclic process, or temporarily reverse it. For example, if water containing nitrates or nitrites loses its oxygen, some of the saprophytic organisms are able to continue to oxidize organic matter by extracting the oxygen from the nitrites and nitrates, thereby reversing the cycle and returning the nitrogen to the form of ammonia. This is the basis for the use of sodium nitrate in polluted waters for the temporary alleviation of nuisance conditions. A few bacteria can, in the absence of oxygen, convert nitrates to nitrogen gas, which then leaves the cycle by escaping to the atmosphere. On the other hand, an important group of soil bacteria are able to "fix" nitrogen—that is, to extract

it from the atmosphere and assimilate it into protein. Ultimately this assimilated nitrogen becomes available to plants. In water, nitrogen fixation, although it may sometimes occur, is of minor significance.

It is evident from this discussion that much information about the sanitary history and present state of a water can be derived from quantitative determinations of the various forms of nitrogen present. As self-purification progresses, the nitrogen is successively converted from the organic form to ammonia nitrogen, then to nitrite and finally to nitrate. While this process is going on, the pathogenic organisms contained in the polluting material are dying off, and the putrescible organic matter is being eliminated. The relationships between the various forms of nitrogen serve as a useful index of how far the self-purification has proceeded, when properly interpreted in the light of previous experience. Before the modern bacteriological indices of pollution were developed, sanitary chemists were forced to rely too heavily on the nitrogen determinations for this purpose, and unjustified or erroneous conclusions were sometimes drawn from them. For this reason, there has been a tendency to undervalue the usefulness of the nitrogen determinations. However, the increasing interest in stream-pollution studies is returning these determinations to their proper position of importance in the sanitary analysis.

**TOTAL ORGANIC NITROGEN.** All protein matter contains nitrogen, whether it be of plant or animal origin. The organic matter in water comes from both these kingdoms and the protein exists in both living and inert substance. It is present especially in suspended and colloidal particles. The total organic nitrogen may be determined by the Kjeldahl method, and it may be divided by filtration of a sample before analysis into suspended organic nitrogen and dissolved and colloidal organic nitrogen. The former includes that from microscopic organisms, except the bacteria, and organic debris of every sort; the latter, that from extracted and dissociated material. The organic nitrogen determination does not differentiate between plant and animal nitrogen, but high values generally point to animal pollution because of the higher nitrogen content of animal tissue. High values also indicate fresh pollution—that is, that time enough has not elapsed for bacterial digestion of organic matter and oxidation of the nitrogen to more stable forms.

**ALBUMINOID NITROGEN.** A simpler and quicker procedure than the Kjeldahl method is the determination of the "albuminoid nitrogen," or "albuminoid ammonia." In this method only that portion of the nitrogen is oxidized which is not held in stable combination. The yield is ammonia. The albumins fall into this category, hence the term "albuminoid nitrogen." The method consists in distilling a sample of water with strong alkaline permanganate and Nesslerizing the distillate for ammonia. The result is expressed in terms of nitrogen.

The figure obtained is approximately one-half the total organic nitrogen which exists in ground waters or surface waters which have little pollution. In sewage and waste-polluted waters the albuminoid figure is variable and usually constitutes more than half the total nitrogen because nitrogenous matter of animal origin contains not only more nitrogen, but more nitrogen in the form of easily decomposable compounds, such as the albumins.

Like the Kjeldahl method this one also fails to distinguish between plant and animal nitrogen. Ordinarily, high albuminoid nitrogen values are due to a large number of microscopic organisms or to sewage pollution. The determination

therefore, provides a fair index of the organic pollution in water. The organic matter itself is not dangerous to health, but is undesirable because it offers food for bacterial growth, defiles the water, and produces disagreeable tastes and odors.

No arbitrary standard can be set as to the maximum amount of albuminoid nitrogen a good water may contain. It is not uncommon to find as high as 0.1 part per million in surface waters of acceptable quality, but collateral evidence should show this amount to be principally of plant rather than animal origin. Ground waters of good quality contain less than this amount; in most cases practically none.

**AMMONIA NITROGEN.** Ammonia nitrogen is often spoken of as "free ammonia" because it can be driven off or freed by boiling. The amount of free ammonia is determined by distilling a 500-ml. sample and Nesslerizing the first 200 ml. of the distillate in 50-ml. portions. Nessler's solution contains mercuric chloride and potassium iodide and gives a brown color in the presence of ammonia, due to the formation of a complex mercury-ammonia-iodine compound. The amount of ammonia found is expressed in terms of nitrogen.

Ammonia nitrogen exists in water in its free state and in the form of ammonium ion. The sources of ammonia in water are varied; usually it comes from the decomposition of organic matter, as a result of bacterial action. Ammonia is not the last stage in the mineralization of organic matter (see nitrogen cycle, page 1173) for, with the lapse of time, ammonia is oxidized by bacterial action to unstable nitrites and finally to stable nitrates. Both the time and the processes necessary to effect nitrification bring about destruction of organic pollution and substantial elimination of pathogenic bacteria.

Ammonia nitrogen is also formed during the process of bacterial denitrification, by which nitrates and nitrites are reduced to ammonia. This action takes place near the surface of the soil to a limited extent. In natural waters this source is not significant unless anaerobic conditions exist. Denitrification also takes place at times in ground waters when nitrates are reduced by the action of ferrous salts. The water of some deep wells contains several parts per million of ammonia nitrogen derived in this way.

The ammonia itself found in drinking water is harmless; its significance lies in the fact that it indicates the presence of decomposing organic pollutorial matter which may be infected. High ammonia values signify recent pollution, that is, within a period of time which has not allowed oxidation.

Not all the free ammonia in water originates from organic matter. Rain water takes free ammonia from the atmosphere, more especially above industrial communities. The presence of ammonia in clean and properly stored rain water has little significance. It denotes pollution of the atmosphere with gases.

**NITRITES.** Nitrites never accumulate to any extent in water because they are soon oxidized to nitrates, the final and stable form of mineralization of organic nitrogen. Nitrites represent a transitional stage of decomposition between ammonia and nitrates. Nitrites, when high, suggest bacterial activity. Nitrites are an index, just as the presence of coliform organisms is an index. Their significance varies with the amount, the source, and the relation to other constituents in the water.

Nitrites have less significance when ammonia nitrogen is low and nitrate nitrogen is high, and greater significance when the reverse is the case. A low ammonia content is evidence of little protein material in a state of decomposition.

In unpolluted ground waters nitrogen will not be found as nitrites, except as there may have been reduction of nitrates by ferrous compounds or other reducing agents. When this happens the amount of nitrites is likely to be high and can be disregarded in the light of other tests which register an absence of pollution.

Concerning the amount of nitrites in water it must be remembered that the colorimetric test for nitrites with sulphanilic acid and  $\alpha$ -naphthylamine acetate is one of the delicate tests in chemistry. With this method we are able to detect quantities of nitrogen as small as one part per billion. When, therefore, a water analyst reports a trace of nitrites it means an exceedingly minute quantity.

Nitrites are poisonous compounds, but the minute amounts found in water can scarcely have a pharmacological effect.

**NITRATES.** Nitrates represent the final stage in the mineralization or oxidation of nitrogen originally present in organic compounds. Nitrates are used as food by plants for the upbuilding of new protein, which important step completes the cycle that nitrogen passes through in its continuous circulation in nature (see **nitrogen cycle**, page 1173).

The detection of nitrates in water depends upon the yellowish color produced by the reaction of the nitrate ion with phenoldisulphonic acid and sodium hydroxide. The amount can be determined by comparison with standard solutions.

In the same sense that nitrites may suggest danger, nitrates may indicate safety. Nitrates, being the final stage of protein decomposition, are a sign that decomposition of polluting protein is complete, provided that organic nitrogen and nitrites are absent. The presence of nitrates is not of itself evidence of safe quality in drinking water, for nitrates must be interpreted in the light of the bacteriologic findings and other contributing data. When the nitrates are high but other forms of nitrogen are absent or present only in traces, it means that the water was polluted, but purification has taken place. Under these circumstances nitrates tell the chemical story of the past history of the water.

Nearly all surface waters of safe quality contain nitrogen as nitrates in amounts varying from 0.1 to 1.0 part per million. There is considerable seasonal fluctuation due to use of nitrates for food by algae and other forms of plant life. Nitrates in surface waters come largely from the soil where there is constant mineralization of nitrogenous organic matter. When surface water has been heavily polluted at some distant point with either soil washings or liquid wastes the nitrate content may be several parts per million of nitrogen.

Shallow ground waters often show large amounts of nitrates, from one to several parts per million. This may be due to oxidation of soil nitrogen or of wastes thrown upon or in the ground. If the latter, there is a considerable element of danger shown by the nitrate content, unless organic matter and other forms of nitrogen are practically absent.

High nitrates in deep ground waters usually have their origin in underground mineral deposits and are without sanitary significance. Young (1911) has shown that the ground waters of Kansas sometimes contain large amounts of nitrates—as much as 500 parts per million. The medicinal dose of potassium nitrate is 0.3 gm. Less than a liter of such water would, therefore, contain sufficient nitrates to produce effects such as irritation of the mucous membrane of the stomach, and also diuresis, with irritation of the mucous membrane of the bladder. Much lower

amounts of nitrate, perhaps as little as 10 to 20 p.p.m., cause cyanosis in infants (see Chapter 40).

**OXYGEN CONSUMED.** One of the oldest tests for organic matter in water is the oxygen-consumed test which measures the amount of potassium permanganate consumed by this organic matter in the presence of acid. Unstable organic compounds are oxidized by the permanganate, which in turn is reduced and decolorized. The amount of permanganate used up may be expressed in terms of oxygen, and this value is taken as the "oxygen consumed" by the oxidizable matter present.

There are several facts which operate to impair the usefulness of this test. In the first place, the oxygen values will vary with the temperature and time of digestion. It is, therefore, important to record the conditions of the test, or results will not be comparable with the results of others. Again, the determination tells nothing as to the source or kind of organic matter. It was thought at one time that carbonaceous organic matter was oxidized in this way in contrast to nitrogenous material by the albuminoid nitrogen test, and that the results accordingly registered pollution by plant material. This is only partially true, and the test in no way can be used to distinguish between organic matter of plant and animal origin. Neither does it record the oxygen necessary to stabilize all the organic matter present, for the test is not carried that far; nor does it give much idea of the ease with which the organic material is oxidized—that is, how unstable it may be. However, there is a great need for a rapid chemical test for unstable organic matter, and considerable effort is being made to improve this test, or to develop others. The use of potassium dichromate has been investigated and shows possibilities.

Oxygen-consumed values when used alone are not of great significance but give corroborative information in interpreting the results of other determinations, such as color, loss on ignition, organic nitrogen and albuminoid nitrogen. They are also useful in comparing periodical fluctuations in oxidizable matter.

Good ground waters show practically no oxygen consumed, for they contain very little organic matter. In surface waters free from waste pollution the oxygen consumed will usually vary as the color, ranging from 1.0 to 10 parts per million.

**Dissolved Oxygen and Biochemical Oxygen Demand.** Water in contact with the air becomes saturated with oxygen. Being held in solution, as a gas in a liquid, the oxygen is termed "dissolved oxygen." This quantity has no relation to "oxygen consumed." The actual amount of gas present will depend upon the partial pressure of oxygen in the atmosphere, upon the barometric pressure, and upon the temperature of the water. In most cases temperature is the controlling factor, for the amount of oxygen dissolved varies greatly with temperature. Thus, distilled water at 0° C and 760 mm. pressure holds, when saturated, 14.6 parts per million of oxygen; at 20° C it holds 9.2 parts.

There are many processes which go on in water that influence the dissolved oxygen content. Clean surface waters are ordinarily saturated with dissolved oxygen, but in the presence of rapidly growing plant life, particularly algae, supersaturation often occurs due to liberation of oxygen by the plant cells. At the same time there is a reduction of the carbon dioxide content which is used as food for plant growth. The relation of dissolved gases to microscopic growth in water is close and important.

When water is polluted with any oxidizable material, such as the extracted

matter from dead vegetation, sewage, or other wastes, the oxygen content will be diminished, but may be replenished by absorption from the atmosphere if the pollution is not heavy and decomposition not too rapid. When the demand of bacterial and related activity for oxygen exceeds the rate at which oxygen can be dissolved from the air, the concentration of dissolved oxygen in the water will fall and, as it approaches zero, putrefaction arises due to anaerobic bacterial processes. This results in the production of compounds which possess obnoxious physical properties. In surface waters receiving sewage or industrial wastes this condition may produce a nuisance.

Dissolved oxygen is a most important determination in the study of pollution. The amount of oxygen found is an indication of the load which is being put upon natural processes of purification. The amount found in the water of a flowing stream at different points, for instance, furnishes valuable information as to the rapidity with which self-purification is taking place below a given point of pollution.

The amount of oxygen required for the aerobic bacterial oxidation of the organic matter present in a sample can be measured by diluting the sample with water containing a buffer and certain necessary minerals, and seeding the mixture with an active bacterial culture. The mixture is incubated at 20° C in a closed bottle containing no air space for a specified number of days, customarily five. The amount of dissolved oxygen used up by bacterial action during the incubation period is determined by measuring the dissolved oxygen content of the mixture before and after the incubation. This figure, when multiplied by the reciprocal of the dilution, gives the biochemical oxygen demand of the sample, expressed as p.p.m. of oxygen. The biochemical oxygen demand may also be determined in manometric or volumetric incubation vessels; in these, the oxygen is taken from a closed gas space above the liquid. The amount of oxygen used is measured either by the decrease in pressure or the decrease in volume of the gas; any carbon dioxide produced in the course of the oxidation must necessarily be removed.

The biochemical oxygen demand test is of the greatest importance in stream-pollution studies and in the evaluation of sewage treatment. Despite certain shortcomings, it is the only method available for approximating the actual demand for oxygen which will be exerted during the bacterial decomposition of organic matter in water. The balance between the rate and amount of biochemical oxygen demand, the available dissolved oxygen, and the rate at which oxygen can be absorbed from the atmosphere, is what determines whether a polluted body of water becomes a nuisance inhabited only by anaerobic bacteria, or remains in a reasonably acceptable state, with a normal biological population.

Oxygen concentration has an important relation to fish life. Most fish will live when the oxygen content is as low as 3 to 4 parts per million. Below this point suffocation takes place, the critical value depending upon the variety of fish.

Nearly all lakes and impounded water supplies show a decrease in oxygen content with increasing depth. Frequently none is found near the bottom during the summer months. This results from the thermal stratification of the water which creates a zone of stagnation at the bottom. Due to its greater density the water here does not reach the surface for aeration, and decomposition at the same time is more active than at the surface, due to concentration of organic impurities from natural sedimentation. Water in the zone of stagnation is impregnated with foul

products of decomposition and should be avoided for general domestic use unless it is suitably treated before consumption.

Ground waters are usually partially or wholly depleted in oxygen content, due to percolation of the surface water through the soil where oxidation of organic matter is in progress.

**Fluorides and Iodides.** The fluoride content of drinking water has considerable importance in sanitary analysis because of its effect on the tooth structure of infants and growing children who use the supply. Fluorides in excess of one p.p.m. cause structural defect in the teeth known as mottled enamel; on the other hand, very low fluoride concentrations in water appear to promote susceptibility to dental caries. Therefore, it may be necessary in some water supplies to consider either the removal or addition of fluoride. The subject is discussed in more detail in Chapter 40. Analysis of waters for fluoride content becomes necessary both to determine the desirability of addition or removal, and to control such treatment once it is instituted. Fluoride is determined by making use of the decolorization of a zirconiumalizarin lake; the degree of decolorization, which is proportional to the amount of fluoride present, is determined by comparison with standards. If interfering ions, such as chloride, sulphate, or iron, are present, the sample must be distilled before making the test.

The iodide content of drinking water also has possible sanitary significance. In regions where iodides are low or absent in the soil and water, the incidence of goiter is believed to increase. This is true particularly in regions which were once covered by glaciers. At one time, sodium iodide was added to a few water supplies to overcome this defect. The practice ceased when it was found to be more effective and economical to supply the needed iodine in the form of iodized salt. However, it may sometimes be advisable to investigate the iodine content of a water supply to determine whether a deficiency exists. A concentration of less than 5 parts per million as iodide is considered to indicate a deficiency.

### MICROSCOPIC EXAMINATION

The term "microscopic organisms" as used by the water analyst includes all organisms, whether plant or animal, free floating (plankton) or attached that are visible or barely visible to the naked eye, other than bacteria. The bacteria are apart, inasmuch as their significance and the method of studying them are different from all other micro-organisms.

The microscopic organisms comprise the diatoms, green algae, blue-green algae, fungi, protozoa, rotifers, crustaceans, numerous small worms, insect larvae, and other organisms minute in size. Fragments of organic matter, broken-down organisms, zoogaea, etc., should be termed amorphous matter and measured, but oxide of iron and mineral matter in general are excluded.

The chief object of the microscopic examination of water is the determination of the presence or absence of those micro-organisms which produce objectionable tastes and odors. The determination is also of value as an index of pollution or as evidence to the identity of the water. A full discussion of the subject of microscopic organisms will be found in *Microscopy of Drinking Water* (Whipple, 1927).

The sanitary quality of water cannot be definitely shown from a microscopic examination. Surface waters are usually rich in microscopic life, while ground

waters are comparatively free. However, as soon as ground waters stand in pipes or are exposed to the light, microscopic organisms may develop.

**The Sedgwick-Rafter Method.** This is the standard method for counting the number of microscopic organisms in water and measuring their volume. It consists in collecting the microscopic particles suspended in a known quantity of water, and estimating their volume in a cell of known depth under the microscope. The microscopic particles are concentrated upon sand by filtration. An alternative method is the use of a specially designed high-speed centrifuge. Full details of the procedure may be found in *Standard Methods for Examination of Water and Sewage*. The results are expressed as standard units of organisms per ml. of water, a standard unit being a cube 20 microns on a side.

**Significance of the Examination.** The microscopic examination of water is of value in supplementing the chemical and bacterial analyses. It may explain the cause of odors and tastes in a water; it may explain certain chemical determinations, as albuminoid ammonia, dissolved oxygen, oxygen consumed, carbon dioxide, etc.; it may indicate sewage contamination; it may suggest the state of self-purification of a polluted water; it may identify the source of the water.

Several of the microscopic organisms, when present in sufficient quantities, give rise to objectionable odors and tastes, either when in a vegetative state or upon decomposition. The natural odors of organisms are due to oils analogous to the essential oils. In general, the diatoms have an aromatic odor, increasing to that of a geranium leaf, and even to an intensity that is fishy. The Cyanophyceae, or blue-green algae, have a grassy or musty odor. The Chlorophyceae or green algae ordinarily have grassy odors that are not particularly undesirable, although some of the motile forms give rise to faintly fishy odors. The ciliated protozoa have, in general, no odor. The Chrysophyceae (yellow-green), notably *Synura*, *Uroglenopsis* and *Dinobryon*, and the Dinophyceae or dinoflagellates, especially *Ceratium* and *Peridinium*, give rise to particularly objectionable oily and fishy odors. Of the other microscopic organisms, such as the rotifera and crustacea, no forms have been recorded as giving rise to objectionable odors.

Certain members of the blue-green algae, for example, *Anabaena*, *Microcystis*, and *Aphanizomenon* have caused the death of cattle and other domestic animals when present in water in sufficient quantities to form heavy scums. Such water would not ordinarily be consumed by humans, but a few instances of illness due to smaller concentrations of the algae have been reported. These algae have been shown to secrete a toxin, as yet unidentified because of the difficulty of isolating it from other organic compounds present in the algae. A much greater menace to humans is the dinoflagellate, *Gonyaulax catenella*, a sea water organism. During the warm months these organisms are sometimes ingested in great numbers by mussels, and occasionally by other shellfish. Consumption of these shellfish by humans produces a violent and often fatal poisoning, due to the presence of a toxic alkaloid in the *Gonyaulax*. Outbreaks of mussel poisoning have been reported from Nova Scotia and from the West Coast. The outbreaks are often associated with a concentration of *Gonyaulax* sufficient to give a red tinge to the sea water.

The plankton population is a good indicator of sewage pollution and self-purification. Being sensitive to its environment, the population changes in character as purification proceeds. There is usually a sequence of forms following the B

of pollution and these forms are potent factors in purification. The protozoa utilize complex organic matter and the bacteria as food. Their growth is followed by that of the algae, which use up the  $\text{CO}_2$  of decomposition processes, as light conditions improve. Then come the rotifera and crustacea, the former feeding largely upon minute algae, and the crustacea making use of certain protozoa and decayed fragments of plant and animal matter. Thus, some of the microscopic organisms play the role of scavengers, others are predatory in their food habits.

Besides these animal and plant forms there may be present also sponges, mosses, yeasts, and molds, the significance of which is varied and dependent upon local conditions.

### BACTERIOLOGICAL EXAMINATION

Practically all natural waters contain bacteria. This is true of rain water, ground water, and the waters of lakes, rivers, and oceans. The number and variety of the bacteria vary greatly in different places and under different conditions. The bacteria are washed into the water from the air, from the soil, and from almost every conceivable object. The intestinal contents of animals pollute waters with enormous numbers of micro-organisms, but it is the infection with certain species from man that makes water most dangerous when consumed by other men.

A final judgment of the potability of a water should never be based upon the bacteriological examination alone, but should be combined with a sanitary survey and other laboratory tests. A sanitary survey may discover possibilities of danger, even though the sample examined contains few bacteria and no members of the coliform group. On the other hand, a water may contain large numbers and miscellaneous kinds of harmless bacteria and a sanitary survey will confirm absence of human pollution. The chemical and microscopic examinations assist in the interpretation of bacteriologic findings.

**Number of Bacteria in Water.** Incubation of samples of water of appropriate volume in solid nutrient media contained in Petri dishes permits the growth of visible bacterial colonies which can be counted at the end of the incubation period. The medium ordinarily used is tryptone glucose agar, and the plates are incubated either at  $20^\circ \text{C} \pm 0.5^\circ$  for  $48 \pm 3$  hours, or at  $35^\circ \text{C} \pm 0.5^\circ$  for  $24 \pm 2$  hours. The results are expressed as numbers of bacteria per ml.; this involves the assumption that each colony developed from a single organism. Formerly the results were termed "total bacterial counts," but it has long been recognized that only a fraction of the bacteria present in the sample are counted, and that no single incubation medium can be prepared that will yield even an approximation of the true total number of bacteria in the water. For example, the autotrophic bacteria, including nitrifying organisms so important in stream purification, cannot be grown on organic media, and therefore do not appear in the "total count." The latest edition of *Standard Methods of Water Analysis* simply designates the results secured by the incubation procedure as "standard plate count at  $20^\circ \text{C}$ ," or "standard plate count at  $35^\circ \text{C}$ ," and expressly avoids the term "total count."

The standard plate counts, then, include only that portion of the bacteria in the water that are capable of growing in the standard medium at the temperature of incubation. These are predominantly the common saprophytic bacteria: they

do not necessarily have any sanitary significance. However, in conjunction with other information, and particularly when past records exist, the standard plate counts may serve as useful indices of changing sanitary conditions. For example, if a well water previously showing low counts, should suddenly show a count of several hundred per ml., contamination of the well would be suspected. In general, uncontaminated well waters can be expected to yield plate counts not greater than 100 to 200 per ml. In surface waters, the plate counts are generally much higher than they are in ground waters, and vary roughly with the degree of pollution, including in the term any kind of organic addition from sewage to the washings from completely uncontaminated soils. Unfortunately, a dangerous fecal contamination may not increase the plate count of a surface water as much as a completely harmless influx of washings from a virgin soil.

At one time, specific standards were set up for maximum permissible numbers of bacteria as determined by plate counts in waters to be used for various purposes. Because of the uncertainty in the interpretation of such counts, these standards have been largely abandoned. The use and significance of plate counts is further discussed in the section on bacteriological limits of pollution.

**Kinds of Bacteria in Water.** There are available bacteriological technics which make it possible to isolate and determine a large number of the species of bacteria which may be present in water. Many, although not all, of the water-borne pathogens, particularly those causing cholera, typhoid, and dysentery, can be thus isolated and enumerated. Such investigations are, however, rarely made except in special research studies. The test for the presence of a single group of organisms—the coliform group—is used almost exclusively as a bacteriological index of the degree of pollution of the water.

There are a number of reasons why this should be so. For one thing, the isolation of the coliform group is comparatively easy, whereas the isolation of many of the other significant species of bacteria, especially the pathogens, is cumbersome and difficult. Again, when one considers the purpose of a sanitary analysis, it is evident that what is sought is evidence of possible avenues of infection rather than the actual presence of infective organisms at the time of analysis. The coliform group is present in large numbers in the feces of all animals that are known to be possible carriers of water-borne disease; the average person excretes from 200 billion to 400 billion of these organisms per day, depending on the season of the year. It is therefore evident that any fecal pollution of water results in the presence of organisms of the coliform group. It is even possible to estimate the degree of pollution of a water with a fair accuracy by determining the numbers of coliform organisms present, and by combining such estimates with knowledge of the incidence of a given water-borne disease, say typhoid, in a community, to estimate the probability that the disease will be acquired by an individual drinking the water.

The coliform group, like the water-borne pathogens, is not adapted to live and multiply indefinitely in water. However, its resistance to the forces of natural purification has been shown to be somewhat greater than that of the common water-borne pathogens. Consequently, the assumption is justified that if coliform organisms have been eliminated from water by long-continued storage, the pathogens have also disappeared. The same thing is, for the most part, true of the comparative resistance of the two groups to the methods used in water purification.

particularly the procedures used in disinfection. Such evidence as we have indicates that the resistance of the organisms of typhoid and dysentery to chlorination is certainly not greater than, and is very probably less than, that of the coliform group. Unfortunately, the same cannot be said of the cysts of the organism causing amebic dysentery, which are much more resistant to disinfecting agents than are the coliform organisms.

It can, therefore, be concluded that the determination of coliform organisms furnishes a highly satisfactory index of water quality with respect to the presence or absence of dangerous pollution. Like all other tests, it has its defects; the principal one is the inclusion in the group of a certain number of species which are of nonfecal origin, and therefore of debatable significance with respect to the safety of a water supply. Consequently, there has been considerable effort to find an organism which will serve as a more precise and exclusive index of fecal pollution. Although some possibilities—for example, the fecal streptococci—have recently been suggested, there is as yet no visible tendency to substitute any of them for the coliform group, except in special investigations.

**The Coliform Group.** The coliform group includes all aerobic and facultative anaerobic Gram-negative, nonspore-forming bacilli which ferment lactose with gas formation and grow aerobically on standard solid media. The standard tests for members of this group are the *presumptive*, the *confirmed* and the *completed* test. For complete information on these tests, Standard Methods of Water Analysis should be consulted.

**Types of Coliform Organisms.** The group includes both fecal, or intestinal, organisms and nonfecal organisms. Typical of the first group is *Escherichia coli* and of the second *Aerobacter aerogenes*. The former has its normal habitat in mammals and birds, and even in some cold-blooded animals, and, therefore, is properly called fecal. The nonfecal type is found in soil, on fruit, leaves, grain and in many other places in nature. The significance of the two types is not very distinct, since feces of man and other animals also contain a number of nonfecal types. Because of the difficulty of differentiation, the doubtful significance of the results, and the general advance of sanitary standards, most sanitary authorities, at least in this country, are of the opinion that acceptable drinking water should be substantially free from all coliform organisms, fecal or nonfecal. In England and on the European continent, differentiation into fecal and nonfecal types is still regarded as important, and the presence of nonfecal coliforms is permitted to a considerable extent (Prescott and others, 1946).

**Presumptive Test for Coli-Aerogenes Group.** Presumptive or incomplete tests for members of the coli-aerogenes group afford useful information as to their possible presence. Except for waters in the process of purification, such tests are usually confirmed or completed, as indicated below. The presumptive test is made by adding to each of five fermentation tubes containing suitable amounts of lactose lauryl sulphate tryptose broth, 10-ml. or 100-ml., portions of water. For non-polluted waters, smaller portions should also be tested, such as 10 ml., 1 ml., and 0.1 ml., so as to obtain a quantity small enough to give a negative test. The fermentation tubes are incubated for 48 hours at  $35^{\circ} \pm 0.5$ . Formation of gas within  $48 \pm 3$  hours constitutes a *Positive Presumptive Test*. Absence of gas formation in this period constitutes a negative test.

It may be presumed in the absence of fermentation that coliform organisms are absent, and also that fermentation with gas production suggests their presence. Both these conclusions may be misleading. Grossly polluted waters containing many such bacilli may be slow in fermenting sugars with the production of gas on account of the preponderance of other more active species. On the other hand, organisms other than members of this group often found in water ferment sugars with gas production. It is, therefore, necessary to isolate the suspected organism in pure culture and pass it through the confirmatory tests before it is labeled a member of the coli-aerogenes group.

**Confirmed Test.** This is made from tubes showing gas formation in the presumptive test. Streak plates of either Endo or eosin-methylene-blue agar should be made from the tubes containing the smallest and next smallest amounts of water that gave gas formation. The plates should be incubated for 24 hours at 35° C. If colonies typical of members of the coli-aerogenes group form, it is a *confirmed test*. If no typical colonies form, incubation is prolonged to 48 hours, when two or more colonies considered most likely to be members of this group are treated as in the completed test. As a substitute for the plates, inoculation into brilliant-green lactose bile may be used; formation of gas within 48 hours at 35° C constitutes a *confirmed test*.

**Completed Test.** From the Endo or eosin-methylene-blue agar plates of the partially confirmed test, one or more typical colonies should be transferred to an agar slant and to a lactose broth fermentation tube, which should be incubated at 35° C for 24 hours and 48 hours, respectively. If brilliant-green lactose bile has been used as the confirmatory medium, the Endo or eosin-methylene-blue agar plates may be streaked either from the original lactose tubes or the brilliant-green tubes.

Demonstration of Gram-negative, nonspore-forming bacilli on the agar slant and formation of gas in the lactose broth constitute a *positive completed test*. Failure in either of these steps constitutes a negative test.

A positive completed test gives assurance of the presence of a member of the coli-aerogenes group in the original sample of water. Any evidence that may be desired of the fecal or nonfecal nature of the organism must be obtained by applying a number of differentiating tests, as described in Standard Methods of Water Analysis.

To express the density of coliform organisms in the water, use is made of the Most Probable Number, which is determined from the results of incubating several portions of water; for example, 5 portions each of 10 ml., 1 ml., and 0.1 ml. Tables are given in Standard Methods of Water Analysis for the evaluation of Most Probable Numbers. The Most Probable Number of coliform organisms is that number per 100 ml. of water that would be most likely to give the results observed in the series of fermentation tubes. The usual practice in the analysis of potable water is to incubate five 10-ml. portions and a single 1-ml. portion. The most probable numbers of coliform organisms for the various possible combinations of positive tubes are given in the table below.

Increasing the number of portions incubated, and using portions of three sizes such as 10 ml., 1 ml., and 0.1 ml., increases the precision of the Most Probable Number.

Number of Positive Tubes		Most Probable Number per 100 ml. of Water
10 ml.	1 ml.	
0	1	2.0
1	0	2.2
1	1	4.4
2	0	5.0
2	1	7.6
3	0	8.9
3	1	12.0
4	0	15.0
4	1	21.0
5	0	39.0
5	1	Indeterminate

**Significance of the Coli-Aerogenes Group.** The absence of members of the coli-aerogenes group in water proves its safety so far as bacteriology can prove it. It is fair to assume that typhoid bacilli, dysentery bacilli, and other intestinal parasites would not be likely to be present in a water in the absence of these bacilli. It is possible to conceive that a water might be polluted with urine alone containing typhoid bacilli, but no colon bacilli, but such an event is highly improbable.

The presence of a member of the coli-aerogenes group, then, is a danger signal; its absence, a sign of probable safety. Final judgment, however, should not be made on the presence or absence of these bacteria alone. The findings should be interpreted in the light of other information obtained in the laboratory and in the field.

## INTERPRETATION OF SANITARY WATER ANALYSIS

EDWARD W. MOORE, M.A.

The interpretation of a sanitary water analysis is much more difficult than the analysis itself. Single or occasional analyses are of limited value. A single water analysis may even be misleading, especially of surface waters. A river water may require repeated examinations extending over long periods of time and correlated with conditions of rainfall, stream flow, wind, temperature, sewage pollution, and other factors in order to secure helpful information. Ground waters should certainly be examined both during wet and dry seasons.

The ordinary routine chemical and bacterial examination of water affords but meager information, especially when only one analysis has been made. Fortunately, the inferences drawn from a sanitary water analysis are on the safe side, and many good waters are condemned; in fact, it is very difficult for an unsafe water to pass a complete sanitary analysis.

The information furnished by an analysis relates only to present conditions and is not a guarantee of future safety. A surface water or a ground water may today be exceptionally free from chemical impurities and practically sterile bacteriologically, whereas tomorrow it may contain organisms causing typhoid, dysentery, cholera, or other water-borne infection; these may come from sources that would at once be evident from a sanitary survey of the watershed. Therefore, a sanitary survey of the catchment area is frequently of much greater practical importance than all the information furnished by the laboratory. Neither a chemical nor a bacteriological analysis is needed to tell us that the water from a creek with an overhanging privy a short distance above will some day carry infection; or that the water from a shallow well in limestone or coarse gravel near a leaking cesspool must be a source of danger. A sanitary survey should discover the sources of contamination, the kinds of pollution, and the degree, often with greater precision than combined chemical or bacteriological tests. No sanitary analysis of a water can, therefore, be considered complete unless it includes an examination of the watershed and a study of the geology and topography of the catchment area.

With the progressive improvement of bacteriological methods, chemical indices of contamination have lost some of their former importance, but valuable inferences may be drawn from the determinations of organic matter, free ammonia, nitrates, chlorides and, in some cases, hardness and alkalinity. The various tests for organic matter are difficult of interpretation, unless they registered marked differences from values known to be normal for the source of the sample, or unless they are used in conjunction with other tests. An experienced observer can learn much

about the condition of the water by use of the odor test. Odors of vegetable decay, such as "peaty" and "vegetable," indicate organic matter from dead vegetation or the presence of a few microscopic organisms. Grassy, aromatic and fishy odors point to heavier growths of more objectionable plankton. Musty, moldy and disagreeable odors like those accompanying putrefactive processes indicate the possible presence of sewage or other organic wastes which may carry contamination. Tarry, oily, and chemical odors serve to detect certain industrial wastes. Albuminoid nitrogen should be small in amount in good ground waters and also in surface waters which have very little vegetable matter, as shown by the color test. High albuminoid nitrogen is due to vegetable coloring matter, algae and similar organisms, or to nitrogenous waste, which usually means sewage. If much sewage is present, there will be a noticeable increase in turbidity.

All the nitrogen tests, if taken together, give evidence as to sanitary conditions. High ammonia nitrogen figures are suspicious in any sample of water, except in occasional deep wells, where the ammonia is derived from mineral sources. Good ground waters contain only traces. Surface waters not subject to contamination will

g. 38-1. Diagram illustrating the character of the ground water in relation to soil pollution, assist in the interpretation of a sanitary analysis. (See also nitrogen cycle, page 1173.)

ve little ammonia except in the presence of algal growths which are in a state of integration. Ammonia indicates proximity to a source of pollution. Nitrites, too, e a danger signal, for the reason that they show incomplete oxidation of nitrogen-s waste. Nitrites in the presence of nitrates are also an indication of incomplete rification. Nitrates (in the absence of nitrites) indicate complete mineralization organic matter and, therefore, are evidence of distant or past pollution. Chlorides ove the normal for the region can be attributed to sewage or other wastes. The rce may be near or distant, for the chlorides are stable.

Hardness and alkalinity are usually derived from mineral sources, but in soft ter regions sewage adds appreciable quantities of the hardness constituents. rdness and alkalinity may, therefore, furnish contributing evidence of sewage llution although, like chlorides, they afford no measure of the proximity of llution.

Waters that vary in composition from time to time without evident cause must be regarded as questionable. This applies particularly to ground waters. Surface waters vary greatly as the result of freshets, etc., but a ground water should show no sudden variations.

**Bacteriological Limits of Pollution.** Although it is possible to define limits of pollution more closely in terms of bacterial content than in terms of chemical constituents, the standards once set for the standard plate counts of bacteria growing at 20° C and 37° C have been abandoned. The plate counts are still considered to furnish useful information in conjunction with other analyses, particularly with respect to stream pollution studies, control of purification plants, and the like. General ranges for unpolluted waters may also be stated; for example, unpolluted surface waters will seldom yield more than 300 to 400 organisms at 20° C, and about one-sixth as many at 35° C, whereas deep ground waters will usually show less than 200 at 20° C, and less than one-tenth of this number at 35° C. Shallow-ground waters may often contain large numbers of bacteria at 20° C without pollution, although the number of organisms at 35° C will remain low in the absence of pollution. Very high counts at 35° C are usually an index of sewage pollution in water. However, the interpretation of the results obtained from plate counts has proved to be difficult for a given water in the absence of an extensive previous record, and the importance of the plate counts in the sanitary analysis of water has greatly diminished in recent years. Many laboratories now make them only in connection with special studies where many data are to be accumulated, as, for example, in studies of the effect of chlorination on the disposal of sewage in a stream, or in an evaluation of the performance of a water purification plant.

On the other hand, determination of the number of coliform organisms has become the principal criterion of the sanitary quality of water. The standards of the U. S. Public Health Service are based primarily on this determination, as the sole measure of potential infectiveness. In the most recent revision of the standards (1946), the following criteria are adopted for drinking waters:

(1) Of all the standard 10-ml. portions examined per month, not more than 10 per cent shall show the presence of organisms of the coliform group, as indicated either by the *completed* or the *confirmed* test.

(2) Occasionally three out of five of the 10-ml. portions constituting a single standard sample may show the presence of coliform organisms, provided that this does not occur in consecutive samples, or in more than 5 per cent of the standard samples examined per month, or in more than one standard sample when less than 20 standard samples are examined per month.

The number of samples required to be examined per month is determined by the population served by the water supply, and is specified in the reference given. It ranges from one per month for a supply serving less than 2,500 people, to 500 per month for a supply serving 5,000,000.

That portion of the Public Health Service standard that requires that not over 10 per cent of all portions be positive is, in effect, a requirement that the average most probable number of coliforms per 100 ml. shall be 1.05 or less. However, if the actual analysis of individual samples, each consisting of five 10-ml. portions, one positive tube signifies a most probable number of 2.2 per 100 ml. For the

reason, some laboratories now use five 100-ml. portions as a standard sample, instead of the 10-ml. portions. Comparable standards for the larger portions as set up by the Service are as follows:

(1) Of all standard 100-ml. portions examined per month, not more than 60 per cent shall show the presence of coliform organisms.

(2) Occasionally all five of the 100-ml. portions constituting a single standard sample may show the presence of the coliform group, provided that this does not occur in consecutive samples, or in more than 20 per cent of the standard samples, or in more than one standard sample when less than five standard samples are examined per month.

The use of 100-ml. portions allows a sharper differentiation of waters as to most probable number of coliform organisms at and near the allowable level. The most probable number corresponding to requirement (1) is 0.51 per 100 ml. (three out of five tubes positive), and the next step above it (four out of five positive) corresponds to a most probable number of 0.92.

For waters to be used for purposes other than drinking, but where potential infection is still of some importance—for example, bathing waters and those used for shellfish culture—there is as yet no general agreement on standards. For public swimming pools the American Public Health Association has set up the following specifications: a plate count of less than 200 bacteria per ml. at 35° C and absence of coliforms in five 10-ml. portions in at least 85 per cent of all samples. This is substantially equivalent to the drinking water standards. For outdoor bathing places, the standards applied by various states run all the way from 50 to 3,000 coliform organisms per 100 ml., with the trend toward the lower values. The State of Connecticut, for example, classifies outdoor bathing waters as follows:

	Coliform Organisms per 100 ml.
Class A, Good . . . . .	0-50
Class B, Doubtful . . . . .	51-500
Class C, Poor . . . . .	501-1,000
Class D, Very poor . . . . .	over 1,000

The figures for bathing places are in terms of the "coli index"; the most probable number is 2.3 times this value.

For waters used for the growing of shellfish, the U. S. Public Health Service recommended the following standards in 1945:

	Coliform Organisms. Most Probable Number per 100 ml.
Approved areas . . . . .	Not over 70
Restricted areas . . . . .	70 to 700
Grossly polluted areas . . . . .	over 700

Shellfish grown in approved areas may be marketed without treatment, and those in restricted areas after proper chlorination. Grossly polluted areas are closed.

## EXAMPLES OF ANALYSES AND INTERPRETATIONS

Several sample analyses of waters, ranging from good to highly polluted, are presented as illustrations of the principles previously outlined.

## ANALYSIS No. 1: Gross Pollution

	Parts per Million
Free ammonia . . . . .	0.214
Albuminoid ammonia . . . . .	0.810
Nitrogen as nitrites . . . . .	0.005
Nitrogen as nitrates . . . . .	21.0
Chlorine as chlorides . . . . .	47.0
Total residue . . . . .	412.0
Volatile residue . . . . .	279.0
Fixed residue . . . . .	133.0
Bacteria per ml. upon gelatin at 20° C . . . . .	65,000
Bacteria per ml. upon agar at 37° C . . . . .	120,000

Fermentation in lactose broth in 0.001 ml. Coliform bacilli confirmed in 0.01 ml.

This represents a grossly polluted water and should unhesitatingly be condemned, no matter what its source. All of the chemical indices of pollution, the ammonias, nitrites, and nitrates, are high; chlorides are also high, although this would depend on the normal for the region. The bacterial counts are large, and the number of coliform organisms present is excessive.

## ANALYSIS No. 2: Stony Brook Reservoir in the Winter

	Parts per Million
Free ammonia . . . . .	0.050
Albuminoid ammonia . . . . .	0.197
Nitrogen as nitrites . . . . .	0.001
Nitrogen as nitrates . . . . .	0.37
Chlorine as chlorides . . . . .	6.0
Color . . . . .	37
Odor . . . . .	distinct vegetable, faint aromatic
Microscopic organisms . . . . .	59 standard units per ml.
Bacteria per ml. at 20° C . . . . .	500
Bacteria per ml. at 37° C . . . . .	80

Coliform organisms, present in 1 ml.

This water is from an impounding reservoir that delivers raw water to the Cambridge, Mass., purification works. A fairly well populated catchment area, on which there is control of wastes, contributes to it. At times analysis would indicate the water to be fit for consumption without purification. The purpose of this analysis is to show that the supply is subject to deterioration at certain seasons and hence requires purification for year-around protection of its consumers.

The ammonias are moderately high and reflect the entrance of organic matter into the supply. They are not due to microscopic organisms, which are few in number. The nitrates are high enough to indicate wash from fertilized fields, or remote sewage pollution. Chlorides exceed normal for the region by 2 to 3 parts per million, indicating the presence of human or animal wastes.

Color is too high and odor too conspicuous for the water to be attractive without purification. The bacterial content is considerably higher than usually obtained in clean surface waters, and the density of the coliform group is indicated to be higher than that shown by a safe water. The water is of questionable sanitary quality, as judged by both the chemical and bacteriological analyses.

ANALYSIS No. 3: Boston Tap Water Typical in 1915 (not averaged results)

	Parts per Million
Free ammonia . . . . .	0.010
Albuminoid ammonia . . . . .	0.114
Nitrogen as nitrites . . . . .	0.000
Nitrogen as nitrates . . . . .	0.02
Chlorine as chlorides . . . . .	2.7
Total residue . . . . .	27.0
Volatile residue . . . . .	10.0
Fixed residue . . . . .	17.0
Hardness . . . . .	13.0

Bacteria per ml. upon gelatin at 20° C . . . . . 77

Coliform organisms, absent in 50 ml.

This is a surface water, collected in impounded reservoirs and stored about 10 days before it reaches the consumer. The watershed is fairly well protected. The chemical analysis shows little organic pollution; the ammonias are moderate in amount, nitrites absent; nitrates low; chlorides normal; bacteria indicate nothing suspicious. The water is of good sanitary quality, judged by chemical and bacterial analysis. For such a water chlorination is the only treatment necessary to ensure safety.

ANALYSIS No. 4: A Suspicious Shallow Well Water

	Parts per Million
Free ammonia . . . . .	0.018
Albuminoid ammonia . . . . .	0.020
Nitrogen as nitrites . . . . .	0.007
Nitrogen as nitrates . . . . .	1.5
Chlorine as chlorides . . . . .	19.3
Total residue . . . . .	106.0
Volatile residue . . . . .	37.0
Fixed residue . . . . .	69.0
Hardness . . . . .	33.8

Bacteria per ml. upon gelatin at 20° C . . . . . 60

Bacteria per ml. upon agar at 37° C . . . . . 45

No fermentation in lactose broth in 10-ml. portions.

This water came from a driven well at Wenham, Massachusetts. Upon inspection it was found that the well was 400 feet from a stable, 200 feet from a cesspool, and 250 feet from the house.

The first thing that strikes our attention in this analysis is the high amount of chlorides. This, however, lacks precise sanitary significance, as it is close to the normal for the ground waters of this neighborhood. The hardness of the water is due to the mineral deposits in the surrounding soil through which the water percolates. The organic matter as represented by the ammonias is low. The nitrates are high and indicate that the water has dissolved this end product of the oxidation of organic matter in its passage through the soil and perhaps in seepage from the cesspool. The fairly high quantity of nitrites indicates that all the organic matter has not been consumed and that the mineralization is not complete. The small number of bacteria present shows that the filtering action of this soil through which

the water passes is effective in keeping out sewage contamination either from the surface or from the cesspool. This conclusion is strengthened by the absence of fermenting organisms.

This particular sample of well water shows nothing injurious to health, and, if subsequent analyses are equally satisfactory, the water may be used without fear for drinking purposes. It is plain, however, that this well needs watching, for it is evident that the soil is already surcharged with organic matter, some of which appears in the water, and a further loading of the soil or a break in the cesspool might readily contaminate the water.

## ANALYSIS No. 5: Pollution of a Well

	Parts per Million
Free ammonia . . . . .	0.022
Albuminoid ammonia . . . . .	0.035
Nitrogen as nitrites . . . . .	0.007
Nitrogen as nitrates . . . . .	1.0
Chlorine as chlorides . . . . .	19.0
Total residue . . . . .	356.0
Volatile residue . . . . .	151.0
Fixed residue . . . . .	205.0

(Residue charred with disagreeable odor upon ignition.)

Bacteria per ml. upon gelatin at 20° C . . . . .	9
Bacteria per ml. upon agar at 37° C . . . . .	275

Fermentation in lactose broth in 0.1 ml.  
Coliforms confirmed in 1 ml.

This was a shallow well (28 feet deep) in Washington, D. C. The water depth was four feet. There was a sewer 60 feet from the well and a privy within a block. The pump was old and the cover to the well was rotten at the base.

Although this water contains only a moderate amount of nitrogenous organic matter, as indicated by the ammonias, every other factor indicates serious contamination. The nitrates and nitrites are high; the chlorides are excessive. It is important to notice that this water has only nine bacteria per ml. when judged by the colonies that grow upon gelatin at 20° C. Nevertheless, it contains 275 bacteria per ml. growing at 37° C, and coliform organisms in 1 ml. It is probable that most of the contamination in this case came from the sewer. The water should obviously not be used for domestic purposes.

## ANALYSIS No. 6: Well Water, Surface Pollution

	Parts per Million
Free ammonia . . . . .	0.007
Albuminoid ammonia . . . . .	0.018
Nitrogen as nitrites . . . . .	0.0005
Nitrogen as nitrates . . . . .	2.5
Chlorine as chlorides . . . . .	14.0
Total residue . . . . .	62.0
Volatile residue . . . . .	32.0
Fixed residue . . . . .	30.0

(Residue charred with disagreeable odor upon ignition.)

Bacteria per ml. upon gelatin at 20° C . . . . .	820
Bacteria per ml. upon agar at 37° C . . . . .	640

Fermentation in lactose broth in 1 ml.  
Coliforms confirmed in 10 ml.

This water came from a shallow well (18 feet deep) in Washington, D. C. The water stood three feet from the bottom. The high nitrates and chlorides in this case represent past pollution. The small amount of organic matter with a trace of nitrites plus the number and character of the bacteria indicate surface pollution. This view is strengthened by the fact that repeated examinations of the water from this well showed marked variations in the number of bacteria. Upon inspection the pump and covering to the well were found in very bad condition and leaky; surface drainage was toward the well.

#### ANALYSIS NO. 7: Illustrating Remote Pollution

	Parts per Million
Free ammonia . . . . .	0.006
Albuminoid ammonia . . . . .	0.011
Nitrogen as nitrites . . . . .	trace
Nitrogen as nitrates . . . . .	20.0
Chlorine as chlorides . . . . .	89.0
Total residue . . . . .	430.0
Volatile residue . . . . .	113.0
Fixed residue . . . . .	317.0

(No charring upon ignition.)

Bacteria per ml. upon gelatin at 20° C . . . . .	92
Bacteria per ml. upon agar at 37° C . . . . .	16

No fermentation in lactose broth in 10 ml.

This was a ground water from a shallow well in Washington, D. C. The well is 29 feet deep and the water stood four feet from the bottom. The top was well protected; waste water drained to a sewer nearby. There were two privy vaults within two blocks of the well.

The analysis shows high chlorides and nitrates, otherwise nothing suspicious. This means remote pollution. The organic matter has been completely mineralized and the bacteria held back by the soil. The high result for volatile matter was due to volatilization of mineral constituents.

#### ANALYSIS NO. 8: High Free Ammonia; Deep Well

	Parts per Million
Free ammonia . . . . .	0.170
Albuminoid ammonia . . . . .	0.000
Nitrogen as nitrites . . . . .	trace
Nitrogen as nitrates . . . . .	0.0
Chlorine as chlorides . . . . .	3.1
Total residue . . . . .	115.0
Volatile residue . . . . .	45.0
Fixed residue . . . . .	70.0

No bacteria per ml. upon gelatin at 20° C.  
No bacteria per ml. upon agar at 37° C.  
No fermentation in lactose broth.

This water was from a driven well 96 feet deep in Washington, D. C.; water stood 81 feet from the bottom. Good platform and drain, and pump in first-class condition.

It is exceptionally pure, both chemically and bacteriologically, except for the large amount of free ammonia. It is not too uncommon to find water from deep wells to be high in free ammonia, and it is assumed that this comes from a chemical reduction of the nitrogenous mineral matter by ferrous compounds. Another possibility may be the release of ammonia from natural zeolites.

ANALYSIS NO. 9: Rain Water Stored and Polluted

	Parts per Million
Free ammonia . . . . .	1.050
Albuminoid ammonia . . . . .	0.175
Chlorine as chlorides . . . . .	2.0
Nitrogen as nitrites . . . . .	distinct trace
Nitrogen as nitrates . . . . .	0.0
Oxygen consumed . . . . .	2.25
Total residue . . . . .	20.0

Bacteria per ml. upon gelatin at 20° C 625  
No coliforms.

This is rain water from a dirty cistern. In appearance the water was clear and good. The analysis shows that the water is polluted with organic matter as evidenced

ANALYSIS NO. 10: Chemical and Bacteriological Changes in Potomac River Water as the Result of Storage and Filtration

(The figures are averages of weekly samples over a period of a year.)

	Dalecarlia Inlet: Raw Water Entering Storage Reservoir	Dalecarlia Outlet: Raw Water After About 2 Days' Storage	Georgetown Reservoir: Second Storage Reservoir (Water Remains Here About 2 Days)	Washington Reservoir: Third Storage Basin (Water Remains Here About 3 Days)	Filtered Water from Filtered Water Reservoir
Turbidity	86.0	30.0	29.0	18.0	1.0

\*Includes 150 standard units of rotifer.

Results of chemical analysis are expressed in "Parts per Million" i.e., Milligrams per Liter.

by the albuminoid ammonia, oxygen consumed, and plate count. The bacteriological results indicate absence of fecal pollution. The water is undesirable, but not dangerous, as far as the possibility of infection is concerned.

Analysis No. 10 is a good illustration of the bacteriological and chemical character of a river water, and illustrates the changes that occur during short storage (about seven days) and after filtration through a slow sand filter.

It will be seen from this table that the turbidity is markedly reduced by sedimentation during storage and by filtration. There is a gradual diminution in the amount of free ammonia and a more marked diminution in the amount of albuminoid ammonia. The nitrites show a marked decrease after filtration, indicating the rapid completion of the oxidation of the organic matter in the filter. The nitrates show a tendency to increase in amount, which would be expected as the nitrites diminish. It is evident that storage and filtration have little effect upon the chloride content of the water.

Adapted from Whipple, G. C., *Microscopy of Drinking Water*, New York, John Wiley & Sons, Inc., 1927.

Fig. 38-2. Location of sampling stations.

The number of bacteria decreases as the result of storage, but the most marked decrease occurs as the result of filtration. Likewise, the effect of the few days storage materially affects the number of coli-aerogenes organisms, and there is a marked diminution in their number following filtration.

The analyses of surface waters, shown in Analysis No. 11, with diagram (Fig. 38-2) of the locations from which samples were obtained, will repay careful study.

## THE PURIFICATION OF WATER

EDWARD W. MOORE, M.A.

The purification of water—that is, the production of hygienically safe and aesthetically pleasing water from a polluted or contaminated source—makes use of a number of physical and chemical processes for the removal of undesirable constituents. Some of these processes, such as aeration, sedimentation, and filtration through sand, are also active in natural purification; others have no counterpart in nature—for example, chlorination and adsorption by activated carbon. The art of purifying water on a practical scale consists of combining in proper sequence those processes which are essential to the removal or modification of the undesirable constituents present in the particular water to be treated. The objective is twofold: the removal of disease-producing bacteria and other organisms, and the elimination of substances which may be harmful, unpalatable, or objectionable in appearance, or may interfere with the use of the water for technological purposes.

A list of the principal processes used in water purification, together with the effects they produce on the composition of the water, is given below. Those processes which are active in natural as well as artificial purification are placed first in the list.

## PROCESS

## RESULTS

Aeration . . . . .	Tastes and odors diminished. Iron and manganese made insoluble. Corrosiveness decreased by $\text{CO}_2$ removal, increased by $\text{O}_2$ addition. In natural purification, supplies $\text{O}_2$ for oxidation of organic matter.
Coagulation . . . . .	Turbidity, color, iron, manganese and bacteria brought together into large flocs that settle readily. Natural coagulation by agglomeration of soluble and colloidal material; artificial coagulation by addition of chemicals, e.g., aluminum sulphate.
Sedimentation . . . . .	Turbidity and bacteria reduced. Coagulated substances removed.
Filtration . . . . .	Turbidity, iron, manganese and bacteria removed. Color, tastes and odors reduced. Includes natural filtration through soil.
Softening . . . . .	Hardness removed.
Disinfection (chlorination) . . . . .	Bacteria removed. Odors and tastes possibly increased; decreased by superchlorination and dechlorination, by break-point chlorination, or by chlorine and ammonia treatment.

Adsorption (activated carbon)	(Slower kill of bacteria than straight chlorination.)
Corrosion correction	Odors and tastes prevented and removed.
	Reduction of tendency to dissolve metal from pipes, tanks and other structures and to form tubercles or rust deposits.

No method or combination of methods of purifying water can be considered satisfactory that does not first of all eliminate water-borne diseases. To effect this with certainty generally requires the removal or destruction of all but a few of the original bacterial population. There is perhaps no final reason for permitting a few to remain. They are allowed under present practice because such a degree of purification represents one that appears to eliminate water-borne infection and one that can be accomplished at reasonable cost. At present there is no evidence that the few bacteria left in water after a satisfactory process of purification, such as filtration and disinfection with chlorine, are injurious. Certainly, if injurious influence is exercised, it is too small to be determined by any methods now at our disposal.

If the water is to possess esthetic appeal, any process of purification used must also reduce turbidity, color, odors and tastes to inappreciable amounts. Likewise, purification should produce a water that is economical to use. It should not seriously corrode pipes, boilers and fittings; it should not stain clothes in the laundry; it should not cause excessive waste of soap in the household or in industry; it should not cause heavy incrustations in boilers, nor should it possess any quality that will cause consumers to resort to bottled waters. The standards of quality demanded have tended to rise as rapidly as advances in the art of purification have permitted.

**Nature's Methods.** In nature, water is purified by various methods, the chief of which are: (1) evaporation and condensation, which makes rain water the purest of natural waters; (2) the self-purification of streams, which is a variable and uncertain process; (3) storage in lakes and ponds, which clarifies water and which in time eliminates danger; and (4) the physical, chemical, and biologic action of the soil upon water that filters through into the earth, one of nature's greatest purifying agencies.

**EVAPORATION AND CONDENSATION.** The distilling and condensing process through which all meteoric water passes is one of nature's more reliable purification processes. Enormous quantities of sea water, marsh water, and polluted water of all kinds are thus returned to us suitable for domestic use. The ocean has been compared to a boiler, the sun to a furnace, and the atmosphere to a vast still. The cooler air of the higher atmosphere and colder zones act as a condenser, causing the precipitation of the distilled water as rain.

**SELF-PURIFICATION OF STREAMS.** There can be no denial of the fact that streams become purer during the course of their flow. But this is at best a half-truth based upon chemical data and has in the past too often been used to justify acceptance of unsafe waters. Streams become purer, but not pure. Some dangerous components may remain, particularly disease-producing organisms. All surface supplies, except those from uninhabited catchment areas, are now regarded with

suspicion and are stored, filtered, chlorinated, or otherwise purified before they are used.

It was formerly said that a stream purifies itself in seven miles. Such a generalization is absurd. It is not the distance that controls but the time and opportunity for natural purification to become effective.

The pollution and recovery of several large streams in the United States have been studied and reported upon by various government agencies, principally the U. S. Public Health Service, and the Public Health Departments of various states (Crohurst, 1933; Crohurst and Veldee, 1927; Hoskins and others, 1927; Massachusetts, Merrimac Joint Sewerage Board, 1947; Purdy, 1930; U. S. Ohio River Committee, 1944).

The forces active in natural purification are of three kinds: (1) *physical*, the most important of which are aeration, light and gravity; (2) *chemical*, outstanding among which are oxidation, reduction, and coagulation; and (3) *biological*, principally concerned with the food habits of various micro-organisms that promote purification.

**AERATION.** This force operates by exchange of gases between the atmosphere and the water. Wind action, turbulent flow and waterfalls all promote the influence that aeration plays. Oxygen is absorbed from the atmosphere and the gases of decomposition, such as carbon dioxide, hydrogen sulphide, and methane, are liberated from the water. The rate of oxygen absorption is controlled by various factors, the chief of which is the degree of undersaturation of the water, that is, the ability the water has further to absorb oxygen before becoming saturated.

**LIGHT.** The natural color of water, originating for the most part in swamps, is leached somewhat by the action of light, a contribution to self-purification processes. The greatest contribution of light, however, is its stimulation of the process of photosynthesis in aquatic plant life, as a result of which oxygen is added to the water and  $\text{CO}_2$  is removed. The activity of plant life also leads to the consumption of amino acids and possibly other soluble organic nitrogen compounds. Sunlight also exercises some germicidal power upon all surface waters. The depth of penetration is slight in any natural water containing color and turbidity.

**GRAVITY.** Gravity causes sedimentation of suspended impurities and of colloidal particles that have coagulated into larger masses. Sedimentation is favored in quiet water and in slow moving streams containing organic and inorganic suspended solids. Coagulation and sedimentation likewise remove organic bacterial food from the water. The same principles are used to clarify water with chemical coagulants such as aluminum sulphate.

**OXIDATION.** Organic matter is gradually oxidized and converted to mineral substances. The aerobic bacteria are the principal agents in this oxidation. During the course of flow the complex nitrogenous substances are thus mineralized. Chemical analyses show a rapid decrease in the amount of organic matter and an increase in nitrates, and diminution of nitrites. It was these facts that led chemists to conclude that flowing rivers soon purified themselves. In addition, oxidation is a aid to the precipitation of such dissolved mineral substances as iron and manganese compounds.

**REDUCTION.** Although aerobic processes predominate in most places, anaerobic decomposition proceeds where oxygen is lacking. In zones of heavy pollution and

at the bottom a variety of reactions may go on in the absence of oxygen. Hydrolysis and splitting of organic compounds result in their liquefaction and gasification and prepare the way for subsequent oxidation. The products of such reductive reactions are often objectionable. The agents are anaerobic bacteria.

**BIOLOGICAL FORCES.** All living organisms in the polluted water, from bacteria and plankton, to mollusks, fish, and water weeds, contribute to further the process of natural purification. Physical improvement and stabilization go forward in series of zones, often well marked in streams by a succession of forms of life.

High bacterial numbers are followed by growths of protozoa which are largely bacteria-eaters. Then, as physical improvement of the water permits penetration of light, the green algae make their appearance. They consume  $\text{CO}_2$ , nitrates, nitrites and ammonia, and produce copious amounts of oxygen. The large aquatic plants act similarly to the algae and also utilize the food elements found in bottom deposits.

Following the protozoa and algae, such forms as crustacea and rotifers may become numerous. They consume algae, bacteria and protozoa and some of them ingest quantities of decaying organic detritus. All these biological forces tend to free the water from impurities. In addition, worms, larvae, and mollusks are at work in the water and in the bottom deposits, pushing forward the work of stabilization of raw food substances.

The efficiency of all the agencies that tend to decrease numbers of bacteria improves with prolongation of the period over which they act. Time is essential for the self-purification of water. Pathogenic bacteria tend to die in water because it is an unfavorable environment. They succumb somewhat more quickly in a polluted water than in a clean one because of hostile biological forces. It is probable that bacteriophages, among other things, play a part.

**STORAGE IN LAKES AND PONDS.** The same forces that have been described as potent in the self-purification of streams manifest themselves in the improvement of stored waters, although the zones in which this takes place are not as clearly delimited as in streams. Almost no organisms pathogenic for man multiply in water under natural conditions. In time they die out. Hence a properly stored water is reasonably safe. In addition, the organic matter undergoes decay and is transformed to simple mineral constituents. A stored water will in time free itself not only of harmful parasites, but also of most of its organic pollution. Storage is a natural and economical method of improving the quality of the water. Many large communities rely in part on long continued storage in large reservoirs to provide a safe water. In times of drought, the storage period in such reservoirs may be seriously reduced, and their protective value thus diminished.

**Distilled Water.** The distillation of water effects practically complete removal of chemical impurities, and unless there are gross defects in the equipment or its operation, distilled water is also substantially free from bacteria.

However, the cost of distillation is comparatively high, so that it can only be considered as a means of water purification under special circumstances, particularly when water of excessive salinity is the only kind available. There is great interest in reducing the cost of distillation, so that it can be used to produce adequate water supplies from sea water and excessively salty well waters in regions where fresh water is lacking. The development of the vapor compression still has materially reduced the cost of distillation, but it is still high compared to the cost

of purifying fresh waters by the conventional methods. Distilled water, despite statements to the contrary, is entirely suitable as drinking water as far as physiological effects are concerned. The so-called "flat" taste, often present in distilled water, and ascribed to the absence of air, is more probably due to the concentration of volatile odoriferous substances from the raw water in the distillate. The vapor compression still, which operates at a comparatively low temperature, is less prone to produce water of disagreeable taste than the direct-fired still.

**Boiled Water.** Boiling water for five minutes will destroy any of the organisms of water-borne disease, and a shorter time will suffice for most of them. This applies at sea level only; at higher altitudes the period of boiling should be lengthened. Boiling is an effective disinfection measure which is simple enough to be carried out by the general public, and as such should be always resorted to in an emergency. It does not remove toxic chemicals, unless these are highly volatile substances such as hydrogen sulphide.

**Coagulation and Filtration. SAND FILTERS.** Sand filters consist of basins or containers filled with sand, supported on gravel and stone, and suitably underdrained. The water is passed downward through such a filter. If the rate of filtration is low (usually 5 million gallons per acre per day or less) the filter is called a slow filter; if the rate is high (generally 125 million gallons per acre per day or over) the filter is called a rapid filter.

The water in the slow sand filter passes very deliberately through the layer of sand; the filter chokes by the clogging of the superficial layer of sand, and this type of filter can only be cleaned by removing this surface layer of *Schmutzdecke*,

Fig. 39-1. The arrangement of a slow sand filter.

it is called. In rapid sand, or mechanical, filtration the water is first coagulated by chemicals, such as aluminum sulphate, settled, and then passed rapidly through coarser sand. The filter is cleaned by backwashing with water, sometimes with the aid of air or mechanical stirring. Because of the greater efficiency and economy of rapid sand filtration, the slow sand filter is rapidly becoming obsolete.

**Slow Sand Filters.** The slow filtration of water through sand originated as an empiric process, imitating nature's method of purifying water as it slowly passes through the soil. It was used before the chemistry or bacteriology of the process was understood. We know that the spaces between the sand are large when compared with the size of bacteria; nevertheless, about 99 per cent of the bacteria are held in the superficial layers of the sand. Nitrification and oxidation of organic matter also take place. The process is by no means a simple straining. Bacteria and other micro-organisms in the upper layers of the sand grow and form a geluleal mass; each grain of sand becomes coated with a gelatinous and adhesive film. A continuous sticky layer forms upon the surface a carpet-like mass constituting the *Schmutzdecke*, which aids in holding back the bacteria in the water.

Adsorption and absorption by this layer are the major forces in purification of the water passing through it.

A slow sand filter requires an extensive tract of land. The filtering surface is divided into units known as filter beds. In the filters most recently constructed each bed occupies about one acre. Each bed must be an independent unit, so that the rate of filtration, the cleaning and all other operations may be carried on without disturbing the other beds.

Sand used for filtration contains particles of various sizes; it is the finest portion which mainly determines the efficiency of the sand for filtration. According to Hazen (1916), the finer 10 per cent on a weight basis has as much influence in filtration as the coarser 90 per cent. Therefore, the size of grain such that 10 per cent by weight of the particles are smaller and 90 per cent larger is designated as the *effective size*. It is determined by sifting a weighed amount of the sand through a series of sieves. The effective size of sand for slow sand filtration should be from 0.25 to 0.35 mm. Another important point in regard to the sand is its degree of uniformity; that is, whether the particles are mainly of the same size or whether there is a great range in their diameters. This is shown by the *uniformity coefficient*, a term used to designate the ratio of the size of grain than which 60 per cent of the sample is finer to the size than which 10 per cent is finer. Sand suitable for slow sand filters should have a uniformity coefficient of about 2.5.

The usual depth of the sand layer is three to four feet, and this is reduced by successive scrapings for the purpose of cleaning until it approaches 24 inches, when the sand is replaced. The depth of the water above the sand is usually four to six feet.

Probably the most important factor in the operation of a slow sand filter is the rate of filtration, which is 2,500,000 to 5,000,000 gallons per acre per day. The rate of filtration may be governed by automatic devices or may be controlled by hand. Careful attention is required in order to maintain a steady flow and a constant rate, which is essential, for sudden variations in rate are fatal to the successful purification of water by the slow sand process.

The resistance to flow in the sand is measured by the *loss of head*, which is the difference between the level of the water above and that below the sand layer as measured in water gauges. The loss of head increases as the filter clogs. When a filter is new or perfectly clean the loss of head is usually 0.2 to 0.3 foot; when it reaches a value at which the rate of filtration cannot be maintained the filters must be cleaned. Ordinarily, however, the filter is cleaned before this value is reached in order to avoid irregular performance.

The length of time a filter may run before the loss of head makes operation unprofitable and before the bed requires cleaning varies from a few days to many months.

*Efficiency and Control.* The efficiency of a sand filter is fairly measured by a comparison of the number of bacteria in the raw and filtered water. A properly operated slow sand filter will remove 98 or 99 per cent of the bacteria in the applied water when the latter contains as many as a few thousand bacteria per ml. If preliminary treatment is used, such as sedimentation or coagulation, the number of bacteria (standard plate count) in the effluent of a filter will usually be less than 100 per ml., and members of the coli-aerogenes group will usually be absent in 10 ml. of water. It is to be noted that all bacteria in the filtered water do not

represent those that actually pass through the sand. Some of them grow in the underdrains and gravel layer and are, so far as known, harmless.

The filtered water should normally be treated with chlorine. The dose required for disinfection of the filtered water is relatively small.

It is to be expected that the few slow sand filters now in operation will be replaced eventually by rapid sand filters, which produce a greater quantity of water from a smaller area at less cost, and which, furthermore, are able to treat waters which cannot be treated by slow sand filters. The main advantages still possessed by the slow sand filter over its competitor are less need for highly skilled operation, and a lower head requirement.

**Rapid Sand Filters.** The essential and characteristic features of rapid sand filtration are: (1) the addition of a chemical precipitant or coagulant to the water, followed by sedimentation; (2) passing the water rapidly through a layer of sand; (3) washing the sand when dirty by reversing the flow of water and in some cases using pneumatic or mechanical means of agitating the sand. The filters may be either of the gravity or the pressure type. The filtering sand is contained in a large wooden, iron, or concrete tank or box, usually built with a rectangular cross section. These filters are sometimes called mechanical filters, not only because the filtering sand is sometimes washed mechanically, but because the action more nearly approaches a mechanical straining, whereas biological processes may be important features in the purification of water passing through a slow sand filter (Baylis, 1937).

Rapid sand filters produce a minimum of 125 million gallons per acre daily of filtered water; the trend is toward even greater yields, as for example, at the Chicago plant where the rate is 250 million gallons per acre daily. Rapid sand filter plants are built up of many units of small size, the individual filters having an area from 0.01 to 0.1 of an acre. They are sometimes built in the open in warm climates but are usually housed. The sand is 24 to 36 inches deep and is underlaid with 12 to 18 inches of gravel in graded sizes.\* There is a trend toward the shallower beds. The effective size of the sand used varies from 0.35 to 0.60 mm., the usual size being about 0.45 mm., but there is a trend toward the use of coarser sands. The uniformity coefficient should be less than 1.8. As with a slow sand filter, the loss of head increases as the period of service is extended. Finally, it reaches a point where the rate of filtration can no longer be maintained. The filter is washed at or before this point, usually when the head loss has built up to 10 feet.

**Washing Filters.** The filters are washed by providing a reverse flow of water of sufficiently high velocity to lift and expand the bed of sand. The agitation and rubbing action to which the sand grains are thus subjected frees them from the accumulated coagulum, and this is carried off by the wash water. The usual rate of wash is about two to three cubic feet of water per minute per square foot of

Fig. 39-2. Diagram illustrating "loss of head."

\* In some recent filters the gravel is replaced by porous plates and all or part of the sand by fine anthracite coal.

filter; the trend is toward coarser filter sands and consequently higher wash rates. The washing process consumes from 2 to 5 per cent of the total water filtered.

Some of the first rapid sand filters had revolving rakes to aid the washing process by agitation of the sand. These are now less frequently used. Some filter have been designed to use compressed air for the same purpose. The air is admitted through a separate distribution system below the sand bed. The most recent improvement in washing technic is the provision of surface wash, which is the application of a part of the wash water at high velocity to the surface of the sand bed, in such a way as to provide additional agitation of the sand. In one widely used system, high pressure jets are directed downward at the surface of the bed. Surface wash appears to justify the expense of installation; the sand is more thoroughly cleaned without much increase in the amount of wash water used and filter troubles, such as mudballs and cracking, are much reduced. The result has been a fairly widespread adoption of surface wash.

**COAGULANTS.** The *coagulants* used are aluminum sulphate, commonly called "filter alum," and occasionally ferric sulphate, ferric chloride, or ferrous sulphate (copperas) in conjunction with chlorine. The alkalinity present in the water reacts with the aluminum sulphate to form aluminum hydroxide, which is thrown out of solution as a flocculent, colloidal, jelly-like precipitate.

Bicarbonates or carbonates (alkalinity) are consumed by this reaction; one part of commercial filter alum consumes 0.45 part of alkalinity as  $\text{CaCO}_3$ . If the water does not contain sufficient natural alkalinity for the alum, lime or soda ash must be added. Although the stoichiometric reactions are not representative of the actual mechanism of coagulation, they are useful in approximating the quantity of natural or added alkalinity required, and the changes produced in the coagulated water.

The reaction for alum can be written as follows:

1 grain of alum per gallon = 143 lbs. per million gallons.

1 grain of alum per gallon = 17.1 parts per million parts of water.

1 grain of alum per gallon requires therefore

$$17.1 \times \frac{300}{666.7} = 7.7 \text{ parts per million of alkalinity expressed as } \text{CaCO}_3$$

In water, however, the reaction is with bicarbonate:

Therefore 1 grain of alum per gallon liberates 6.8 parts per million  $\text{CO}_2$ .

Also, 1 grain of alum per gallon converts 7.7 parts per million bicarbonate alkalinity to 7.7 parts sulphate or incrustants, all expressed in terms of  $\text{CaCO}_3$ .

**Reaction using soda ash with alum:**

1 grain per gallon alum requires  $\frac{300}{666.7} \times 17.1 = 8.2 \text{ p.p.m. } \text{Na}_2\text{CO}_3$

1 p.p.m. = 8.3 lbs. per million gallons.

1 p.p.m. alkalinity as  $\text{Na}_2\text{CO}_3 = 8.3 \times \frac{100}{100} = 8.3 \text{ lbs. } \text{Na}_2\text{CO}_3 \text{ per mg.}$

1 grain per gallon alum liberates  $\frac{300}{666.7} \times 17.1 = 8.2 \text{ p.p.m. } \text{CO}_2$

Reaction using lime with alum:

1 grain per gallon alum requires  $\frac{168}{666.7}$  of 17.1 = 4.3 p.p.m. CaO = 36 lbs. per ng. CaO.

This liberates no  $\text{CO}_2$ .

1 grain per gallon alum reacting with lime increases hardness 7.7 p.p.m. as  $\text{CaCO}_3$ .

If the natural or added alkalinity present in the water is insufficient to react with the alum added, two undesirable effects will occur. First, the hydrolysis of the excess aluminum salt, according to the reaction

will increase the acidity, or lower the pH value of the water, making it highly corrosive and otherwise undesirable. Second, since the solubility of  $\text{Al}(\text{OH})_3$  is increased as the pH is lowered, the amount of residual aluminum present in the water as  $\text{Al}^{+++}$  will be increased to objectionable levels. The residual aluminum causes after-precipitation of floc in mains and services and interferes with many industrial operations, notably dyeing. Aluminum hydroxide is an amphoteric substance; it is soluble in both acids and alkalies. Hence, if a great excess of alkaline reagent is added in coagulation, producing a high pH value, the result will also be an increase in the dissolved aluminum coming through the filters.

Coagulation with alum therefore requires a fairly delicate balance; the pH value of the coagulated water must not fall far outside the range 6.0 to 7.0. Ferric salts are not subject to this disadvantage; ferric hydroxide is quite insoluble over the pH range 4.0 to 12.0. Therefore, whenever it becomes necessary to coagulate water at low or high pH values, ferric salts are used. The stoichiometric reactions for the common ferric salts are given below:

grain per gallon of ferric chloride requires  $\frac{300}{324} \times 17.1 = 15.8$  p.p.m. of alkalinity as

$\text{CaCO}_3$

grain per gallon of ferric chloride liberates  $\frac{264}{324} \times 17.1 = 14$  p.p.m.  $\text{CO}_2$

grain per gallon of ferric sulfate requires  $\frac{300}{400} \times 17.1 = 12.8$  p.p.m. alkalinity as

$\text{CaCO}_3$

grain per gallon of ferric sulfate liberates  $\frac{264}{400} \times 17.1 = 11.3$  p.p.m. of  $\text{CO}_2$

Ferrous sulfate heptahydrate,  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ , commonly called copperas, is the cheapest source of soluble iron, but unfortunately iron in the divalent (ferrous) state is much less effective than trivalent (ferric) iron as a coagulant. A solution

of copperas treated with chlorine has its iron content oxidized to the ferric state and is the equivalent of ferric chloride or ferric sulphate. The reaction is as follows:

1 part of chlorine oxidizes  $\frac{1,668}{213} = 7.8$  parts of copperas

At high pH values, ferrous iron is oxidized to the ferric state with fair rapidity by the dissolved oxygen of the water. This is the basis of coagulation by copperas and lime, a process which has been used extensively in the past, and is still resorted to under special circumstances. The stoichiometric reactions are as follows:

1 grain per gallon of copperas requires  $\frac{56}{278} \times 17.1 = 3.5$  p.p.m. of CaO or 4.6 p.p.m. of Ca(OH)<sub>2</sub>

This adds  $\frac{100}{278} \times 17.1 = 6.2$  p.p.m. of noncarbonate hardness expressed as CaCO<sub>3</sub>, and extracts from the water  $\frac{32}{4 \times 278} \times 17.1 = 0.49$  p.p.m. of oxygen.

The precipitated aluminum or ferric hydroxide clears the water of suspended matter, including bacteria and inorganic particles, by enmeshing them in a flocculent precipitate, which is subsequently deposited in the sedimentation basin, or on the filter. This is a somewhat oversimplified picture of coagulation; actually the effect of the trivalent aluminum or ferric ions in coagulating the colloidal particles present in the water into flocculent precipitates is more important than the formation of insoluble hydroxides. The "floc," so called, actually contains only a small proportion of aluminum or iron hydroxides.

The proper amount of coagulant in solution is added to the water by means of a calibrated orifice, or in dry form by means of some type of "dry feed" apparatus. Most waters require from a quarter of a grain to three grains of alum for each gallon of water; this is 4.3 to 51.3 parts per million, or 35.5 to 426 lbs. per million gallons. A few waters are difficult to coagulate and will require larger amounts.

The optimum amount of coagulant is dependent on a number of factors, many of them as yet imperfectly known. It cannot be predicted from analysis of the water, but must be determined by experiment or observation; furthermore, the coagulant demand of a single raw water source will vary from time to time. The most important of the factors determining coagulant demand are the amount and nature of the turbidity and color present, the pH value and alkalinity of the raw water, and its temperature. Laboratory equipment for making periodic tests of the response of the raw water to different amounts of coagulant is almost indispensable to the economical operation of a rapid sand filtration plant.

Coagulation of the raw water is followed by a holding period to allow the floc

to grow in size, and ultimately to settle out, prior to application of the water to the filter. An ideal installation would provide a rapid mix to disperse the coagulant in the water, then a period of slow stirring at velocities sufficiently high to accelerate the growth of floc particles by frequent collisions, but not great enough to rupture the floc, and finally a period of comparative quiescence to allow the enlarged floc to settle. In older installations, both flocculation and settling were effected by the provision of coagulation basins designed for retention periods of 2 to 6 hours, with no attempt to separate the two processes. Subsequently, a portion of this space was provided with mechanical flocculators (essentially, stirring devices operating at low speed) thus separating the flocculation and sedimentation stages. Material increases in coagulation efficiency resulted. A further reduction in the space and time required for coagulation has been brought about by the upward-flow or "sludge-blanket" flocculator, in which the water, with coagulant added, moves up through a hydraulically suspended blanket of previously formed floc. The newly formed small floc particles are picked up by the larger particles in the blanket, and the excess floc settles to the bottom of the device. This amounts to a recombining of the flocculation and sedimentation stages, but because of the intimate contact between water and floc, the efficiencies far exceed those obtained in the old style sedimentation basins. At present, the upward-flow coagulators exist largely as patented devices of several types.

Rapid sand filtration is the only known method of treating water from a very turbid or highly colored source. The process is particularly applicable to the muddy streams of our South and West and the highly colored waters of the Atlantic seaboard. It is also the only known method of treating waters heavily polluted by sewage or industrial wastes.

Rapid sand filters, when properly designed and operated, will remove from 5 to 99 per cent of the bacteria contained in the raw water. There are limits to the amount of raw-water pollution that can be successfully dealt with by rapid sand filtration or by any combination of treatment processes. This is well brought out in the papers of Streeter (1927, 1929, 1933). He observed in their various stages of treatment the efficiency and limitations of some 31 municipal filtration plants on the Ohio River and on the Great Lakes. He showed that the bacterial relationships between the quality of the raw, or influent water, and the corresponding quality of the effluent conformed to the equation:

$$E = c R^n$$

$R$  = bacterial content of the raw water

$E$  = corresponding bacterial content of the effluent

$c$  = an empirical constant defining value of  $E$  when  $R$  = unity

$n$  = an empirical constant defining the linear slope of the straight line representing the relationship between the logarithms of the two variables

The consistency with which the bacterial relationships observed in the plant studies conformed to this equation suggested that it represents a basic relationship which underlies water-purification processes in general and which is applicable both to individual stages of treatment and to combinations. The equation bears a close analogy to the Freundlich equation for the law governing adsorption phenomena. This further suggested to Streeter that water-purification processes, which

are essentially extractive ones, are probably subject to laws similar to those governing adsorption.

Results obtained from observation of the 31 plants gave bacterial relationships consistent with those predicted by the use of this equation.

In Table 39-1 are given the number of coliform organisms suggested by Streeter as the maxima permissible for Ohio River and Great Lakes waters if effluents that meet the primary requirement of the U. S. Public Health Service standard are to be obtained from the various combinations of treatment indicated.

Table 39-1. Limiting raw-water coliform index, and various combinations of treatment

Treatment	Limiting Raw-water Coliform Index per 100 ml. (Round Numbers)	
	Ohio River	Great Lakes
1. Chlorination alone	80	50
2. Coagulation, sedimentation and rapid sand filtration (without chlorination)	80	60
3. Same as (2) with prechlorination	3,500	no observation
4. Same as (2) with postchlorination	6,000	4,500
5. Same as (2) with both prechlorination and postchlorination	20,000	no observation
6. Same as (4) with double-stage sedimentation (relatively long period)	60,000	no observation

**DIATOMITE FILTERS.** The diatomite filter for water purification is an outgrowth of industrial filtration practices. The water to be filtered is mixed with a comparatively large amount of diatomaceous earth and passed into a pressure shell, where it is forced through a porous septum. The diatomaceous earth is strained out and forms a filtering layer from one-sixteenth to one-fourth inch thick on the surface of the septum. If necessary, the septum can be precoated with the diatomaceous earth by filtering a heavily dosed portion of water to waste. As in the rapid sand filter, the head loss increases with the amount of water passing through, and when the loss reaches a specified amount, the diatomaceous earth layer is dislodged by reversing the flow through the septum and discharged with the backwash. A new cycle of operation is then begun. Rates of filtration are somewhat higher than those of the rapid sand filter, but at the very high rates sometimes used (15 gallons per minute per square foot), bacterial removals are not particularly good. Suitable effluents can be produced at lower rates.

The diatomite filter is considerably lower in weight and bulk than a rapid sand filter of comparable capacity, which makes it advantageous for mobile installations such as military field water supplies (Black and Spaulding, 1944). It must, however, have continuous supplies of diatomite. There is some evidence that it is more effective than the sand filter in removing cysts of *E. histolytica*. It is not likely that the diatomite filter can compete with the rapid sand filter in fixed installations except under unusual conditions.

**HOUSEHOLD FILTERS.** The small domestic filter attached to a household supply is a most unsatisfactory device and, fortunately, is nearly obsolete, except for

special applications such as the removal of precipitated iron. It is of no value in removing harmful bacteria, and in many cases has been known to increase rather than decrease the bacterial content of a water. An effective filter requires expert maintenance, which is not available in the home.

**Storage of Filtered Water.** Purified water stored in open reservoirs is subject to contamination by trespassers, birds and animals, dust, and surface washings. Open reservoirs must be especially carefully protected if no disinfection is provided beyond the reservoir. Another disadvantage of open storage reservoirs is the possibility of algal growths which may produce disagreeable tastes and odors. For these reasons filtered water is preferably stored in covered reservoirs, both at the plant and throughout the distribution system.

**Disinfection of Water.** It is now general practice to subject water for public consumption to the action of a disinfecting agent regardless of the purity of the water or the previous treatment it has undergone. The disinfection serves as a final barrier to the passage of any pathogenic organisms. Many disinfecting agents have been tried in the past, but elemental chlorine and the hypochlorites now hold a practical monopoly of the field by reason of their effectiveness, cheapness, and ease of application. Chlorination does, however, produce objectionable tastes in certain waters, so that a few other disinfecting agents are occasionally used. These will be discussed before taking up the subject of chlorination, but it is to be emphasized that their use is not nearly as extensive or successful as is often indicated in the literature.

**OZONE.** Ozone is an effective disinfecting agent. The amounts required are about the same as those of chlorine. It will not produce objectionable tastes in waters containing phenols and other compounds which give objectionable tastes when chlorine is used. It is produced by passing dry air through a corona discharge produced between electrodes to which a high voltage is applied. The reaction is  $O_2 \rightleftharpoons 2O_3$ . The ozone is transferred to the water by passing the ozonized air through the water. The major impediment to the development of ozonization of water has been the expense of the equipment and of the current required to operate it. The need for expert supervision over and above that provided by the plant operator has also been a factor. There is also a need for a dependable method of determining the amount of ozone present in the water. One of the shortcomings of the ozone process frequently cited is that it leaves no residual of germicide to give subsequent protection to the water, but it should be pointed out that the small residuals of chlorine carried by most water plants are also of dubious value against subsequent pollution.

Ozone probably owes its effectiveness as a disinfectant to its powerful oxidizing action. The same is true of its ability to eliminate substances having objectionable tastes when it is applied in sufficiently large amounts. If the problems of high cost of production and delicacy of the equipment can be overcome, ozonization may have a future in water treatment. Up to the present, a large proportion of the installations of the process have been subsequently abandoned.

**IONIC SILVER.** Small quantities of silver dissolved in water in the form of silver ion ( $Ag^+$ ) will kill bacteria; the amounts required are of the order of 0.015 to 0.05 parts per million. As with ozone, the principal advantage over chlorine disinfection is the absence of any tendency to produce objectionable tastes. The

process has received much attention, particularly in Europe, and many ways of introducing the silver into the water have been developed, for example, contact with silver coated sand or porcelain rings (Katadyn process), silver electrodes with periodic change of polarity (Electro-Katadyn process), and simple addition of silver nitrate. Disinfection by silver ion is very slow, requiring about an hour at 0.05 p.p.m., and is ineffective in the presence of organic matter. Practical use of the process is negligible at present.

**ULTRAVIOLET LIGHT.** Direct exposure to light of wave lengths below 2,800 Ångstrom units will kill bacteria in a few seconds, and even resistant spores are eliminated by slightly longer exposure. Light of suitable wave length may readily be produced by mercury arc lamps with tubes of quartz or special glasses with high transmission in the ultraviolet. The principal wave length of the light emitted by the mercury arc is 2,538 Ångstrom units. There have been a few attempts to sterilize water by passing it under or around banks of such lamps in shallow flumes. The depth of water must be five inches or less because of the rapid absorption of the ultraviolet rays by water. The process has failed in practice for several reasons, among which are the relatively high cost of operation, the difficulty of maintaining efficient operation of the lights, especially in the absence of any rapid test for efficiency, and the fact that even small quantities of color or turbidity in the water seriously diminish the effectiveness of the disinfection by absorbing the ultraviolet light.

**CHLORINATION.** Although the use of chlorine compounds as disinfectants and deodorants antedates 1854, when the British Royal Commission recommended the use of bleaching powder for deodorizing sewage, the use of chlorine compounds for disinfecting water was initiated in 1908 by G. A. Johnson. The water supply was that of the Chicago stock yards, and the compound used was chlorinated lime. In the same year, the process was applied to the water supply of Jersey City. In 1912, the water supply of Niagara Falls was disinfected by elemental chlorine, produced by electrolysis of brine, and compressed to liquid form in steel cylinders. The purity, stability, and low cost of liquid chlorine led to its rapid adoption by most water plants of any size, and today the use of chlorine compounds is substantially restricted to small or temporary installations. The types of chlorine derivatives now available for use are numerous, and they are listed below in the approximate order of their importance as water disinfectants.

Substance	Active Ingredients	Per Cent "available chlorine" *	Remarks
Liquid chlorine	$\text{Cl}_2$	100 —	.....
Calcium hypochlorite	$\text{Ca}(\text{OCl})_2$	70	.....
Sodium hypochlorite solution	$\text{NaOCl}$	4 to 5 or 16	Produced as a solution only
Ammonia chloramines	$\text{NHCl}_2$ $\text{NH}_2\text{Cl}$		Produced directly in water by reaction of $\text{Cl}_2$ and $\text{NH}_3$

\* "Available Chlorine" is actually a measure of oxidizing capacity expressed in terms of an equivalent amount of  $\text{Cl}_2$ .

leaching powder or chlorinated lime	CaClOCl	35	First compound used; relatively unstable
Chlorine dioxide	Cl <sub>2</sub> O	.....	Produced directly in water by reaction of Cl <sub>2</sub> and NaClO <sub>2</sub>
Organic chloramines	— NCl or — NCl <sub>2</sub>	.....	Special compounds of high stability and portability, for special uses. Examples: Halazone, HOOC-C <sub>6</sub> H <sub>4</sub> -SO <sub>2</sub> NCl <sub>2</sub> ; Succin-chlorimide, (CH <sub>2</sub> CO) <sub>2</sub> NCl; Chloramine T, CH <sub>3</sub> C <sub>6</sub> H <sub>4</sub> SO <sub>2</sub> Na NCl

*Liquid Chlorine.* Liquid chlorine is available at substantially 100 per cent purity in pressure containers holding from 10 to 2,000 lbs., and in tank cars holding 2,000 to 60,000 lbs. In water works practice the 100-, 150-, and 2,000-lb. containers are generally preferred. The chlorine is administered to the water by means of special patented devices which control a slow evaporation of gaseous chlorine from the cylinder into the device, dissolve the gaseous chlorine in a small flow of water, and then add the concentrated solution so produced to the main flow of water. The amounts of chlorine applied range from fractions of a part to several parts per million, depending on the character of the water to be disinfected.

The gaseous chlorine reaching the water is hydrolyzed immediately and, in the concentrations used in water disinfection, completely, according to the following reaction:

The hypochlorous acid so formed ionizes in part according to the following reaction:

The amount of ionization is governed by the pH value of the water, in conformance with the laws of chemical equilibrium.

Hence, the immediate result of dissolving gaseous chlorine in water is a solution which contains no chlorine as Cl<sub>2</sub>, but only hypochlorous acid (HOCl) and hypochlorite ion (OCl<sup>-</sup>). The distribution of the chlorine between these two forms is a function of the pH value of the water; at pH values below 5.0 all of it is present as HOCl, above 10.0 all exists as OCl<sup>-</sup>, and at pH 7.5 equal amounts of each are present. This has an important bearing on the efficiency of disinfection, as will be presently shown. A more complete discussion will be found in the papers of Fair and others (1947, 1948) and Griffin (1947).

Chlorine in the form of hypochlorous acid or hypochlorite ion is a powerful oxidizing agent and as such, reacts rapidly with any reducible organic matter or other reducing substances that may be present in the water. In such reactions, the chlorine is converted to chloride, and is no longer of value as a disinfectant. Hence, the amount of reducible substance in the water, measured in terms of the chlorine consumed, and referred to as the "chlorine demand" of the water, is a major factor in determining the amount of chlorine required to disinfect the water. The amount of unreacted chlorine remaining in the water at any specified time after addition of chlorine is termed "residual chlorine"; it is the amount of chlorine

still remaining as an effective disinfectant at this time. The Manual of Water Sanitation Practice of the U. S. Public Health Service issued in 1946 recommends that a chlorine residual of 0.2 p.p.m. should be present after 20 minutes; this will normally ensure adequate disinfection. The chlorine residual is measured by means of the ortho-tolidine test or the ortho-tolidine-arsenite test as described in the tenth edition of Standard Methods for the Examination of Water and Sewage.

The one great disadvantage of chlorine disinfection is the tendency of chlorine to react with certain substances often present in water to produce compounds of objectionable taste and odor. These tastes and odors are regularly attributed by the public to chlorine itself, but actually pure chlorine is detectable by most persons only at concentrations far above those usually remaining in waters reaching the consumer. Few of these taste-producing compounds have been identified as yet, but phenol and its homologues are well-known offenders. The presence of a few parts per billion of phenol in a water will produce a characteristic medicinal or "iodoform" taste when the water is chlorinated. Certain unidentified components present in beet-sugar plant wastes will also produce taste and odor upon chlorination, even when the dilution is extremely high. Taste and odor production as a result of chlorination is a serious problem in many water plants treating waters containing even relatively small concentrations of industrial wastes. The various methods which have been devised to overcome this problem will be discussed subsequently.

Chlorine is a highly toxic gas; exposure to 40 to 60 parts per million in air for as much as 30 minutes is dangerous, and 1,000 parts per million (0.1 per cent) produces death in a few minutes. It is also highly corrosive to metals, and tends to create leaks. Hence, separate chlorinator rooms with forced-draft ventilation are highly desirable, and the provision of suitable gas masks is mandatory. The precautions to be used in handling chlorine have been so well stressed by the manufacturers of chlorine and chlorinator equipment and by a special committee of the American Water Works Association (1935), that very few accidents have taken place, despite the large numbers of liquid chlorine installations.

*Hypochlorites.* The hypochlorites of both sodium and calcium are used extensively as alternatives to liquid chlorine. Bleaching powder or chlorinated lime is a monohypochlorite of calcium,  $\text{CaClOCl}$ , produced by passing chlorine gas over hydrated lime. It is a hygroscopic white powder which readily absorbs both moisture and carbon dioxide from the air, with liberation of chlorine and consequent loss of strength. It has been largely replaced by the dihypochlorite,  $\text{Ca(OCl)}_2$ , which is produced by a complex crystallization process, and marketed under various trade names. This is a white powder which has less tendency to lose strength through absorption of moisture and carbon dioxide and, in addition, contains twice as much available chlorine as bleaching powder. The hypochlorites of calcium are fed by dissolving them in water, allowing any calcium carbonate sludge to settle, and adding the clear solution, containing 1 to 3 per cent of chlorine, to the water to be disinfected by means of orifices or proportioning pumps which control the quantity added.

Sodium hypochlorite is available as a solution containing  $\text{NaOCl}$  and some  $\text{NaOH}$ , two strengths are marketed, one containing about 4 per cent available chlorine, and the other about 16 per cent. The solution may be purchased or

ade at the plant by electrolyzing a sodium chloride solution. It is relatively un-  
able and has a high proportion of inert ingredients, mostly water; long-distance  
ipment is inadvisable. It is fed by diluting as desired, and adding the diluted  
lution to the water in the same manner as the calcium hypochlorite solutions.

When hypochlorites are added to water, they ionize immediately to hypo-  
chlorite ion ( $\text{OCl}^-$ ) and calcium or sodium ions. The hypochlorite ion then dis-  
tributes itself between  $\text{HOCl}$  and  $\text{OCl}^-$  by the same equilibrium as previously noted:

accordance with the pH value of the water. Hence the end result is precisely  
e same as that secured by the addition of liquid chlorine, with a slight modifica-  
on in that hypochlorites tend to raise the pH of the water because of alkaline  
ubstances present along with them, whereas liquid chlorine tends to reduce the  
H value slightly.

Since the end products in the water are identical, the comments on chlorine  
demand and on taste and odor production made in the discussion of liquid chlorine  
apply with equal force to the hypochlorites. Under the same conditions of tem-  
perature and pH value the disinfecting efficiencies of liquid chlorine and the hypo-  
chlorites are also identical.

*Ammonia Chloramines.* When ammonia or its salts are present in water to  
which chlorine or hypochlorites are added, chloramines are formed according to  
the following reactions:

Reaction (1), resulting in the formation of monochloramine ( $\text{NH}_2\text{Cl}$ ) is about  
90 per cent completed in one minute at ordinary water temperatures and in the  
pH range 6 to 8. Reaction (2) is favored by somewhat more acid conditions;  
dichloramine ( $\text{NHCl}_2$ ) predominates only at pH values in the vicinity of 5 to 6.  
The range of reaction (3) is yet imperfectly understood, but no very great pro-  
portion of nitrogen trichloride ( $\text{NCl}_3$ ) is believed to be present except at pH values  
well below 5.0.

Chloramines are much less active as oxidizing agents than hypochlorous acid.  
This has two results: the effective "chlorine demand" of the water is materially  
less for chloramines, so that chloramine residuals persist for a much longer time;  
also, the chloramines do not react as readily with substances like phenol to pro-  
duce objectionable tastes and odors. As a result, chloramine disinfection has been  
adopted by many plants where persistent residuals are desired or where taste and  
odor difficulties are experienced when chlorine alone is used. The ammonia re-  
quired is added in the form of ammonia gas, aqua ammonia, or ammonium salts.  
Any ammonium compound naturally present in the water will also be converted  
to chloramines upon the addition of chlorine to the water.

Chloramines are, unfortunately, much less effective as disinfectants than hypo-  
chlorous acid. The Manual of Water Sanitation Practice of the U. S. Public Health  
Service recommends that the residual chlorine should be two parts per million at  
the end of three hours to secure effective disinfection when chloramines are em-  
ployed. A comparison with the recommendation previously cited for chlorine alone

will illustrate the very great difference in effectiveness. Dichloramine is more effective than monochloramine, but it is not formed in substantial amounts except at rather low pH values. A more complete discussion will be found in the paper of Fair and others (1948).

**SUPERCHLORINATION AND DECHLORINATION; BREAKPOINT CHLORINATION.** If sufficiently large amounts of chlorine are added to water, the result is the complete elimination of the chlorine demand by oxidation of reducing substances and by the satisfaction of other substances capable of reacting with chlorine. In the course of this process, taste- and odor-producing compounds are destroyed or rendered innocuous, and any chlorine remaining exists only as hypochlorous acid or hypochlorite. Disinfecting activity is also at its highest efficiency at this point, since there are no competing reactions.

A few plants faced with serious taste and odor problems have, in the past, resorted to the practice of superchlorination and dechlorination, which involves the addition of an excess of chlorine, followed, after a suitable contact period, by removal of the bulk of the remaining chlorine. Removal is effected by the controlled addition of some reducing agent such as sulphur dioxide, sodium sulphite, or sodium thiosulphate. Activated carbon has also been used as a dechlorinating agent. The process has been successful with many difficult waters, but is somewhat cumbersome, and is being replaced by the newly developed "breakpoint" method.

"Breakpoint chlorination," so called, consists essentially of careful adjustment of the chlorine added to the water so that the total chlorine demand is eliminated and a very slight residual remains. The addition of successive increments of chlorine to water, especially if the water contains ammonia, results in a residual chlorine content which at first increases as the chlorine dose increases. This residual consists principally of ammonia chloramines and similar chlorine derivatives. However, as the chlorine dose is increased further, these chloramines are destroyed by the additional chlorine, and the observed residual begins to decrease. The mechanism of this destruction is as yet somewhat obscure, but it apparently involves oxidation of the nitrogen of the chloramines. This decrease in residual with observed chlorine dose continues until the residual reaches nearly zero; this is the so-called "breakpoint." Beyond this point, any additional chlorine dose appears in its entirety as residual chlorine; furthermore, all of this residual exists in the form of hypochlorous acid or hypochlorite. Thus, the end point is substantially the same as that reached by superchlorination and dechlorination. A highly effective disinfection is secured, and in most cases the taste and odor problem is eliminated. The only difficulty lies in adjusting the dose of chlorine exactly to the breakpoint, but unless the water is subject to rapid changes in composition, it is not a serious one. The breakpoint process is gaining favor rapidly because it requires no additional equipment above that required for simple chlorination.

**OTHER HALOGEN DISINFECTING AGENTS.** Chlorine dioxide, an oxidizing agent more powerful than hypochlorous acid, is formed in water by the addition of sodium chlorite ( $\text{NaClO}_2$ ) and liquid chlorine. It has recently been shown to be very effective in the destruction of resistant taste- and odor-producing compounds and is being used in a few plants in combination with chlorine to produce a palatable disinfected water.

A number of organic chloramines, such as halazone ( $\text{HOOC-C}_6\text{H}_4\text{-SO}_2\text{NCl}_2$ ),

accinchlorimide  $[(\text{CH}_2\text{CO})_2\text{NCl}]$ , and chloramine T,  $(\text{CH}_3-\text{C}_6\text{H}_4-\text{SO}_2\text{NaNCl})$ , can be made into tablets of relatively high stability which are useful for emergency disinfection of small quantities of water. Elemental iodine can be similarly used; its effectiveness in disinfection is but slightly less than chlorine, weight for weight, and it has less tendency to produce objectionable tastes and odors. Ordinary tincture of iodine can be used for water disinfection. A recent development is a tablet containing a glycine-iodine compound,  $(\text{NH}_2\text{CH}_2\text{COOH})_4\text{HI} \cdot 1.25\text{I}_2$ , called Iobalaine. This tablet, which is more stable than the organic chloramines, releases iodine in water, and offers many advantages for field and emergency disinfection. Bromine has been applied experimentally to water disinfection; it is effective, but appears to offer no advantage over chlorine, and is more expensive.

**FACTORS AFFECTING THE EFFICIENCY OF DISINFECTION.** The organisms which are to be eliminated by disinfection of water are varied in character; the following list comprises those known at present:

1. The enteric bacteria, comprising members of the groups *Salmonella*, *Shigella*, and *Vibrio*.
2. The intestinal protozoa, of which *Entamoeba histolytica* is the most common.
3. A few worms—for example, the schistosomes.
4. Viruses—for example, that of infectious hepatitis.
5. Coliform organisms which, although not pathogens, are the primary indices of contamination of water.

These organisms vary widely in resistance to disinfection; the enteric bacteria are most easily destroyed by chlorine compounds, and the coliforms are comparable with them. The cysts of *E. histolytica* are the most resistant organisms known at present, and should be employed more frequently as indicators in studies of water-disinfecting agents. Schistosomes are comparatively easily destroyed when swimming; the resistance of the viruses is but little known, but it is indicated to be at least lower than that of *E. histolytica* cysts.

Given a specific organism, a specific disinfecting agent, and a fixed water temperature, the disinfecting activity is a time-concentration relationship which can be expressed as follows (Fair and others, 1948):

$$C^n t = \text{constant}$$

where  $C$  represents the concentration of disinfectant in the water,  $t$ , the time to achieve a given percentage of the organisms present, and,  $n$ , a numerical exponent dependent on organism, disinfectant, and water temperature. In all studies made to date,  $n$  varies from 0.75 to 2.00, with 1.00 as the most common value. When  $n = 1.00$ , the implication is that contact time and concentration of disinfectant are of equal importance; if  $n$  is less than 1, time is of greater importance than concentration, and if  $n$  is greater than 1, concentration is more important than time. Lowering the temperature of the water materially decreases the rate of kill; a few complete studies that have been made indicate that the rate is approximately halved for each  $10^\circ \text{C}$  decrease in temperature. This demands a considerable increase in concentration of disinfectant in cold waters if suitable efficiencies are to be secured.

Much has been learned in the last few years about the relative disinfecting efficiencies of the various forms that chlorine assumes in water. For example, it

has been known for a long time that disinfection by chlorine is hindered by high pH values. The explanation lies in the fact that the distribution of chlorine between HOCl and OCl<sup>-</sup> ion is governed by the pH value of the water. HOCl is many times as effective, per unit of chlorine, as is OCl<sup>-</sup>, but a high pH value transforms most of the chlorine into OCl<sup>-</sup>. The rate of kill of an organism by the system HOCl, OCl<sup>-</sup> can actually be formulated in terms of the known distribution ratio as governed by pH value (Fair and others, 1948).

The effectiveness of the chloramines is also materially less than that of HOCl at equal concentrations of "available chlorine." For the enteric bacteria, HOCl appears to be 80 to 100 times as effective as dichloramine, the most active of the ammonia chloramines. Thus the success of superchlorination-dechlorination and "breakpoint" chlorination is demonstrated to be based on sound theoretical considerations, since both replace chloramine residuals with uncombined HOCl. The importance of differentiating between chlorine "residuals" consisting of uncombined HOCl and those consisting of chloramines is also demonstrated; this is recognized in the tenth edition of Standard Methods for the Examination of Water and Sewage by including several methods for differentiation.

**Corrective Treatment for Corrosion.** One of the most important phases of water treatment is the correction of corrosive quality. All metals tend to dissolve in any water to some extent, but waters which are soft and low in pH value are especially active. Furthermore, iron and steel, which are still the metals most generally used for piping, are highly susceptible to subaqueous corrosion, and although such metals as copper, brass, and lead are less readily attacked, the corrosion products may be objectionable or even dangerous in drinking water. The correction of corrosiveness is of importance in two ways: (1) from the standpoint of protection of the pipes, which tend to clog with the products of corrosion or to fail because of penetration; and (2) from the standpoint of protection of the quality of the water, which is debased by the presence in solution and suspension of metallic salts derived from the pipes.

Cast-iron pipes are commonly used in municipal water-distribution systems. They may be protected by coating them with tar, bitumen, or cement before and even after installation. All pipes may be protected during use by treating the water in such a way that thin films of certain substances are continuously maintained on the pipes, which are thereby protected from corrosive action by the water. The most common type of treatment is that which produces a film of calcium carbonate. This is accomplished by adding to the water prior to delivery to the system either lime, sodium carbonate, or both, to combine with carbon dioxide and bicarbonate of the water, forming calcium carbonate slightly in excess of saturation requirement at the final pH value. Experiments by Baylis (1927) have shown that this requirement varies between about 20 and 300 parts of calcium carbonate per million in the range pH 9 to pH 7. The chemical equilibria have been worked out by Langelier (1936, 1946), and further developed by others (Hoover, 1938; Moore, 1938), so that the amount of treatment necessary can be predicted from an analysis of the water. This treatment requires reasonably accurate control, for excessive treatment causes heavy incrustation of the pipes, and insufficient treatment permits corrosion.

Sodium silicate may also be added to water to inhibit corrosion; it forms a protective film composed of calcium silicate. If the water is low in calcium, lime may be used with the sodium silicate. Sodium poly-metaphosphate and certain complex sodium pyrophosphates are now used extensively for corrosion control; they produce films of calcium metaphosphates or pyrophosphates that are very effective on ferrous metals. They have advantages over the calcium carbonate treatments in that the amounts of chemical used are very small, and no incrustation results from overtreatment. Any of the treatments previously mentioned will, properly applied, reduce the corrosive attack of a water on piping to a negligible quantity, but none of them will prevent all corrosion, and for any particular case, one will usually prove better than the others.

**Copper Sulfate.** The use of copper sulfate to control algal growths in drinking waters was first proposed by George T. Moore of the United States Department of Agriculture in 1904. It has proved to be valuable for the elimination of taste- and odor-producing algae from reservoirs.

The copper sulfate is applied in the proportion of 0.1 to 1.0 part per million. The concentration required depends largely on the algal species to be controlled. Some of the copper is precipitated and settles to the bottom and in this way is removed from the water. If the water is afterwards filtered most of the remaining copper is removed. The copper remaining in the water in the absence of filtration is so minute that there is no evidence of real danger in using it in this way or even its occasional use in somewhat larger doses where the water is very bad. Copper is not an accumulative poison. Further, more of it is found in milk and some other foods than in a water treated with copper sulfate for the removal of algae.

The usual method of applying the copper is to place weighed quantities of copper sulfate in loose cloth bags and to tow them back and forth with boats through the water of the reservoir until the material is dissolved. It can also be cast over the water surface, or sprayed in the form of a solution. While the copper kills some species of organisms in the amounts used, it has little effect on others. In fact, it permits the growth of certain species by removing the guarding symbionts, thus clearing the way for stronger growths of the forms that are not directly affected. Copper sulfate may, therefore, entirely change the flora of a reservoir. This change is frequently accompanied by a great improvement in odors and tastes. On the other hand, the destruction or suppression of one species may be followed in a few weeks by an overgrowth of an equally objectionable and noisier form. A regular program of treatment, based on continued microscopic counts, is essential for continuous successful control of algae in a reservoir.

**Activated Carbon.** One of the most effective methods of dealing with tastes and odors in water supplies is that which employs activated carbon. This reagent acts both as a preventive and as a remover of these qualities, in that it will adsorb organic constituents that later react to give taste or odor, as well as adsorbing compounds which already have made themselves evident. Thus, the chlorophenols may be prevented by the use of activated carbon to take out phenolic compounds before the application of chlorine, while vegetable, musty and chlorine odors may be removed to improve physical quality.

Ordinary carbon, such as charcoal, was widely used in the nineteenth century in the form of filters for removal of bacteria, odor and color from water, but the

efficiency was not great and the life of the material not long. Chars of high adsorbing activity, hundreds of times greater than that of charcoal, were developed during 1910 to 1920. The general name of "activated carbon" was applied to these materials. They were first used in the purification of a wide range of products such as foods, chemicals and pharmaceutical preparations and as the active principle of gas masks. Research by Baylis (1929) in this country, Imhoff and Sierp in Germany, and others (American Water Works Association, 1938; Braidech, 1938; Helbig, 1938; Smith, 1938; Sigworth, 1943), proved the power of activated carbon to remove from water phenolic compounds and chlorine. Later work showed that this reagent will also take out odor- and taste-producing substances derived from algal growths and from dead vegetation. The removal is nearer to being complete by this process than it is by any other now known. Costly or complicated equipment is not necessary for the purpose. The cost of the carbon itself is the principal consideration.

Some of the early installations used beds of granular activated carbon through which the water was filtered. Such a practice involves a considerable initial outlay for material and its frequent removal or regeneration when it becomes charged with adsorbed impurities. Present practice in most cases makes use of a powdered activated carbon which is added to the water by means of a dry-feed apparatus to which is attached a water ejector. Obviously such a method of application is restricted to rapid sand filter plants.

Powdered activated carbon is generally a vegetable char made from a variety of woods, waste liquors from paper manufacture, nut shells or other vegetable products. It is activated by superheated steam or other heat methods. Activated carbon used for water purification is a more or less pure form of carbon which has a high adsorptive capacity for foreign molecules, due largely to its porous, capillary structure which presents an enormous total surface. It is light, weighing 10 or 11 pounds to the cubic foot, and it is fine; over 90 per cent of it will pass a 200-mesh sieve. The powder has a low apparent density (about 0.2) which causes it to settle slowly and to give sustained action. It functions by the power of adsorption whereby the carbon surface exhibits greater attraction for impurities in the water than does the water itself.

The amount of powdered activated carbon necessary to remove taste- and odor-producing substances has been found to be between 5 and 24 pounds per million gallons in the majority of cases. Occasionally more is required.

The point of application differs with local conditions and must be carefully selected. In practice it varies, being: (1) directly on the filters, (2) in the settling basin, (3) midway in the coagulation process, or (4) with the coagulant. The most common procedure by far is the latter, the activated carbon either being mixed with the coagulant or being separately added to the water at about the same point as the coagulant. There are two principal advantages in method (4). It follows: (1) Only a small amount of carbon reaches the filters and so excessive losses of head do not result as when adding carbon directly to the filters, and (2) The sludge in the sedimentation basin shows less tendency to putrefy in the presence of carbon, so that taste and odor troubles from this source are minimized. However, a part of the carbon is rapidly taken up by the floc, so that the

efficiency of a unit of carbon in removing taste and odor is less in method (4) than in methods (1) or (2).

Treatment with activated carbon is the most widely used method of controlling taste and odor. The cost is moderate for most waters, the method of application is simple, and the results in many cases are striking. A few waters are resistant to carbon treatment, in the sense that excessive amounts are required to make the water palatable. For further details, the reader is referred to the report of the American Water Works Association Subcommittee on Activated Carbon (1938).

There are also several other water-treatment processes that may be applied in special circumstances. Among these may be mentioned softening, which has been discussed in Chapter 37 on Sanitary Analysis, and the removal or addition of fluoride to control defects in tooth structure caused by an excess or deficiency of this element. Fluoridation and defluoridation are discussed in Chapter 40.

## WATER AND ITS RELATION TO DISEASE

EDWARD W. MOORE, M.A.

Water is a vehicle for certain infections such as cholera, typhoid fever, dysentery and other diseases having their primary seat in the digestive tract (see Chapter 3). It may carry inorganic poisons such as lead, or substances such as nitrate, which, when present in large amounts, is dangerous to infants. It may be responsible for certain nutritional and dietetic disorders that are less well understood. It may lack qualities which bring about derangements of metabolism resulting in such conditions as goiter. It is also occasionally responsible for conveying animal parasites, amebae, worms, etc. (see Chapter 3). From time to time new troubles are disclosed—epidemics of leptospirosis and of infectious hepatitis have been traced to water, and it has been demonstrated that excessive amounts of fluorine in water are the cause of mottled enamel of teeth; while inadequate amounts are associated with high rates of dental caries.

While water has an established place among the carriers of certain infections, it has not a supreme or exclusive place, and this should be kept carefully before us. The tendency to exaggerate the importance of water as a bearer of disease and death has sometimes led to overstatement. The facts are bad enough and do not require extravagant language to emphasize their importance. The greatest danger in water is pollution from human sources. All the discharges from the body (urine, feces, expectoration, secretions from the nose, and washings from the skin) find their way sooner or later into our streams and other bodies of water, especially where modern water-carriage systems are installed for the disposal of wastes. All sewage-polluted water must be regarded as dangerous, whether there are any known cases of typhoid fever on the watershed or not. It is highly probable that the sewage of large communities contains typhoid bacilli and other disease organisms in larger or smaller numbers, because even when no overt cases appear carriers and missed cases may be expected.

Water differs in several essential particulars from any other article of diet. Above all, it is partaken of raw, while perhaps 90 per cent of all our other food is disinfected by cooking before it is used. Again, it is a vehicle which comes in contact with many objects spread over broad areas, and it is the natural vehicle for the removal of wastes from these areas.

### NONSPECIFIC DISEASES DUE TO WATER

Impure water may be responsible for disorders other than specific gastrointestinal infections, but these disorders are obscure and are generally overlooked.

It is not always plain just what quality or what impurity in the water is responsible for these nonspecific disorders, and the diseases themselves may present a vague and ill-defined clinical picture.

A turbid, malodorous, or unpalatable water may not in itself be particularly injurious to health, but, on account of its unattractive appearance or repulsive condition, less may be taken than is necessary for the maintenance of good health or recourse may be taken to more palatable waters that are less safe. In this way water may be indirectly responsible for harm. The drinking of too little water is a common dietetic error.

*Organic matter* in the quantities usually contained in a natural water is not of itself harmful. Excessive organic matter, on the other hand, has been regarded with some suspicion, even when it is of natural origin. No positive evidence has ever been obtained to relate gastro-intestinal disturbances to natural organic matter except in the cases of excessive growths of certain of the blue-green algae (*Anabaena*, *Aphanizomenon*). These algae contain a toxic substance which has been fatal to cattle; instances of human illness so produced are rare, because the concentration of algal growth required to produce an effect is such as to cause rejection of the water on esthetic grounds. Even though the case is not clear, sanitary engineers have tended to err on the safe side by condemning waters containing much organic matter, or by treating them to remove it.

As far as the *inorganic impurities* usually found in water are concerned, the chlorides, carbonates, sulphates, and silicates, and lime, magnesia, and aluminum can scarcely be harmful in the amounts ordinarily found. In fact, most of the mineral matter, especially lime, carried by water is needed by the body. The amount secured in this manner, however, is negligible in comparison to that secured from foods. The trace of iodine in water may be an important source of this element in the diet, unless other sources are purposely provided. It is commonly stated that water containing 500 parts per million of clay and silt is unfit for drinking purposes on account of its irritating effects upon the gastro-intestinal tract; but beyond this probability, natural turbidity is of no special sanitary significance. Turbidity due to wastes may contain harmful substances.

Repeated attempts to correlate the formation of concretions such as urinary and biliary calculi with the inorganic salts in hard water have not been successful. Biliary calculi usually form about a colon bacillus or a typhoid bacillus or about some pathological particle as a nucleus. Urinary calculi probably have a similar pathogenesis. There is no known relation, therefore, between these concretions in the body and the inorganic salts in water, even those in a very hard water. Change from a soft to a hard water or vice versa may cause disturbance of bowel functions. Magnesium salts and sulphates in particular act as cathartics.

**Dental Fluorosis.** It has been conclusively demonstrated that the presence of fluoride in drinking water has profound effects on the structure and resistance to decay of the teeth. These effects are exerted in infancy and early childhood when the teeth are in process of formation, and there is no evidence that adult teeth are influenced. The effects are manifested in two ways: an excess of fluoride in the drinking water produces dental fluorosis, or in popular language, "mottled enamel," whereas a deficiency of fluoride has been recently demonstrated to increase the susceptibility of the teeth to caries.

Dental fluorosis was the first to be discovered (Smith, 1935). It usually takes the form of a modification of the tooth enamel to produce brown or yellow stains, or an unnatural opaque white appearance, or occasionally a blackening. The teeth are otherwise normal, but the stain is permanent. However, very large amounts occasionally produce disintegration in tooth structure. Dental fluorosis has been produced experimentally by the addition of sodium fluoride to the drinking water of white rats (Dean and others, 1934, 1935; Sebrell and others, 1935). It is endemic in several regions of the United States (Dean, 1933), and has been demonstrated to occur wherever the fluoride content of the water exceeds 1.5 parts per million as F. The incidence is directly related to the concentration of fluoride; for example, at Lubbock, Texas, where the concentration was 4 parts per million, about 97 per cent of the children were affected, whereas in certain Ohio towns where the concentration was 1.5 to 2.0 parts per million, the incidence was 20 to 30 per cent.

Surface waters are almost always low in fluorides; concentrations high enough to induce dental fluorosis occur only in deep wells in special aquifers. These aquifers are not of one geological type; for example, in Ohio and Florida, limestones are responsible, whereas in the Dakotas, Kansas, and Nebraska, a specific type of "Dakota" sandstone provides the fluoride. The fluoride-bearing aquifers are sufficiently widely, though irregularly, distributed to constitute a significant problem. It is estimated that over a million people are dependent on water supplies containing over 1.5 parts per million of fluoride.

Extensive research has revealed a number of possible methods of treating water to reduce the fluoride content of high fluoride water to tolerable levels, but these methods are complex and costly (Maier, 1947). The only one widely used at present is based on the fact that in softening hard waters, fluoride is removed along with magnesium in a direct relationship to the amount of magnesium taken out in the softening process. Empirically, the amount of fluoride removed is equal to  $0.7 F \sqrt{Mg}$ , where F represents the parts per million of fluoride initially present and Mg, the parts per million of magnesium taken out by the softening process. The water must be treated to a caustic alkalinity of 30 parts per million, and a pH value of 10.5; hence recarbonation is necessary. Few waters contain enough natural magnesium to effect the desired removal of fluoride, so that magnesium must be added prior to softening, in the form of dolomitic lime, magnesia, or epsom salt. The process is suitable for hard waters containing less than 4 parts per million fluoride (Scott and others, 1937).

For soft fluoride-bearing waters, a reversible exchange process, similar in nature to the zeolite process of water softening, but using granules of specially-processed calcium phosphate, has been proposed. The material takes up fluoride from the water, and is regenerated by a caustic soda solution, followed by a carbon dioxide solution. The process is effective, as demonstrated by a few plants in operation, but present costs appear to be high. Other ion-exchange processes have shown possibilities, but are as yet incompletely developed.

In the course of investigation of dental fluorosis, it became apparent that the prevalence of dental caries (tooth decay) was significantly less in areas where the water was high in fluoride than for the country at large. Further study demonstrated that, like fluorosis, the effect of fluoride in reducing susceptibility to caries

was apparent only in those who consumed the water during the period of tooth formation, and that the resistance to caries was probably carried over into later life. For example, Dean (1949) and Dean and others (1942) were able to demonstrate that 7,000 children using water containing 1.0 to 1.5 parts per million of natural fluoride showed an incidence of caries 50 to 65 per cent less than the national average.

The result of this discovery has been an increasing interest in the addition of soluble fluoride, usually in the form of sodium fluoride, to water supplies of low fluoride content. The desirable level of fluoride concentration is considered to be about 1.0 part per million; at this level, the danger of dental fluorosis appears to be negligible. Controlled studies on the effect of such additions are in progress, and in many communities fluoride addition has been adopted on an empirical basis. Such evidence as has been collected so far is highly favorable; reductions in caries of 50 to 60 per cent, as compared with neighboring towns used as controls, have been secured by fluoridation over test periods of five to seven years (Fluoridation as a Public Health Measure, 1954). The addition of fluoride in such small amounts is quite inexpensive; far less per person per year than the cost of a single filling. Since sodium fluoride is poisonous at high concentrations and can produce dental fluorosis at levels not far above that desired for caries prevention, it is obvious that careful control is imperative. The substitution of sodium fluosilicate ( $\text{Na}_2\text{SiF}_6$ ) for sodium fluoride offers some reduction in cost and a considerable reduction in toxicity; it may replace the sodium fluoride when studies on its effectiveness are complete.

**Infant Methemoglobinemia.** Nitrate had always been regarded as a harmless constituent of water until the observations of Comly (1945) led him to suspect it as the cause of certain cases of methemoglobinemia in infants fed on artificial formulae containing well water. Further investigation by others confirmed Comly's hypothesis; several cases were recorded where the condition of the infant cleared up on removal of the suspected water, only to reappear when its use was resumed. In all cases investigated, the condition was associated with the presence of a high concentration of nitrate nitrogen (20 p.p.m. or more) in the water. It was also produced experimentally by feeding to infants formulas containing water to which nitrates had been added.

The mechanism of the disease is believed to be as follows: in infants in whom the pH of the gastric juice is relatively high (over 4.9), nitrate-reducing bacteria grow in the intestine, producing nitrite, which is absorbed in the blood stream. The nitrite combines with the hemoglobin, rendering it incapable of absorbing oxygen, and thus producing cyanosis (Cornblath and Hartmann, 1948). If ingestion of nitrates is continued, death may result; the case fatality rate appears to be about 10 per cent. The condition is largely confined to infants of less than two months of age, and is unusual in infants over six months of age; it is unknown among adults except in cases of excessive ingestion of certain nitrogen-containing drugs and chemicals.

The dangerous level of nitrate concentration is believed to begin at about 20 parts per million as nitrogen, although in most of the cases recorded, the observed concentrations have been in excess of 50 parts per million (American Public Health Association, 1950). Variations in individual susceptibility, amount of water consumed in proportion to body weight, and method of preparation of formulae

make the exact establishment of safe limits somewhat difficult. Furthermore, the analyses may frequently not represent the actual nitrate concentration at the time onset of the disease. However, since only two or three incompletely authenticated cases out of several hundred investigated appear to be associated with less than 20 parts per million, it is probable that this represents a reasonably safe limit.

The disease has in all cases been related to private water supplies, principally in rural areas; no public supplies have been implicated. The waters involved are exclusively well waters, with shallow dug wells predominating. Inferior sanitary condition of the well is frequently, but not always, observed. A few deep drilled wells without sanitary defects have been found to contain high nitrates. No surface supplies containing dangerous amounts of nitrate have been found. The source of the large concentrations of nitrate nitrogen in wells appears to be mainly that leached from rich and well-fertilized soils, rather than nearby pollution. The nitrate nitrogen concentrations found in shallow ground waters in farm areas are surprisingly high; values up to 1,000 parts per million have been observed.

The geographical occurrence of cases of methemoglobinemia is peculiar. The cases are concentrated in the North Central United States and Canada. This distribution is as yet unexplained, since waters of high nitrate concentration are known to exist in other regions, from which cases have not so far been reported. It may be that differences in the character of the nitrate nitrogen exist in different regions, or that additional factors must be present in the water before the disease can be produced. On the other hand, the discrepancy in distribution may be due to regional differences in feeding habits or to inadequate reporting. In any case, it is evident that further investigation is required.

**Lead Poisoning.** Lead is practically never found in natural waters. The source of the lead in the water is lead service pipes, house-distribution pipes, or some other lead object used in collecting, storing or delivering the water. Lead is one of the most dangerous inorganic substances with which our drinking water may be contaminated. Lead poisoning from this source is not as common as it was formerly because of the use of corrosion-corrective measures applied to water and because of diminished use of lead pipes.

The various factors that determine the corrosive action of water upon lead are complex. It is not possible to determine in advance whether or not a water will have serious plumbosolvent action. All natural waters have some solvent power. The only sure method of determining to what degree a given water will have corrosive action on lead is by testing the question under practical conditions.

When fresh surfaces of lead are exposed to water, the solution pressure of metal causes it to dissolve, lead ions going into solution and hydrogen ions being precipitated on the metal surface. The action would cease when the water becomes saturated with lead were it not for the fact that the lead ions in solution unite with oxygen with carbon dioxide to form insoluble lead oxide, or carbonate or basic carbonate. Thus, lead ions are removed from solution and corrosion proceeds, although at a slower rate, for the deposited film of oxide or carbonate tends to protect the metallic surface. A proper pH value of the water suppresses the tendency of lead to go into solution by promoting film formation. This is between pH 7.0 and 9.5 according to Baylis. At Providence, Rhode Island, city water drawn through lead

pipes contained about 0.02 part of lead per million parts of water (a small amount) when the pH value was about 8.0; and no lead when the pH value was 9.0.

As a general rule, clean waters have a greater corrosive action upon lead than turbid waters. This is partly for the reason that the silt or organic compounds coat the pipes and protect them mechanically. Acid waters are almost sure to take up lead if allowed to come in contact with that metal. Even so feeble an acid as carbonic acid may under certain circumstances greatly increase the plumbosolvent action of water. Soda water (highly charged with carbon dioxide under pressure) takes up relatively large quantities, if lead pipes are used in soda water fountains or "syphon" bottles. Waters containing carbonates or sulphates are not apt to take up lead because the corresponding salts of lead are insoluble, and thus form a protective coating. Even though a water has no plumbosolvent action, the use of lead piping, lead cooking utensils, lead-lined cisterns, etc., is entirely unjustified for domestic service, for the reason that under certain circumstances electrolytic action, changes in the character of the water, or other causes may lead to lead poisoning.

**ILLUSTRATIVE INSTANCES.** Lead poisoning may occur when a comparatively small surface of lead is exposed to the solvent action of the water (Massachusetts State Board of Health, 1898). This is well illustrated in the following cases:

Case 1. A man about 50 years old contracted lead poisoning from using cistern water. Twelve feet of the distribution pipe were of lead, and almost wholly in the water, as the pipe was bent at right angles and ran across the cistern under the water.

Case 2. In this case the patient was poisoned by cistern water pumped through 10 feet of lead pipe. The symptoms were acute multiple peripheral neuritis, with extensive paralysis. After the lead in the water was removed, recovery was only partial after a period of two years.

**AMOUNT OF LEAD.** The exact amount of lead which may be taken into the system without producing harm is not definitely known. The amount that produces symptoms of poisoning varies with different persons and even in the same person at different times. The continuous use of water containing quantities of lead as small as 0.5 of a part per million has caused serious injury to health. The maximum allowable limit should be 0.1 mg. per liter; this is in accordance with the drinking water standards of the U. S. Public Health Service.

## SPECIFIC DISEASES DUE TO WATER

The principal diseases of man contracted by drinking infected water are typhoid fever, cholera, and bacillary and amebic dysentery. Others, such as schistosomiasis and infectious hepatitis, although less well known, do exist. Water-borne epidemics of these diseases have frequently occurred in the history of the world. It should be remembered that endemic and sporadic cases may also contract their infection through water. The great water-borne tragedies for a time occupied an exaggerated position. They overshadowed the less dramatic, but more insidious, and probably more frequent transmission of infection through other channels. A quantitative estimate of the amount of these diseases spread by means other than water has been realized only in recent years, and since these infections have been eliminated from

water supplies of most large communities, epidemics of typhoid, cholera, and dysentery usually occur independent of water-borne infections.

The general improvement in our water supplies should not lull us into a false sense of security. Eternal vigilance over methods of control for water supplies and water purification must ever be practiced. Laxity invites disaster. A report by Holman and Gorman for the period 1920 to 1936 lists 470 epidemics of water-borne disease in the United States and Canada, of which 33 were in cities of over 10,000 population. For the period 1938-1945 a total of 327 outbreaks of water-borne disease was recorded. Of these, 100 were in public water supplies, three of them in comparatively large cities. It is evident that outbreaks of enteric disease traceable to water are possible, even in larger communities, unless stringent control measures are constantly practiced.

It is worthy of note that almost all the large water-borne outbreaks that have been investigated have been traced to a quick transfer of the infected material from the patient to the victim. In Pittsburgh, the Typhoid Fever Commission showed that most of the fever there had been due to nearby rather than to remote pollution of the river. The greater the distance and the longer the time between the source of the infection and the use of the water, the less are the chances of harm because of nature's purifying agencies.

Typhoid, cholera, and dysentery bacilli are not known to multiply in water under natural conditions. Almost all the great water-borne epidemics of typhoid fever have occurred in the spring, winter, or fall of the year, when the water is cold. Water-borne epidemics of typhoid in the summertime, when the conditions would seem to be favorable for multiplication of the bacilli, are relatively infrequent. The dilution must have been enormous in many of the cases recorded; that is, there must have been very few typhoid bacilli in a tumblerful of water. This illustrates how very few bacteria, when fresh and virulent, may induce disease.

Many large epidemics have been traced to individual instances of pollution. The typhoid epidemics at Butler, Plymouth, New Haven, Nanticoke and Reading, involving 3,929 cases with 361 deaths, were each caused by the careless treatment of the discharges of one individual patient.

The great water-borne epidemics of disease have always been caused by polluted river or lake waters, and not by ground waters. Ground water, however, has been responsible for a larger number of small outbreaks of typhoid fever, especially in limestone districts, as at Lausen, Switzerland; Paris, France, etc. Usually, when well becomes badly infected it is from a nearby privy or sewer, as in the instance of the Broad Street cholera epidemic in London, and the epidemic of typhoid fever at Santa Ana, California.

Public water supplies become contaminated in various ways. The use of a raw water into which is continually discharged the sewage of other towns has occurred at Pittsburgh, Lawrence, Niagara Falls, Albany and Philadelphia. A city may drink the water of a lake which has become its own cesspool, as once did Chicago, Cleveland and Burlington. The pollution may come from the wastes of individual houses, as at Plymouth, or from institutions or factories; or the pollution may come from privies situated directly over the stream or on its banks, as at Ithaca; or the pollution may come indirectly after the offending matter has been deposited on the surface of the ground, later gaining access to the water course by the washing

of rain or seepage through ground seams. In some instances epidemics originate through carelessness in a town that has been supplied with a pure or purified water. Thus a water pipe laid through a polluted pond or stream may become sufficiently disjointed to permit admission of the infected water, as occurred at Baraboo, Wisconsin; Palmerton, Pennsylvania; and Olean, New York. There is a record of numerous epidemics due to mixing in cities having dual water supplies. Epidemics have originated as a result of the unusual drain upon the water supply at times of fire, as in the case of Lawrence; or through failure of valves to operate, as in the case of Wilkesburg, Pennsylvania; when the ordinary water supply was judged to be insufficient and no public warning was given of the substitution as at Newburyport; when a valve in a forgotten cross connection was unintentionally opened, as at Rochester, New York; or when polluted water was furnished temporarily while the filter plant was undergoing repair, as at Lawrence, Massachusetts, in 1902; in Brewer and Poughkeepsie, New York; and in Millinocket, Maine. Various public wells have become infected through ground seams, and have thus caused epidemics of typhoid fever at Trenton, Newport, and Mt. Savage, Maryland. In recent years outbreaks have resulted from the failure of chlorination plants, or other processes used to purify a polluted supply.

In addition to the usual sources of pollution of a surface water, the following, while relatively infrequent, may be particularly dangerous, for the reason that they are apt to take place near the source of supply: discharges from water-closets of railroad trains while crossing bridges or passing the banks of reservoirs and streams; picnic parties; camping parties; construction gangs; fishermen; ferryboats and other craft upon navigable streams. Boats plying lakes may discharge dangerous and obnoxious material very near an intake.

Illustrative water-borne outbreaks are given in Chapter 3, pages 190-197.

**Diarrhea.** Polluted waters not infrequently cause diarrhea, sometimes as widespread epidemics, sometimes as small outbreaks or sporadic cases. Whenever there is a water-borne outbreak of typhoid fever or cholera there are also large numbers of cases of diarrhea and gastro-intestinal disturbances in which the precise etiological factor has not been discovered. Some of these cases may be mild instances of the major disease. Infantile diarrheas are especially prevalent at such times and are very likely due to the contaminated water. Thus, Reincke states that infantile diarrhea was greatly lessened after the improvement in the water supply at Hamburg. The same phenomenon was noted by Hiram O. Mills after the filtration of the water supply of Lawrence, Massachusetts. Sedgwick noted an excessive prevalence of both typhoid fever and diarrhea in Burlington and attributed the diarrhea to the sewage contamination of the water supply. Whipple states that in Albany there was a reduction of 57 per cent in the mortality from diarrheal diseases after the introduction of filtration in 1898. Chapin questions whether such statistical evidence is sufficient to incriminate water as an influence to the causation of diarrheal diseases.

Numerous outbreaks of diarrhea have been attributed to the following microorganisms in water, viz.: *Escherichia coli*, *Salmonella enteritidis* (Gartner), *Pseudomonas aeruginosa*, proteus bacilli, *Clostridium welchii*, *Bacillus mesentericus*, and streptococci. Water containing these and other organisms is not infrequently regarded as the cause of outbreaks of gastro-intestinal irritation. The symptoms vary

ately in intensity, but usually the disease is not fatal except in the young and ble. The relation between the diarrhea and the water is usually based upon the t that the same species of micro-organisms are found both in the water and the stools. Corroborative evidence, such as the finding of specific agglutinins and other antibodies in the blood, lends countenance to the claim that the particular micro-organism is, in fact, the cause of the complaint. The evidence is suggestive but not conclusive.

## THE SANITATION OF SWIMMING POOLS

Although there is little or no positive epidemiological evidence of the transmission of disease from person to person in swimming pools and bathing places, there is a strong suspicion on the part of medical and public health authorities that such transmission does occur. Careful attention to the sanitary condition of public pools and bathing places is, therefore, an essential part of a public health program. The American Public Health Association issues periodic reports on recommended practice for the design and operation of such establishments.

The diseases which are considered to be potential hazards in swimming pools are: inflammatory infections of the upper respiratory tract and conjunctiva; injury and inflammation of the ears; skin diseases; and intestinal infections. Typhoid fever and diarrheal conditions have been traced on inferential evidence to swimming pools. One of the most common infections incurred in bathing establishments is ringworm of the feet, or epidermophytosis, commonly called "athlete's foot." It is not contracted from the pool water, but rather by contact with floors and walks of locker rooms and pool if they are not kept clean and well drained. Towels and swimming suits may be another source of this infection.

The chief danger of infection comes from the water, if not kept clean, or from the towels and swimming suits, if not disinfected. The source of the infection comes in almost all instances from the persons using the pool. Stringent regulations should be in force to prevent use of the pool by persons suffering with skin diseases, swimming ears, ulcers, conjunctivitis, venereal disease, or signs of inflammation of the upper respiratory tract. Full showers, with soap, under inspection, should be demanded of all bathers *before* entering the pool. Especial attention should be given to the perineal region. When water strikes a person's body, the natural tendency is to urinate. For this reason ample toilet facilities should be provided, and they should be so located that exit from them is through the showers and not directly to the pool.

Bathers should be instructed in pool sanitation. Nude bathing should be encouraged, because it favors inspection and does away with the danger of contracting infection from the swimming suit.

The water should have an initial purity equal to that of a safe drinking water and should be kept clean by filtration and safe by disinfection. The best present-day practice for keeping the water of swimming pools in a satisfactory sanitary condition makes use of a combination of treatment, including suction cleaners to remove coarse material that has settled out, such as hair, lint and fibers; refiltration with the continuous or intermittent use of alum to remove finely divided suspended

matter; and, finally, disinfection of pool water with chlorine to destroy pathogenic and other forms of bacteria.

Other germicides have been used for disinfection, notably ozone and ultra-violet light. Their use is not recommended, chiefly because they provide no residual disinfectant in the water to take care of fresh, incoming pollution. The bathers are constantly contributing a bacterial load to the water and the transfer of bacteria from one bather to another may occur in a short period of time. Hence, it is necessary to maintain a residual of disinfectant in the water. The recommendations of the American Public Health Association call for a residual chlorine of 0.4 to 0.6 part per million if chlorine alone is used, or 0.7 to 1.0 part per million if chlorine-ammonia disinfection is employed. Too much chlorine is unpleasant and irritates the eyes and nose. The use of chlorine-ammonia disinfection minimizes the irritation, but the disinfecting action is slower, and, therefore, a higher residual must be carried.

It is important to maintain a proper pH value in the water. Acid conditions irritate delicate mucous surfaces. Recirculation with addition of alum and of chlorine results in a lowered pH value. Experience indicates that a pH of 7.0 to 7.6 causes no complaints on this score. To maintain this value or a higher one, it is necessary in many cases to add soda ash.

In open pools algae sometimes cause troublesome growth in the water or on the bottom and sidewalls. An occasional use of copper sulphate combats these growths.

The disinfection and filtration of the water in the pool is economical, in that it is not necessary to change the water as often as without treatment. Decency and safety require frequent additions of fresh water. If clarification and disinfection are properly conducted, the demands of decency and safety will be met by the daily addition of fresh water in a volume equal to at least 10 per cent of that of the pool. Wherever possible, fresh water should be added continuously.

The examination of swimming-pool water for coliform bacilli has long been the usual method of control. If present, they represent, in most cases, contamination from bathers and indicate potential infection with pathogenic intestinal bacteria. They are not, however, associated with the germs of the eye, ear and respiratory infections, which are more often attributed to swimming-pool contacts. There is need of a better index of pool contamination. In recent years some work has been done on the isolation of streptococcus forms from swimming-pool waters, but the standards recommended by the Joint Committee on Bathing Places of the American Public Health Association and Conference of State Sanitary Engineers (1949) are still based on a 37° C plate count of less than 200 per ml., and the absence of coliform organisms in 50 ml. of water. Attention is called to the value of tests for streptococci, but no standards are recommended.

In localities where blood flukes, *Schistosoma*, occur, special precautions are necessary with respect to bathing places. According to Leiper, the cercariae, which produce the infection by penetrating through the skin, are unable to live in water more than 36 hours after their escape from the snails which act as intermediate hosts. Consequently, he recommends that water before it is used be stored for not less than 36 hours, better 48 hours, in reservoirs that are protected from inva-

n by snails. Copper sulphate and copper carbonate have also been used successfully to eliminate snails.

The sanitation of swimming pools requires good design and construction and efficient management. An average of 27 square feet of pool area should be provided for each swimmer who may be expected to be present at the time of maximum load. The pool should have a smooth lining. When empty, the tank should be scrubbed, flushed and dried. The cleanliness of the tank is aided by the construction of troughs at the edges to afford place for expectoration and to prevent sputum from the floor draining into the pool. Sediment on the bottom should be removed with suction pumps. The filtering should be continuous and the filter of sufficient capacity to refilter all the water in the tank in 8 to 12 hours. It is essential that the water be clear, not only for esthetic reasons, but also in order to reduce the hazard of drowning.

Control of foot diseases incited by fungus infection has become an important function of swimming-pool operators. At some pools the spread of such diseases has been held in check by the practice of maintaining scrupulous cleanliness and good drainage of dressing room floors and pool walks, together with the proper cleaning and disinfection of towels and the exclusion of bathers suffering from these infections. At other pools the following preventive measures have found application:

1. Daily washing of floors, benches and stools with a sodium hypochlorite solution containing 0.3 to 0.6 per cent available chlorine, or with a calcium hypochlorite solution of the same strength.
2. Placing of foot baths between the locker room and showers, the baths containing 0.3 to 0.6 per cent available chlorine or 10 to 15 per cent of sodium thiosulphate. Sodium thiosulphate reduces the available chlorine in the pool, and, therefore, a thiosulphate foot bath should be used only by bathers leaving the pool. Many authorities now doubt the value of foot baths for the prevention of fungus infections, and they are often omitted in modern pools.

Satisfactory hygienic conditions in and around swimming pools require suitable administration of the plant, including the supervision of the working force, the inspection and ablution of the bathers before they enter the water, and their instruction in pool sanitation. Finally, sterilization of the towels and bathing suits by boiling or steaming after each use will avoid one of the means of conveying infection.

## DRINKING FOUNTAINS

The movement toward the abolition of the common drinking cup has led to the development of so-called drinking fountains, of which there are many types on the market. They may be divided into intermittent and continuous, and each in turn into those with and without suitable mouthguards.

The water should not pass through a cup sure to become contaminated. Experiments show that it takes a long time for bacteria to be eliminated from these cups. The design should be such that the user cannot touch the ball with the lips, and that waste water cannot remain to endanger the next user of the fountain. The Committee on Sanitary Drinking Fountains of the American Water Works Association (1918) recommended that: (1) mouthguards are a necessity; (2) the intermittent vertical jet fountain is unqualifiedly condemned; (3) continuous vertical

jet fountains are open to suspicion; and (4) a slanting jet protected with a mouth-guard is perfectly safe.

### ICE

Since many potentially water-borne pathogens are not killed by freezing, ice is a possible vehicle for the transmission of water-borne disease. Although few well-authenticated instances of such transmission can be found, the extensive use of iced drinks in this country requires that attention be given to the sanitary quality of ice.

Sedgwick and Winslow (1902) made quantitative studies on the effect of freezing upon cultures of the typhoid bacillus and showed that 50 per cent of the organisms die at the end of the first week, 90 per cent at the end of the second week, and practically all at the end of 12 weeks. They considered that in nature the destruction might exceed rather than fall short of these figures, for the experiments were made in a test tube where all the bacteria are incorporated in the ice, while in nature many are extruded during the process of freezing.

As water crystallizes it extrudes suspended matter and even dissolved substances. The extent to which water thus purifies itself depends, however, upon conditions, for under certain circumstances the impurities may become entangled or even concentrated during the process of freezing.

Both natural ice and manufactured ice present sanitary hazards.

**Natural Ice.** Natural ice should be harvested from water of good sanitary quality and handled in a cleanly manner. It is not unreasonable to demand that the water from which the ice is harvested meet the U. S. Public Health Service drinking water standards. Under natural conditions the surface layer of ice contains most of the impurities and the lower layers are relatively purer, for the reason that ice grows from above downward and extrudes both suspended and dissolved matters; the surface also receives additional contamination from the dust, snow, flooding, and other sources. It is, therefore, good practice to plane the surface of snow ice.

The fact that natural ice is usually purer than the water from which it is taken is shown by the analyses in Table 40-1 which give the chemical and bacterial composition of natural ice and the water from which it was frozen. Only the minimum and maximum values for each set of samples are given. In this case the water was a sewage-polluted stream.

The reduction in the number of bacteria is noteworthy. It is unwise, however, to rely on this natural purification to produce safe ice from polluted water. Another source of contamination lies in improper handling of the ice after harvesting.

**Manufactured Ice.** Manufactured ice is made by the ammonia process. The condensed ammonia in expanding requires heat which it takes from surrounding objects and in this way the water is frozen. The freezing takes place in rectangular cans, the water freezes from the sides of the can toward the center, and the impurities are extruded and concentrated in the core, which is often visible in a cake of can ice. In well-equipped plants this visible core of concentrated impurities is removed by suction apparatus before it freezes, and clean water is substituted. During the freezing process, air is bubbled through the water, in order to facilitate the collection of the impurities in the core, and thus to produce a clear cake.

Table 40-1. Chemical and bacterial composition of natural ice and the water from which it was frozen

	Ice 3 to 6 Inches Thick		Water	
Number of samples	6		6	
Free ammonia	.008	— .034	.046	— .084
Ureminoid ammonia	.156	— .214	.146	— .276
Strates	.05	— .20	.35	— .48
Chloride	2.0	— 3.0	4.5	— 6.0
Hardness	11.0	— 28.5	57.0	— 61.5
Bacteria per ml.	30	— 210	5,200	— 13,000
Coliform group present in	10 ml.	— 10 ml.	1.0 ml.	— 0.1 ml.
Number of samples	7		4	
Free ammonia	.016	— .136	.006	— .038
Ureminoid ammonia	.230	— .726	.116	— .166
Strates	.0	— .050	.260	— .400
Chloride	.8	— 3.5	5.5	—
Hardness	18.0	— 34.0	58.5	— 62.0
Bacteria per ml.	2	— 60	2,500	— 3,900
Coliform group present in	absent		1.0 ml.	— 0.1 ml.

The chemical figures in this table are in parts per million.

Manufactured ice is usually made from water of good sanitary quality, since good ice cannot be produced from contaminated water. The water is often distilled before use. Manufactured ice made from water of good quality is completely safe properly handled and stored after freezing. However, it may become contaminated if the workers are careless. In one case, six specimens of ice made from water containing 64 bacteria per ml. and no coliform organisms gave the results shown in Table 40-2.

Table 40-2. Analysis of six specimens of ice made from water containing bacteria

Number of Sample	Manufacturer	Organisms per ml. (Plate Count)	Coliform Organisms
24	C. P. Co.	455	Absent
29	C. P. Co.	5,000	In 1 ml.
26	G. Ice Co.	230	In 10 ml.
27	G. Ice Co.	650	Absent
32	G. S. Co.	470	Absent
34	P. Ice Co.	8	In 1 ml.

Contamination may be transferred from the shoes of the workers to floors, tanks and cans; it may also come from handling of the cakes, from contaminated crushing machines and from numerous other sources.

The widespread use of ice in iced drinks and in contact with foods makes it necessary to demand that ice be handled under the same conditions of cleanliness that are expected in the handling of other foods.

**Ice and Disease.** A search of the literature discloses but few instances of disease attributable to impurities in ice. While the experimental evidence indicates that there is a quantitative reduction of the number of bacteria in freezing, and that the imprisoned bacteria gradually die, nevertheless, experience has shown that low

temperatures alone cannot be depended upon to remove the danger of typhoid infection. In only a few isolated instances, however, has ice itself been accused of being the vehicle by which the infection of typhoid fever has been spread.

Hutchings and Wheeler (1903) report an epidemic of typhoid fever in the St. Lawrence State Hospital, three miles below Ogdensburg, New York, which seems to have been due to impure ice. The disease was endemic in the hospital for 10 years, increasing from two cases with the opening of the hospital in 1890 to 40 cases in 1900. Although the water supply, tested bacteriologically and chemically, gave negative results, all observers agreed that the disease was water-borne. In December, 1900, the source of the water supply was changed to the Oswegatchie River, a small Adirondack stream supplying Ogdensburg. This practically put a stop to the disease, for there were no cases of typhoid that were not clearly contracted elsewhere until October, 1902.

Following this eight persons were attacked, seven of whom were employees in the dining room. It seems the milk "could not have been infected." The water was excluded and other sources studied, with negative results. The ice fell under suspicion. It had recently been taken from a newly opened ice-house. The ice had been harvested from the St. Lawrence River at about the same spot as the ice previously used. It was gathered in February and consequently had been stored for seven months. This ice yielded a count of 30,400 bacteria per ml. on agar plates and 50,400 on gelatin. Of eight fermentation tubes three showed the presence of coliform bacilli.

The stock of ice was then examined. In the center of certain cakes were found foreign substances in the form of black or dark brown granular matter. Examined under the microscope, this matter was found to be teeming with bacteria, from which both coliform and typhoid bacilli were isolated in pure culture.

With the discontinuance of the use of this infected ice the epidemic gradually subsided. There were in all 39 cases. The evidence of this outbreak was studied by Hill, who doubted the relation of the ice. The disease resembled a carrier outbreak.

Despite the rarity of specific, well-established outbreaks due to contaminated ice, there is little doubt that impure or improperly handled ice may be responsible for many individual cases of illness. The decline in the use of natural ice, and the improvement in the quality of water supplies from which manufactured ice is made, have reduced the chance of direct contamination of ice. The dispensing of crushed ice for iced drinks still leaves much to be desired. Studies made in the dining halls of Harvard University have shown that unless great care is used in dispensing, the crushed ice will show the presence of coliform organisms, presumably from the hands of dispensing employees. It is necessary to emphasize the fact that ice is a food, and should be handled as such.

## SEWAGE

GORDON M. FAIR, M.S., DR.ING.

The water-carried discharges of the human body together with the liquid wastes from household and factory are called sewage. The discharges themselves consist chiefly of feces and urine, but they include also washings and secretions from the skin, mouth, and nose. Savage tribes and nomadic races may move away from their excreta, but civilization requires that the wastes of the human body be removed from habitations promptly and safely, and that they be disposed of in like manner. In rural communities excreta are generally cared for in privies; in urban communities they are usually removed by means of the water-carriage system of sewerage.

Three types of considerations govern the disposal of human excreta: hygienic, esthetic, and economic. *Hygienic* considerations are concerned chiefly with the fate of pathogenic organisms that may be contained in human wastes. The microorganisms of typhoid fever, cholera, the dysenteries, hookworm, and other intestinal worm diseases, as well as infectious hepatitis and certain other intestinal viruses, have their ultimate source in the alvine discharges of man and are conveyed from host to host through many channels: by water, food, soil, or contact; sometimes by human agencies, sometimes by animals, often by flies. Since the wastes from household and industry must be disposed of ultimately on the land or in water, the safe disposal of human excreta requires that the methods chosen shall eliminate or at least minimize dangers to the following:

1. Private and public water supplies obtained from surface or underground sources.
2. Natural ice supplies taken from lakes or ponds.
3. Shellfish layings and other useful aquatic life.
4. Bathing beaches on fresh or salt water.
5. The soil.
6. Food substances that are to be consumed raw.
7. The water supply of domestic animals.

Some consideration must be given also to the prevention of nuisances that affect the public health and comfort. Decomposing sewage matters may release objectionable odors and noxious gases, and recreational facilities may be impaired by improper disposal of human wastes.

The *esthetic* considerations of sewage disposal deal with the destruction of the

organic matter contained in excreta and the avoidance of offensive conditions. They demand that excreta be cared for in such manner that they will become neither unsightly nor objectionable to the sense of smell. They are also concerned with providing privacy during urination and defecation.

The *economic* considerations are concerned chiefly with the price that must be paid to secure the requirements of hygiene and esthetics, and with the possible damage to industrial water supplies, livestock, fish and other useful aquatic life, riparian properties, river and harbor improvements, and navigation. In western countries they do not deal as much as in the East with the utilization of excreta for fertilizing purposes.

## THE RURAL PROBLEM OF SEWAGE DISPOSAL

One of the most difficult problems of modern sanitation is to provide proper disposal of fecal matter for rural communities, summer hotels, temporary camps of laborers, summer colonies at beach and mountain, and individual houses in villages and on the farm. It is difficult because the necessary structures, although small and simple, are often thoughtlessly constructed; because adequate care of the processes is more or less disagreeable and therefore neglected; because the inherent dangers are not understood or appreciated; because the economic status of many rural sections is so low that the construction of satisfactory privies is often too great a financial burden; and, finally, because collective sanitation is more difficult of administration in areas of scattered dwellings than in urban communities.

**Privies.** There are still large areas of the United States in which no attempt is made at the sanitary disposal of human excreta. A clump of bushes or trees satisfies the urge for privacy during defecation, and excreta are scattered on the surface of the ground in disregard of the Mosaic law of burial (Deuteronomy 23:12, 13).

A first step towards sanitation is found in the *latrine* or straddle trench often used in temporary camps. This consists of a relatively shallow trench which the user straddles. A layer of earth is placed daily upon the fecal matter, and the trench is back-filled when camp is broken. Seating facilities are sometimes provided by a supporting pole or rough box seat. This type of trench has its corollary in rural life in the so-called "umbrella type" of privy, consisting of a box placed over a hole in the ground. It is not a privy in the true sense of the word, since it affords no privacy to its user, neither does it protect him against the elements.

**SURFACE PRIVIES.** The surface privy (Fig. 41-1) provides privacy but little else. The excreta accumulate on top of the ground, the liquids leach away or evaporate. Many surface privies are flimsy, malodorous structures with inadequate foundation, with cracks between boards, without screening, with ill-fitting doors, and open at the back so that flies and animals have access to the excreta or so that the privy contents are scattered upon the ground. Such privies are an abomination.

**PIT PRIVIES.** Of proved sanitary value are privies in which the excreta fall into pits in the ground. The pits may be shallow or deep and built so that their contents leach away, or they may consist of tight vaults. The use of pits prevents pollution of the soil, tends to reduce the fly menace, and keeps odors down. Flies shun dark places. The deeper the pit the fewer the flies, especially if the contents are

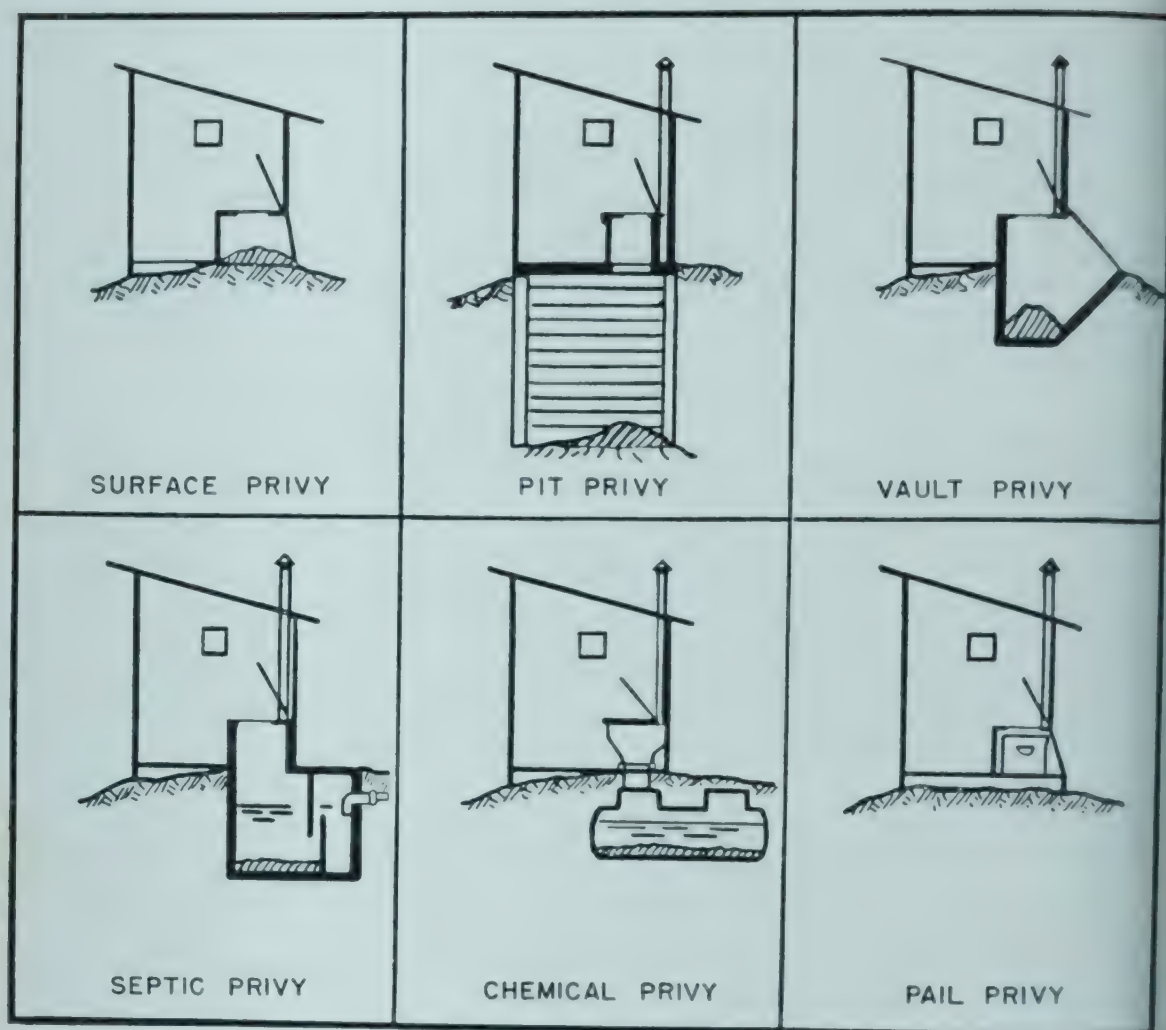

Fig. 41-1. Types of privies.

covered with sand, soil, sawdust or some other absorbent material. If the pit is well constructed and covered by a concrete slab to which a riser of cast iron or concrete is firmly attached and if the seat is made self-closing, little attention need be given to the tightness and screening of the superstructure. Such a pit becomes an independent sanitary unit. The superstructure merely provides privacy and protection. A ventilator rising through the privy roof or terminating in a screened opening near the top of the seat reduces odor and keeps moisture from condensing on the bottom of the privy seat.

Deep pits are a greater menace to neighboring wells than shallow pits, because they are nearer the ground-water table. Such pits become objectionable in places where the soil water rises into them.

No arbitrary rules as to the minimum distance of a privy from a well can be laid down, as everything depends upon the character of the soil, the slope of the ground, the elevation of the natural ground water, and the draught of water from the well. A distance of at least 25 feet is indicated in sandy soil and preferably 50 feet or more. In clay soils that dry and crack and in limestone regions that contain crevices in the rock, leaching privies should not be used. Wells may then be polluted a mile or more away. The pollution of ground water is prevented by

water-tight privy vaults made of brick or concrete. Frequent cleaning is then necessary. For use in rural schools, in particular, vault privies are often constructed with two or more receiving compartments and seats. After one vault has been in service for a time the seat above it is battened down and another vault is called into service. This gives the organic matter in the unused vault time to decompose and thereby reduces the disagreeableness of vault cleaning.

**BORED-HOLE PRIVIES.** In the Orient the bored-hole privy or latrine is favored by health officials. As shown in Figure 41-2, the most important feature of this latrine is a bored hole 10 to 24 inches in diameter sunk to a depth of 12 to 26 feet and preferably penetrating the ground-water table. In silting soil the sides are revetted by a cylinder of bamboo, wire netting, or sheet metal. Since the squatting method of defecation prevails in the Orient, the superstructure commonly consists of a floor slab often provided with foot rests adjacent to a more or less rectangular hole through which the excreta fall into the latrine. A water trap may be installed where the ground-water table rises within a few feet of the ground surface and furnishes a breeding place for insects or renders the privy malodorous. A privy house or more primitive shelter completes the bored-hole latrine. The danger of contaminating ground-water supplies must be clearly recognized.

After Yeager.

Fig. 41-2. Bored hole latrine.

**SEPTIC TANK PRIVIES.** These are said to have originated in India where they have been used from time immemorial. The excreta fall into water, where saprophytes, principally bacteria, decompose much of the organic matter, part of it being liquefied or gasified. The tanks are water-tight, but an outlet pipe into the ground is usually provided near the top of the last compartment. Through this pipe the overflowing liquid passes into the soil. Overflow, together with decomposition and evaporation, prevents the accumulation of water. In some climates, it may be necessary to add water periodically. In warm climates, tank privies are decidedly superior to the older methods, but they are relatively expensive and are not well adapted to the severe weather of the North. The so-called Kentucky privy is made of concrete, but large tile pipe can also be used to create a water-tight chamber.

**CHEMICAL TANKS.** These are water-tight compartments, usually made of sheet metal, filled with water in which caustic soda or a similar chemical is dissolved. The organic matter is decomposed chemically instead of biologically, and microorganisms are largely destroyed. The method is safe but relatively expensive. The chemical has to be renewed at intervals and its cost is likely to induce householders to use too little. The process then breaks down. Means must be provided for disposal of the spent liquor.

**PAIL PRIVIES.** In villages and even in some large-sized communities the so-called pail system, or scavenger system, is sometimes used. Pails placed beneath the privy seat are removed and emptied at intervals by a collector. Earth, ashes, sawdust, or some other absorptive material are put into the pails to suppress odors. The system is often a failure, due to neglect, the difficulties of final disposal, and the cost of maintenance and upkeep. Unless well supervised, such a system, starting off satisfactorily, is likely to degenerate until, after a few years, conditions become dangerous.

**DROP PRIVIES.** Privies have sometimes been built to overhang brooks or rivers. The fecal matter drops into the water and is carried away by the stream. Although this is an approach to the water-carriage system for removing human wastes, such practice cannot be used indiscriminately. Typhoid fever epidemics have been traced to drop privies situated on tributaries of streams used for municipal water supplies. Most states, therefore, do not countenance the building of these structures.

**Disposal of Privy Contents.** No matter what type of privy is employed, it becomes necessary sooner or later to remove part or all of the contents of the receiving chamber. This is especially true of pail privies. Here the pails must be removed at frequent intervals, usually once a week. Vault privies require less frequent cleaning, particularly when the liquid wastes are permitted to leach away through the ground. A semi-annual removal of the accumulated solids usually suffices. Pit privies are sometimes cleaned but, more commonly, the superstructure is moved over a new pit when the old one is nearly full. The old pit is then covered with earth. Septic tank privies are pumped out only at rare intervals, because much of the solid material gasifies or liquefies, the liquid passing into the ground through the overflow which may attach to subsurface tile drains. Chemical tanks, too, are only rarely emptied. A cesspool is sometimes provided to receive the tank contents which are emptied into it from time to time. The chemical tank is then refilled with caustic solution.

Apart from the use of night soil, or privy contents, for fertilizing the fields, other methods for their ultimate disposal are: burial and composting, incineration, and disposal in streams or sewerage systems.

**FERTILIZING.** Human excreta, like animal manure, contain materials of fertilizing value. Urine is particularly rich in nitrogen and phosphoric acid. In primitive civilizations human excreta are commonly used to fertilize fields upon which agricultural products are raised. From the hygienic standpoint this practice is to be condemned. Storms may wash the fecal matter into streams, the soil may become polluted, vegetables that are to be consumed raw may become contaminated, and flies may swarm from the fields to human habitations. The fresher the excreta the greater the danger. When the excreta are well rotted and plowed under and when they are not used for crops that are to be consumed raw in the immediate future, the sanitary hazard is reduced.

**BURIAL.** A safer method of excreta disposal is to bury it in trenches or pits, a layer of earth sufficient in depth to prevent escape of hookworm larvae and access of flies or other animals being placed over the material. Sometimes the pits or trenches are oiled, sometimes they are filled with straw or other combustible material which is burned and forms a carbonized crust upon the surface of the wastes.

reduction of the organic matter is slow, and relatively large disposal areas are required. The excreta can conveniently be mixed with other organic refuse, such as garbage, and composted. Pasteurizing temperatures are then reached as in the "sanitary fill" method of refuse disposal (see Chapter 42).

**INCINERATION.** In some of the larger unsewered communities, excreta, more particularly those collected from pail privies, are destroyed by incineration, the liquids being evaporated, the solids passing into the combustion chamber of the incinerator. Small incinerators have been used for this purpose in army cantonments and construction camps. They afford an opportunity for the simultaneous destruction of garbage and rubbish.

**DISPOSAL IN STREAMS AND SEWERAGE SYSTEMS.** Communities situated near large rivers that do not serve as water supplies for nearby towns may dispose of the collected excreta in central disposal stations in which a jet of water washes the pail contents into a sewer discharging into the river. In communities that contain sewered as well as unsewered areas, the contents of pail privies in the unsewered districts are usually emptied into one of the trunk sewers of the city.

**Disposal of Water-Closet Wastes.** More and more people who live on farms or in small villages are introducing running water into their houses. The electrical distribution of power, gasoline engines, water rams, windmills, and other sources of power have made this possible. Farm plumbing is rapidly increasing and the indoor water-closet is being substituted for the outdoor privy. Whereas this is a sanitary advance, it brings with it new problems that must be solved if healthful conditions are to prevail. Water-closets and other plumbing fixtures greatly increase water consumption, and new means must be provided for getting rid of the increased volumes of waste water. This usually entails the construction of a cesspool, a septic tank, or some other small sewage disposal unit.

**CESSPOOLS.** A cesspool is a pit into which waste water flows. If the pit has impermeable sides or a permeable bottom, it is called a *leaching cesspool*; if water-tight, it is called a *tight cesspool*. Cesspools are generally covered (see Fig. 41-3). Usually the sewage remains in them for a considerable time so that the bacteria and other micro-organisms have ample opportunity to utilize the organic matter for energy and growth. The saprophytes ordinarily found in water require oxygen for their life processes, and fresh sewage from a house usually contains some of it in solution. On reaching a cesspool the saprophytes multiply to enormous numbers and quickly exhaust the available oxygen. The liquid then becomes "anaerobic" or septic. Some micro-organisms can, under these conditions, get the oxygen they need from the organic matter—that is, from the feces and urine, and even from the cellulose of paper. In doing so, they break down the organic matter, and some of the solids are changed to liquids or gases. This *process of digestion* reduces the accumulation of solids in cesspools and prevents the necessity of frequent cleaning.

Cesspools often receive not only fecal matter but also other domestic wastes. When the soil is sandy there is no objection to the use of leaching cesspools; in fact, this method is like that of subsurface irrigation described later in this section, except that the sewage is discharged into the soil below the depth where bacteria are most effectively at work. This may be an important difference, however, as the modification of the dissolved organic matter proceeds by a slower process. Leaching

From N. Y. State Dept. of Health Bulletin 26.

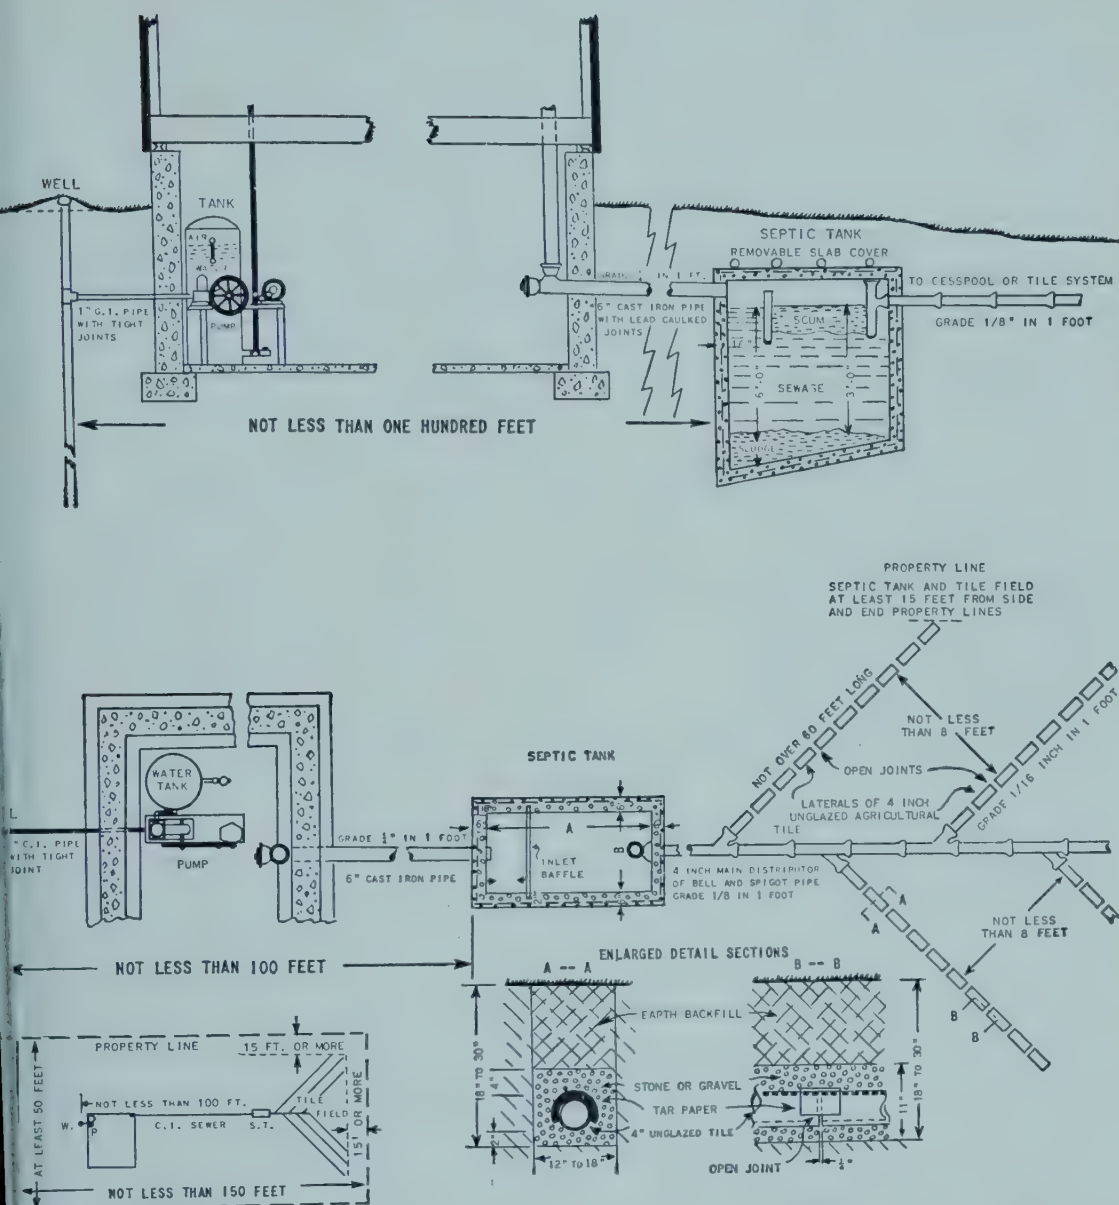

Fig. 41-3. Typical leaching cesspool construction.

cesspools should not be placed near wells used for drinking-water supplies. In sandy soils the danger of bacterial contamination is small if sufficient distance intervenes but, even so, the idea of seepage of sewage into a well is repugnant, and the water may often be tainted by disagreeable odors, even though analyses may show that it is bacterially safe.

Ordinarily, leaching cesspools should not be used in clay soils or in limestone. If they are to be constructed in such formations, they should be made water-tight. They then approximate septic tanks, the effluent being taken care of by subsurface irrigation or some form of land treatment.

**SEPTIC TANKS.** Septic tanks differ from cesspools in having water-tight sides and bottoms, in having a definite outlet as well as an inlet, in having a more or less constant flow of liquid through the tank, and in being advantageously subdivided into compartments. When subdivided, the last compartment commonly serves as a dosing chamber for the irrigation plant or filter. The biological action is the same as in a cesspool. There is liquefaction and gasification of a part of the organic matter, a small amount of more or less stable sludge gradually accumulating at the bottom, a considerable amount of scum being lifted to the top by the entrained gases. The surface scum dries, and its decomposition is retarded.

As for cesspools, the water from septic tanks has to go somewhere. It may be distributed underground by a system of subsurface drains—a good way if the soil is porous—or it may be applied to some sort of sewage filter. A satisfactory construction of a septic tank is shown in Figure 41-4.

From N. Y. State Dept. of Health Bulletin 26.

Fig. 41-4. Typical layout and details of driven well, pressure water system, and sewage disposal plant.

**Other Methods of Rural Sewage Disposal.** Although the cesspool and septic tank constitute the chief devices for the disposal of sewage from small isolated dwellings with water supply systems, a number of other processes can be employed under conditions of soil, location, or volume of sewage to be treated render cesspools and septic tanks unsatisfactory. These methods are much like those used in treatment of sewage from urban communities.

**Disposal of Kitchen and Other Liquid Wastes.** Where privies are used, sink wastes are often put upon the open ground. This may be unsightly, but the danger to health is not great. When plumbing is introduced, the natural thing for plumbers to do is to unite all the waste pipes as they do in cities. This brings wastes from the kitchen and bathroom and fecal wastes from water-closets together and causes

some difficulties because soap curds and grease form a heavy scum and choke the pores of the soil. The grease content of kitchen wastes can be reduced in grease traps. These are tank-like containers in which the grease rises to the surface as the liquid is cooled. The captured grease must be skimmed off from time to time.

**Camp Sanitation.** The disposal of human wastes from camps—that is, from temporary shelters—presents a number of sanitary features not encountered under ordinary urban or rural conditions. The methods of excreta disposal that should be employed are similar to the rural methods that have already been described. Some of the practices of armies on the march or in temporary encampment are applicable to all camps.

**Straddle Trenches.** These consist of relatively shallow trenches which the user straddles. A layer of earth is placed daily upon the fecal matter, and the trench is finally back filled and marked when camp is broken. The shallow straddle trench is recommended only for camps of one night. It is easily and quickly made, and by reason of its slight depth (commonly less than two feet) permits rapid disintegration of the excreta. When trenches of this type are to be used for a longer period of time, they are made deeper and are then called straddle pits. These are sometimes provided with covers. Straddle trenches can be adapted to other temporary encampments as well as to military ones.

**Latrines.** When the camp site is to be occupied for several days or weeks, more permanent facilities must be provided. These commonly take the form of latrines. Pit latrines differ from the straddle trench or pit in being wider and deeper and in providing seating facilities. Latrines are screened from view by brush or by canvas stretched between upright poles. Excreta should be covered with earth, and the trench should be burned out daily with straw and kerosene. When the contents reach to within three feet of the surface, the latrine should be filled, covered with oil and sacking, earthed over, and the site marked. Even when carefully operated, open pits permit the access of flies to the excreta. For this reason, deep-trench latrines may be equipped with self-closing seats that cover the trench tightly. Seats are arranged in single or double rows. The latrine is housed or otherwise screened. A urinal trough draining into the pit or into a separate soakage pit is sometimes provided against one wall of the latrine shelter. Treatment of the pit contents is the same as for the open latrine. Accommodations should be provided to care for about 5 per cent of the personnel at one time.

**URINALS.** Military camps are commonly equipped with galvanized iron cans which are placed in the camp streets at night. These are emptied into soakage pits in the morning and thoroughly cleaned. The ground where the cans stand is burned over each day. Urine soakage pits are sometimes used instead of cans. The pits are filled with stone and covered with sand supported on burlap. Metal funnels carry the urine into the pit from which it leaches into the ground. A pit four feet cube will serve from 200 to 500 men.

**Hygienic Results of Rural Sanitation.** The introduction of sanitary privies is commonly accompanied by other sanitary measures such as the improvement of water supply, the pasteurization of milk, and the screening of houses. The resulting reduction in intestinal diseases, therefore, generally reflects an overall rather than a specific sanitary effect. This fact must be kept in mind in evaluating data such as the following. Typhoid fever deaths in Richmond, Virginia (Harden

ergh, 1924), were reduced from 57 in 1908 to 28 in 1909 following the installation of sanitary privies in all unsewered homes. In Yakima County, Washington, the prevalence of typhoid fever was reduced by about 90 per cent after a campaign for more adequate sanitation. The introduction of sanitary privies in Birmingham, Alabama (Lumsden, 1918), decreased the typhoid fever death rate of 65.5 per 100,000 in 1917 to 17.8 in 1919; deaths from diarrhea and enteritis among children under two years of age dropping 50 per cent during the same period. In North Carolina (Smillie, 1948), sanitary activities reduced the typhoid mortality from 5.8 in 1914 to 0.5 in 1943. Experience has shown, furthermore, that hookworm can be stamped out by the provision and use of sanitary privies and that the incidence of other intestinal diseases can be materially reduced.

## THE URBAN PROBLEM OF SEWAGE DISPOSAL

Although small urban communities can dispose of water-carried household wastes, or sewage, by the methods just outlined, the natural tendency of community sanitation is away from the individualistic methods of the rural householder towards collective sanitation of a more effective nature. The urban problem of sewage disposal naturally falls into two parts: the collection of sewage by what is called the sewerage system, and the disposal of the sewage with or without treatment.

### SEWERAGE

So accustomed are we to present-day methods of urban sewerage that it is hard to realize that the system of water carriage of fecal matter is little more than a century old. The great sewers of antiquity unearthed at Babylon and Nineveh or, the *cloaca maxima* of Rome, still performing service, were built to carry away storm water and underground drainage; not to remove fecal and other wastes from the populations they served. Up to 1815 the public drains of London were not permitted to receive excreta; in Boston fecal matter was rigidly excluded from the sewers until 1833; and in Paris this was so even up to 1880.

Following the report of the Health of Towns Commission in England in 1844, water-closets were rapidly introduced. In 1847 their connection with the sewers was required by law, and the use of cesspools in towns was prohibited. In the United States, Chesbrough designed a general sewerage system in Chicago in 1855; Boston's first sewerage commission was appointed in 1875, but Baltimore was without a sewerage system well into the twentieth century.

The introduction of the water-carriage system accomplished its purpose of getting away with the offensive accumulations of filth around city dwellings, but it gave rise to a series of other problems that sanitarians had to solve. The first sewers, like the ground and storm water drains from which they evolved or after which they were patterned, were naturally built to discharge their contents into the nearest available body of water—into river, lake, or harbor, according to the location of the city. Where the receiving bodies of water were relatively large, no nuisance was caused by doing this; but where they were not, foul conditions were soon manifested. Water supplies also became infected, and in some instances great epidemics followed. Infection was spread in other ways, too, such as the pollution of shellfish layings and of beds of watercress. Thus the problem of the removal of

fecal matter was sometimes solved at one place only to reappear elsewhere. Litigation often arose between riparian owners along the water courses, involving damages caused by the pollution of the water.

**Plumbing Systems.** The house plumbing is the end of the water supply system and the beginning of the town drainage system. On the water supply side, the plumbing system carries water to toilet, washbowl, bathtub, kitchen sink, laundry tray, and other fixtures; on the drainage side, it collects the spent water from these fixtures and discharges them into the public sewers.

**DRAINAGE.** The main features of the house drainage system are one or more vertical *drainage stacks* and the *house drain*. The stacks rise from cellar to roof and collect the wastes from plumbing fixtures. The house drain runs horizontally under the cellar and receives the discharge from the drainage stack, conveying it to the *house sewer*. The latter extends outside of the building to the street sewer or house disposal plant. Pipes carrying the discharge of water-closets or urinals are known as *soil pipes*; those receiving the discharge of any fixture, except water-closets or urinals, are called *waste pipes*. Correspondingly, there are also *soil stacks* and *waste stacks*.

Each fixture is equipped with a *trap* containing a water seal which prevents the passage of air from the drainage system through the fixture into the house. This air is usually malodorous. It may also contain toxic and inflammable gases, such as hydrogen sulphide and the constituents of illuminating gas that has seeped from gas mains into neighboring sewers. In order to prevent the unsealing of traps by aspiration or back pressure as a result of water rushing through them or past

Fig. 41-5. Typical house plumbing system.

em, they are commonly provided with *vent pipes* which carry air into or out of the house drainage system, and thereby relieve unwanted vacuum or pressure conditions. Vent pipes from individual fixtures unite in a *vent stack* which rises vertically through the building from the lowest to the highest fixture. The vent stack parallels the soil or waste stack that it serves and is commonly connected with the drainage stack above the highest fixture. The combined stack passes through the roof into the atmosphere. A typical house plumbing system is illustrated in figure 41-5. A house trap can be installed to seal the entire house drainage system against the air in the street sewer but is commonly omitted, except in cold climates, where cold air entering the sewer through the many house vents might result in frozen sewers, and in houses on steep side-hill locations, where air from the vent pipe of a lower-lying house may be wafted into the living quarters of an upslope neighbor. The plumbing system should be pneumatically tight as well as tight against leakage of waste liquors and egress of cockroaches and other vermin.

**WATER SUPPLY.** The water supply pipes of homes, hospitals, offices and other buildings should convey water to fixtures in such fashion that there is no possibility of waste water being sucked or forced back into the water supply system and polluting or contaminating the water supply. The opportunity for backflow exists

Fig. 41-6. Common backflow hazards in dwellings.

every washbowl, laundry tray, and water-closet, unless the water outlets supply-  
 them are either suitably protected against backflow or otherwise placed at such  
 height above the water surface in these fixtures that an adequate air gap is main-  
 tained, even when the fixtures are flooded, out of order, or operated improperly.

Common backflow hazards of dwellings are shown in Figure 41-6; other fixtures to be watched are sterilizers, water-cooled refrigerators, pumps, and boilers of all descriptions; also swimming pools. Although the water-supply system is normally under higher pressure than the drainage system, reductions in pressure occur at times of high rates of draft within buildings or from street mains. Water demands during fires as well as breaks in pipes and other untoward occurrences may actually place the water distribution system under suction. The unusual combination of circumstances that creates such conditions must be recognized if the dangers inherent in them are to be avoided. For further discussion of this matter, see Chapter 36.

**Sewerage Systems.** The wastes collected by the plumbing systems of dwellings and other buildings are discharged into the street sewers. The sewers and drains of a city are used for various purposes, the two most important ones being the removal of solid and liquid wastes from household and industry and the carrying away of rain water that falls on roofs, yards, sidewalks and streets. When the same system of sewers is used to carry both domestic sewage and storm water, it is called a *combined system*. When the storm water and sewage are carried in separate conduits, a *separate system* of storm and sanitary sewers is created.

**CHOICE OF SYSTEM.** The evolution of sanitary sewerage from surface and ground water drains makes the combined system the older and the one more commonly in use in older cities and crowded communities. It is generally cheaper than the separate system of sanitary sewers and storm drains, except where the storm water can flow off in street gutters without serious inconvenience from flooding or be conducted through short storm drains into nearby water courses or drainage channels. Where the sewage must be pumped or carried long distances or subjected to extensive treatment, the advantages lie with the separate system, as the quantity of sewage is less and its flow more constant. From a sanitary standpoint the separate system is usually mandatory. The choice of the two systems depends upon various engineering questions involving not only cost but also sanitary considerations concerned with the uses and volumes of the water into which excess storm flows from combined sewers must be discharged through storm-water overflows. For reasons stated below, health departments no longer permit the construction of combined systems without special investigation and serious study of the sanitary hazards involved.

**ARRANGEMENT OF SYSTEM.** Sewerage systems consists of *house sewers* or house drains that convey the sewage to the street sewers or *lateral sewers*. These unite in *main* or *district sewers*, and the latter sometimes combine into one or more *trunk sewers* of large size. *Relief sewers* are sometimes built parallel to the old sewers of inadequate capacity, and *underdrains* may be used in connection with the separate system to remove some of the ground water. *Intercepting sewers* parallel surface waters in order to intercept the sewage originally reaching them from combined sewers. The sewage is conveyed to a safer point of discharge. Interceptors are not designed to carry all of the flow during storms but are provided with overflows, so that the excess storm water is discharged into the water course at various points of overflow. They commonly carry but two or three times the dry weather flow. Depending upon the hydrology of the region, one or more per cent of the annual volume of sanitary sewage may still be swept through storm-water overflows into the waters that the sewerage system is intended to protect. The overflowing sewage is almost never

reated before discharge and constitutes a serious danger to the users of, the waters into which the mixed sewage and storm water are emptied.

The sewerage system of a community begins in the high-lying areas that are to be sewered and points progressively down-hill, increasing in size in much the same way as a river system. Where there are districts that drain naturally in a different direction from that taken by the main drainage system, or where there are areas that lie so low that their direct connection to the main system would require a general lowering of the trunk sewers, the sewers of these areas may terminate in pumping stations that lift the sewage through force mains into the main drainage system. Small pumping stations are generally made automatic in operation.

**QUANTITY OF SEWAGE.** The volume of sewage flowing in a separate system, or in a combined system during dry weather, does not differ materially from the water consumption of the community. In small American towns it may be as low as 40 or 50 gallons per capita daily. In large cities it may amount to 100 to 200 gallons per capita or more. Ground water enters the sewers in amounts varying from 10,000 to 100,000 gallons per day per mile of sewer, depending upon the tightness of the sewer joints and the wetness of the ground.

Intercepting sewers are commonly designed to provide for a flow of 200 to 300 gallons per capita daily. The amount of storm water is a function of the intensity and duration of flooding rainfalls and varies widely in different regions of the world. The flow of sewage fluctuates hourly, the maximum rate being from 50 to 100 per cent greater than the daily average. Still greater fluctuations occur in cities where large quantities of water are used for manufacturing purposes.

**SIZE AND GRADE OF SEWERS.** The factors governing the design of the sewerage system are the quantity of sewage to be handled and the velocity at which the sewage must flow to prevent deposition of solids and consequent clogging of sewers by accumulation of deposits that will decompose and release offensive odors. These factors determine the size and grade, or slope, of the sewers. The smallest sewer employed is generally eight inches in diameter, and the grades are so chosen that transporting velocities of flow in the vicinity of two feet per second for sanitary sewers and three feet per second for combined and storm sewers will be maintained. The higher value is needed to transport sand and gravel washed into combined and storm sewers from streets and areaways. Sanitary and combined sewers are laid to such a depth that they will drain the lowest fixtures in the buildings served (usually seven feet below the street line), except in tall buildings that have basements of such depth as to render this procedure uneconomical. The sewage from deep basements must be lifted by pumps or compressed-air ejectors into the street sewer. Storm drains can generally be kept at somewhat smaller depths.

Where the slope of the district is adequate, the grade of the sewer commonly conforms to the street grade; where the slope is inadequate, the sewers become progressively deeper, and it sometimes becomes economical to interpolate a pumping station that will lift the sewage back to the minimum depth below the street level. In flat country, sewage may be pumped repeatedly both at points intermediate in the system and at outfalls.

**SEWER APPURTENANCES.** To permit inspection and cleaning of the sewers, manholes are provided at all changes in grade and direction of the sewers; also at intermediate points in long straight runs of sewers that cannot be entered for

inspection and cleaning. Manholes are placed not less than 300 feet apart in small sewers; their distance may be increased to 400 feet or more for larger sewers.

Normally, sewers are not operated under pressure, as are water mains, but when obstructions are encountered, such as subways, stream beds, or deep valleys or ravines, the sewer may be placed under pressure locally and carried under the obstruction in pressure conduits known as inverted syphons or depressed pipes.

*Catch basins*, through which the street wash generally enters combined sewers, are trapped against the egress of sewer air. The water that stands in them sometimes serves as a breeding place for mosquitoes. Unless catch basins are frequently cleaned, the accumulating organic matter putrefies and the resulting odor may be worse than that of the sewer air. In separate storm sewers, untrapped *street inlets* leading directly to the sewers have long been used rather than trapped catch basins. Such inlets have also been used successfully on combined sewers.

Ordinarily, combined sewers are sufficiently flushed by periodic storms. Separate sewers, if laid on proper grades, need little or no flushing. Automatic flush tanks may be installed at the end of lateral sewers that are laid on flat grades, but these tanks are often troublesome, waste much water, and include a back-flow hazard. Hand flushing of sewers with fire hose is normally more satisfactory.

Since illuminating gas and gasoline vapors, as well as gases of decomposition arising from deposits of sewage matter, may accumulate in sewers, due precautions must be taken by workers entering manholes or large sewers for inspection, cleaning, or repair work. In the past there have been numerous fatalities from asphyxiation; there have also been sewer explosions. In order to avoid such occurrences, the sewers are generally ventilated by allowing a free flow of air from the sewers through the house drains and the house stacks.

**Hygienic Results of Sewerage.** As for the sanitary privy, it is difficult to adduce reliable statistical evidence of the hygienic benefits that accompany the introduction of sewerage into communities, because other sanitary improvements, notably in water supply, generally accompany the construction of sewerage works. A study by H. B. Cleveland for the State of New York for the period 1896 to 1915 established a median typhoid fever mortality of 12.6 per 100,000 for sewered communities and of 19.0 per 100,000 for unsewered communities. Leach and Maxcy (1926) list the following typhoid fever morbidity rates per 100,000 for 1924-1925 in communities of different sizes or types in Alabama:

Size or Type	Rural	500-1,000	1,000-2,500	2,500-5,000	5,000-10,000	10,000-25,000	25,000 and over
Morbidity	52	443	307	180	165	118	63

They interpret these figures as indicating relatively good protection in rural areas by virtue of lack of contact, and in larger cities by reason of community sanitation.

## SEWAGE DISPOSAL

The sewage collected by sewerage systems must eventually find its way into the natural drainage channels of the region, whether they be lakes, streams, or tidal waters. If these receiving bodies of water are to be protected against pollution, the sewage must be treated before being discharged into them. The needed degree of

treatment depends upon the receiving capacity of the body of water and the uses to which it is put. Both treatment and disposal involve a knowledge of the physical, chemical, and biological characteristics of sewage and the changes that accompany treatment and disposal.

**Composition of Sewage.** A city's sewage consists of the spent water supply mixed with the waste products of human life and activity and of the refuse from household and factory. This base flow is increased and modified by a certain amount of ground water which seeps into the sewers and, in the combined system, by varying quantities of rain water and street wash. Disintegrating and decomposing under the influence of mechanical abrasion and biological action, the sewage, as it flows, gradually becomes a more or less homogeneous suspension of fine particles in water, together with organic and mineral matter in solution. The longer the sewage flows or stands, the more its constituents become disintegrated; fecal matter and paper eventually become unrecognizable as such; bacteria and other saprophytes increase enormously and assist in breaking down the complex organic compounds by their scavenging activities. The respiration of the living organisms and incidental biochemical changes reduce the oxygen originally present in the water and it may finally disappear, so that from a fresh condition the sewage may become first stale and then "septic." Mixed with the decomposing organic matter and the swarming hosts of bacteria and other micro-organisms harmlessly engaged in their beneficent work of destroying the organic matter, there may also be organisms that have come from carriers of, or persons sick with, typhoid fever, dysentery, or other diseases.

Sewage is obnoxious to the senses because of its decomposing organic matter, but it is dangerous to health because of the possible presence of pathogenic organisms.

The most important constituents of sewage from the standpoint of treatment are the decomposable organic materials carried either in suspension or solution, such as fecal matter, urine, cellulose, fats, and soaps. The suspended mineral matter, though inert, is of importance because of its physical bulk. The concentration of impurities, or amount present in a given volume of sewage, depends upon the per capita volume of the sewage and the nature and magnitude of industrial activity. As a result it varies widely in different places.

The following diagram shows the normal concentration and physical state of the impurities in sewage of moderate strength.

This diagram presents a general view of the nature and magnitude of the load of solids carried in sewage. It shows in particular how much of the sewage matter is capable of settling out and what is the general nature—mineral or organic—of the substances in suspension, in the colloidal state, and in solution. Disposal and treatment methods must take account of this physical state of the mineral and organic materials included in sewage if the problems involved are to be solved satisfactorily.

**SEWAGE ANALYSIS.** Most of the determinations commonly included in sewage analysis are the same or similar to those of water analysis (Chapter 37). The tests give indirect or inferential information about the properties of the sewage and must be interpreted as a whole rather than drawing information from the separate tests. The variety and interrelation of the tests commonly employed, according to

### CONCENTRATION AND PHYSICAL STATE OF SOLIDS IN SEWAGE OF MODERATE STRENGTH

Numbers are parts per million or milligrams per liter. They are generalized approximations, and considerable departures from them may be expected.

the general nature of the information they present, are shown in the following schedule.

#### Tests Measuring Organic Matter

Biochemical oxygen demand and relative stability

Volatile solids or loss on ignition (includes some mineral matter):

Suspended; settling and non-settling; dissolved

Organic nitrogen

Ether-soluble matter (fats)

#### Tests Measuring Mineral Matter

Fixed solids, or residue after ignition; suspended; settling and nonsettling; dissolved

Ammonia nitrogen (includes some organic matter)

Nitrite and nitrate nitrogen

Chlorides, hardness, alkalinity, and iron

#### Tests Measuring Both Organic and Mineral Matter

Total solids, or residue on evaporation: suspended, settling and nonsettling; dissolved

Hydrogen ion concentration

#### Tests Measuring Gases

Dissolved oxygen

Hydrogen sulphide

Carbon dioxide

#### Tests Measuring Living Organisms

Bacteria: total count, and coliform organisms

Other micro-organisms and larger organisms; animal and plant forms—notable indicators of sewage pollution.

The choice of tests depends upon the information desired. In general, sewage is analyzed for the purpose of predicting or determining its effect upon bodies of water.

water into which it may be discharged; for predicting the required degree of treatment; or for determining the efficiency of treatment processes.

The importance of the tests for solids and their physical state as well as their general organic or mineral nature has already been pointed out. The test for biochemical oxygen demand, which is not common to water analysis, is worthy of special consideration. This test measures the oxygen requirements of bacteria and other organisms (chiefly protozoa) as they bring about the decomposition of sewage matters. It is, therefore, perhaps the most significant measure of the putrescible load placed upon streams that receive the discharge from sewers or sewage treatment works, and in a similar way of the load placed upon biological sewage treatment processes. As this test is commonly performed, known quantities of the sewage are diluted with oxygen-saturated water and incubated in sealed bottles at 20° C for five days. The difference in the initial and final dissolved oxygen content presents the five-day, 20° C, biochemical oxygen demand of the sewage and permits its calculation in parts per million. Since the test is biologically activated, the oxygen demand exerted varies both with time and temperature. During the first stage of decomposition in which principally carbonaceous matter is oxidized, the "rate of demand" appears to be substantially constant. As the sewage matters that can be decomposed are gradually used up, however, while decomposition progresses, the "amount of demand" exerted gradually decreases. The first stage of decomposition extends over about 10 days at 20° C. After that, nitrification and other bacterial activities change the rate of demand, often increasing it. Warm temperatures stimulate the activity of bacteria and other water organisms and raise the rate of biochemical oxygen demand; cold temperatures lower it. The course of the first-stage

biochemical oxygen demand and its variation with temperature can be formulated mathematically and offers an important means for predicting the behavior of receiving bodies of water into which sewage is discharged. Based upon the biochemical oxygen demand of sewage is the relative stability test in which the decolorizing of methylene blue added to the sewage indicates the exhaustion of oxygen through

\* Ultimate biochemical oxygen demand.

the concomitant production of small amounts of hydrogen sulphide. The time elapsing before decolorization is a measure of the relative stability of the sewage. The longer the time, the more stable the sewage, or the less the biochemical oxygen demand.

Approximate values for the composition of the sewage from four groups of American cities are presented in Table 41-1, while Table 41-2 records pertinent information on the more important industrial wastes. Appreciable departures from the values given are to be expected.

The strength of industrial wastes is conveniently expressed also in terms of the number of people whose domestic sewage would exert the equivalent biochemical oxygen demand. This is known as the population equivalent of the waste. The basic per capita value for the five-day, 20° C, biochemical oxygen demand being ordinarily taken at 54 grams.

## DISPOSAL METHODS

As previously stated, a sewerage system constitutes a man-made arterial system of underground drainage channels that must be linked at the end of its course to the natural drainage channels of the region of which the sewered area is a part. Ordinarily, therefore, sewerage systems discharge with or without treatment into nearby water courses: rivers, lakes, or tidal waters. More rarely, they terminate in irrigation ditches that carry the treated or untreated sewage onto the land. The disposal of sewage into water is known as dilution; the disposal upon land as irrigation.

There are but few soils and climates that permit the use of sewage to irrigate crops under such conditions that all of the liquid is used up. In arid regions with open soils, large volumes of sewage can be absorbed; in wetter climates, the sewage discharged upon the ground passes through it and must be collected in underdrains that lead into nearby water courses. Irrigation then becomes a treatment rather than a disposal method, and the disposal of the drainage from the irrigation fields becomes a problem of dilution.

The discharge of sewage whether treated or not into streams, lakes, and harbors is by far the most common method of sewage disposal throughout the world. It can be applied satisfactorily whenever the water receiving the sewage is capable of being returned to a state of desirable purity by the operation of the forces of natural, or self-, purification that are inherent in all bodies of water (see page 1200).

**Pollution and Natural Purification of Receiving Waters.** The discharge of sewage into water sets into motion a series of physical, chemical, and biological reactions that are more or less interdependent. These must be studied if the mechanism of sewage disposal by dilution as well as the sanitary hazards involved are to be understood.

The problem of sewage disposal by dilution is largely a biological one and must be measured in terms of the changed conditions of existence to which the stream is subjected by pollution of the waters. If the pollutorial load is great, the first effect of the sewage upon the water is to make it turbid and impart to it a gray color. Sunlight is shut out, and green plants thus deprived of their energy for growth soon die. At first the organic matter of the sewage is fresh and is consumed by some varieties of fish which therefore gather near the outfall. Decomposition as a result of bacterial activity, however, soon begins and quickly renders the organic materials unfit for all except the most primitive organisms that subsist on decaying matter. These organisms, bacteria, fungi, and protozoa, develop in enormous numbers. As a result the stream soon becomes like an overcrowded, poorly ventilated space in which the demand for oxygen by the living organisms and the chemical changes produced by their activity soon exceeds the supply. Those forms of life which require a relatively high saturation of oxygen succumb. They include the fish and practically all other higher organisms. Since water that is saturated with oxygen contains but 1 per cent of this gas by volume against 21 per cent in the overlying atmosphere, the available oxygen supply is relatively more precious to the aquatic environment than is that of the atmosphere. When the current is not too rapid, much of the suspended matter carried into the stream by the sewage settles to the bottom and forms a pollutorial carpet, and in severe cases a deep deposit of sludge, on the

floor of the stream. Laid down in any appreciable thickness, these deposits decompose anaerobically except at their surface. The rate of decomposition is thereby slowed down, and the oxygen demand is decreased. Spring freshets generally remove the accumulated deposits and return the stream bed to relatively clean condition. New types of life make their appearance in the sludge, the most common organisms being small reddish worms which delve and burrow in the deposits and are factors in their stabilization. There develop, too, attached to the debris, masses of fungi and colonial protozoa that attract nutriment from the waters flowing past them.

As shown in Figure 41-7, these changes are confined to a short stretch of river below the outfall. There follows a much longer river stretch in which the processes

Fig. 41-7. Degradation and recovery of a polluted stream as measured by its content of dissolved oxygen.

of decomposition that have established themselves reach their greatest activity. From a physical standpoint this second zone is characterized in heavily polluted streams by a grayish color of the water; sticky blackened sludge deposits with offensive odor; evolution of gas bubbles especially during the warmer months; foul sewage and privy odors. Decomposition of the complex organic materials is marked by reducing and splitting processes. Soluble and gaseous compounds are formed. By successive stages the end-products become simpler in structure, until they can no longer support the micro-organisms whose activity is responsible for the processes of decomposition. So as long as the water contains dissolved oxygen no serious nuisance results. In grossly polluted streams, however, the dissolved oxygen is sometimes completely exhausted. The organisms of decay then satisfy their need for oxygen by abstracting it first from mineral substances, such as nitrites, nitrates and sulphates, and finally from the organic matter itself. Decomposition then takes place under anaerobic or septic conditions and the river may become extremely offensive. The greater the reduction of dissolved oxygen, however, the greater fortunately becomes the rate at which oxygen is absorbed at the water surface. This is called re-aeration. Eventually decomposition slackens as the available organic materials are consumed, and a point is finally reached when re-aeration balances the demand for dissolved oxygen and finally overbalances it. A new store of dissolved oxygen is then gradually accumulated. More highly organized life re-establishes

shes itself, and the bacteria and protozoa that have held sway are reduced in numbers. The length of river stretch occupied by this zone of active decomposition will vary with the seriousness of pollution, with the time of travel and with the temperature. It is not necessary that the stream should become truly septic. When pollution is relatively light, the zone of active decomposition is not of great length. In heavy polluted rivers, however, it may extend over many miles.

There attaches to this second zone a stretch of water in which the stream gradually recovers its former appearance and life. The outward appearance of this zone is marked by gradually clearing water, by bottom deposits that are granular rather than sticky and have no offensive odor, and by absence of gas bubbles. Judged by chemical standards this third zone is one of mineralization in which the last vestiges of decomposable organic matter are stabilized. Dissolved oxygen gradually increases to complete saturation. Nitrogen end-products are carried to nitrites and finally to nitrates, sulphur to sulphates, and carbon to carbonates, thus completing the cycle of these elements in nature. Green algae make their appearance and are followed by larger aquatic vegetation. By photosynthesis they assist in reoxygenating the water. Small animal forms of life, crustacea, rotifers and insect larvae, some of them important food for fish, reappear.

Below the three zones of visible pollution and natural purification is found the cleaner water zone in which the forces of self-purification continue their beneficent work. This zone is characterized largely by the normal flora and fauna of rivers. The enrichment of the food supply resulting from pollution and self-purification may indeed cause a marked development of all forms of cleaner water life. Green plants, large and small, predominate, and natural and desirable conditions are once more established.

In streams, the zones discussed neither occupy a fixed position in the channel, nor are they sharply bounded. In the same stream the zones may overlap due to variations in temperature and river flow. These cause a shifting of the zones. Sometimes they are extended, sometimes contracted. The cycle of self-purification may be retarded, interrupted, or accelerated by the entrance of new waste materials, by clean or polluted tributary waters, by dams, rapids, ponds, or reservoirs. Toxic waste products, acid mine wastes, strong alkalis, and oil may profoundly modify the course of natural purification by destroying life so essential to self-purification or by interfering with re-aeration. Since the amount of oxygen that can be dissolved in water decreases as the water temperature rises (14.7 p.p.m. at  $0^{\circ}\text{C}$  against 7 p.p.m. at  $29^{\circ}\text{C}$ ) while the rate of biochemical activity or oxygen demand increases with rising temperatures, doubling for every rise of  $10^{\circ}\text{C}$ , it follows that there are profound seasonal changes in the self-purification of streams, offensive conditions being more marked in summer than in winter, except when ice cover prevents re-aeration. This phenomenon of oxygen adsorption from the atmosphere is similar to the renewal of oxygen in the blood stream by the lungs during respiration. The larger the surface of contact between water and air and the more frequent the change of surface the more rapid is the rate of reoxygenation. This explains why swift streams can absorb oxygen more rapidly than quiescent bodies of water. It must be remembered, however, that biological activity resulting in decomposition and its associated deoxygenation as well as re-aeration requires time for completion. It should be apparent, therefore, that a lake or artificial reservoir may store the

polluted waters for days, weeks, or months and thereby become a factor of great importance in the natural or self-purification of a water course. The old adage that running water purifies itself is an incomplete and hence misleading statement of facts. Quiet water purifies itself also, the changes being slower with respect to re-aeration but usually more rapid with respect to sedimentation of suspended matter, reduction of bacteria, and the like. The degree of natural purification accomplished, furthermore, it is not a question of distance but of time of travel.

Similar, but opposite in character to deoxygenation and re-aeration, is the production of carbon dioxide and its removal to the atmosphere at the water surface. The analogy between the respiration of a stream and of the higher vertebrates is, therefore, quite complete. Sea water dissolves about 20 per cent less oxygen than fresh water.

The biological changes taking place in a sewage-polluted stream are illustrated by the figures in the following table for the Illinois River below the point of entrance of the sewage of Chicago.

Table 41-3. Bacteria and plankton below point of heavy pollution, Illinois River, October, 1921, to August, 1922

TIME OF FLOW, HOURS	DISTANCE OF FLOW, MILES	POLLUTIONAL PLANKTON, % OF TOTAL	BACTERIA ON GELATIN, NUMBER PER ML.

After Purdy, W. C., U. S. Pub. Health Bull. 198, 1930.

**REQUIRED DILUTION OF SEWAGE.** The minimum amount of water required to dilute sewage in streams and other bodies of water must usually be sufficient to provide, directly or indirectly, enough oxygen to satisfy the biochemical oxygen demand of the sewage matters. Although the re-aeration as well as the deoxygenation of polluted waters can be formulated in mathematical terms, the presentation of certain overall values will better meet the purposes of this book. Thus it has been established by experience that in normal water courses from 2.5 to 4 cubic feet per second of diluting water must be provided to receive into a stream, without the creation of offensive conditions, the raw, or untreated sewage of one thousand people. The Chicago Drainage Canal was designed on the basis of 3.3 cubic feet per second for one thousand people. Rapidly flowing streams need to supply less than this value; sluggish streams and standing bodies of water have to provide considerably more water. The presence of trade wastes in the sewage may materially increase the dilution required. Oily wastes float on the surface and form scums that may interfere with the absorption of oxygen from the air. Wastes rich in organic matter, such as packing house or tannery wastes, consume much oxygen, i.e., their population equivalent is very high. Tidal waters and large lakes, as well as streams, may act as diluting agencies.

No general dilution requirements governing the discharge of treated sewage

to water courses have as yet been formulated in the United States. Some years ago the British Royal Commission on Sewage Disposal adopted the figures shown in Table 41-4 for English practice:

Table 41-4. Dilution requirements governing discharge of treated sewage for English practice

Condition of Sewage	Required Dilution (Volumes of Water to One Volume of Sewage)	Suspended Solids Less than (Parts per Million)
crude .....	More than 500	—
settled .....	300-500	150
chemically precipitated .....	150-300	60

For lower dilutions the treatment plant effluent is required to contain less than 10 parts per million of suspended matter and have a biochemical oxygen demand of less than 20 parts per million in five days at 65° F. In studying these requirements, it must be remembered that English sewage is two to four times as strong as American sewage.

Of recent years the principle of regulating dilution on the basis of maintaining an adequate oxygen balance in the water acting as a sewage carrier has been widely recognized in situations in which nuisance is to be prevented. Where streams and other bodies of water serve as water supplies, however, consideration must be given primarily to the permissible bacterial loading of water purification plants. This is generally a more rigid requirement, and the volume of sewage discharged, as well as the degree of treatment to which the sewage should be subjected, must be adjusted accordingly.

The International Joint Commission on the Pollution of Boundary Waters between Canada and the United States based the permissible pollution of boundary waters upon their use for water supply purposes and adopted a standard of less than 500 coliform organisms per 100 ml. as a yearly average. This corresponds to a required dilution of 2 cubic feet per second per capita, a figure about 500 times as large as that needed to prevent a nuisance. The permissible loading of water purification plants is discussed more fully in Chapter 39.

**Outfall and Other Dilution Works.** The location and construction of sewer outfalls has an important bearing upon the success of sewage disposal by dilution. In order to be effective it is necessary to have the sewage thoroughly and quickly dispersed through the water. This occurs automatically in moving streams. In standing bodies of water, special means must be provided to effect dispersion. In lakes, the location of sewer outfalls relative to that of the intakes of waterworks and that of bathing beaches must be carefully considered, and the travel of bacteria with currents induced by wind and temperature must be studied. In coastal waters the effects of the tides must be taken into account in connection with the protection of bathing beaches and shellfish layings.

Sewage is generally warmer and lighter than the water into which it is discharged. If sewage is emptied into a receiving water near its surface, therefore, it will ride on top of the diluting water, will not mix readily, and will tend to form a "sleek" which can be noticed for many miles. This sleek will become quite

offensive during hot weather. In coastal waters, sea gulls feed upon the waste materials and may possibly fly from the sewage fields to the water reservoirs of nearby towns.

In order to disperse sewage in quiescent receiving waters, it should be introduced at or near the bottom of the water. The sewage then tends to rise and become well distributed as it makes its way to the surface. Dispersion is further aided by providing a number of outlets at sufficient distance from each other to avoid interference. Large outfalls have been placed at depths of 40 or 50 feet, and a large number of distributing nozzles situated on pipes branching over several acres of harbor bottom have been employed to ensure adequate dispersion.

The natural purification inherent in streams and other bodies of water may be controlled successfully also by engineering works that either supply water for dilution, during periods of low flow, from impounding reservoirs or from natural bodies of water in nearby, but different, drainage areas, or that increase the length of time required for polluted river waters to pass down stream. Examples of these practices are: (1) the Chicago Drainage Canal created by reversing the flow of the Chicago River and carrying its waters together with adequate quantities of clean water abstracted from Lake Michigan through a canal into the Illinois and Mississippi Rivers; (2) numerous impounding reservoirs in this and other countries that release stored water during periods of low flow; and (3) the impounding reservoirs of the Ruhr Valley in Germany that increase the time of flow of the Ruhr River in a 47-mile stretch from 18 to 84 days as well as exposing large new areas of water surface to re-aeration and sunlight. Another example of controlled dilution is found in the fish ponds of some European cities, in which settled sewage is mixed with clean river water to create conditions of existence favorable to the cultivation of fish and raising of ducks. Fish ponds of this kind are analogous to fertilized fields. Large crops of organisms that serve as food for fish and for ducks develop in the aquatic meadows of the ponds.

**Hygienic Aspects of Stream Pollution.** Considering the hygienic aspects of stream pollution with special reference to the pollution of water supplies, it is important to remember that pathogenic organisms do not multiply in the ordinary water of our streams but diminish in number, or die away, at a more or less constant rate.

It follows that recent pollution is the most dangerous, and that waters stored in reservoirs and lakes becomes more and more safe for use as length of storage increases. The longevity of pathogenic organisms is much greater in cold water than in warm water. This is one reason why water-borne epidemics of disease are more common in winter and early spring than in summer, and in northern climates than in southern climates.

The viability of the typhoid bacillus is similar to that of *E. coli*. Hence the death rate of this index organism of sewage pollution can serve as a yardstick of what happens to typhoid bacteria. Some of the results of studies by the U. S. Public Health Service on the Upper Mississippi River during the summer and winter months are shown in Table 41-5. The reduction in bacteria growing on agar at 20° C in 48 hours and at 37° C in 24 hours is shown as well as the reduction in *E. coli*. This permits a comparison of their relative significance.

Laboratory studies of the die-away of *Salmonella typhosa* in clean water record

Table 41-5. Average bacteria remaining in Upper Mississippi River below point of maximum concentration

	20° C Count on Agar		37° C Count on Agar		<i>E. coli</i>	
	Summer	Winter	Summer	Winter	Summer	Winter

1260.0 hours	3.2	1.6	3.1	0.4	0.1	0.1

U. S. Public Health Bulletin 203, 1932.

death rate at 0° C of 55 per cent per day and of 80 per cent at 10° C, the time survival being halved for every rise in temperature of 10° C. The viability in water of the cysts of *Entamoeba histolytica* is relatively much greater. It is almost 10 days at 0° C. The length of survival, however, is cut in three by every rise in temperature of 10° C.

**Legal and Economic Aspects of Stream Pollution.** Whereas it is true that hygienic and sanitary considerations materially affect the use of rivers and waterways as vehicles for the reception, transmission, and ultimate disposal of sewage, the question is primarily an economic one. The power of streams to remove suspended matter and the ability of natural bodies of water to oxidize and destroy offensive substances represent a natural resource that should be utilized just as far as this can be done with safety and without offense. For each river there is a limit to the amount of permissible pollution. The reasons for this limit are not always the same but vary according to the use that is made of the water of the river. No universal standard can, therefore, be wisely set up or maintained. When the extent of pollution is such as to affect public health in any way by any reasonable use of the river, the sanitary aspect of the situation should control.

Long experience has demonstrated clearly and unmistakably that it is possible to purify polluted water and make it reliably wholesome. Some waters, however, are so grossly polluted that the load upon the purification works would be too great to produce an hygienically safe water by economical treatment methods. When this is so, it is usually better to seek a less polluted supply or to require treatment of the sewage or industrial wastes that are polluting the supply. This is a problem in operative sanitation that will be touched upon later.

**Nuisances Caused by Industrial Wastes.** Not infrequently the greatest nuisance in streams and other bodies of water is due not so much to domestic sewage as to industrial wastes that are discharged directly, or allowed to flow into the receiving water through the sewers. For example, the discharge of spent dye liquors may color the water of a stream for many miles; wastes from gas works may form a descent films upon the surface of the water and add phenolic taste-producing compounds; wastes from paper mills may release noxious amounts of hydrogen sulfide; and acid iron wastes from galvanizing works may cause a rusty discoloration of the water that paints the rocks and submerged stumps along the shores for many miles. When nuisances of this character arise, it is wise and proper to install suitable waste-treatment plants. Industrial wastes may complicate the purification of water

even more than sewage itself. Industrial wastes may also interfere with the proper operation of sewage treatment works. Copper and other toxic wastes, for example, may render biological treatment of sewage and sludge inapplicable, and carbohydrate wastes may interfere with the normal operation of the activated-sludge process. As previously shown, the population equivalent of some industrial wastes in terms of their biochemical oxygen demand may be quite high. In some communities it may even exceed the load imposed by domestic sewage.

Some industrial wastes are toxic to man as well as to the lower animals.

### TREATMENT METHODS

By appropriate processes, sewage and industrial wastes can be treated so that the decomposable organic matter is removed or oxidized and the bacteria and other organisms removed or killed. Complete purification is not attempted, as it would be too expensive; purification is incomplete, the degree of purification secured being adjusted to the needs of the situation. In general, sewage treatment works are built to remove as much of the suspended matter and decomposable organic matter as is necessary to enable the effluent to be discharged into some waterway without causing offensive conditions. In some places greater emphasis is placed on the removal of polluting substances with the object of protecting shellfish beds and bathing beaches, or reducing the "load" on water filters.

**Fundamental Principles of Sewage Treatment.** If the waste materials from human habitations and industries retained their identity during their travel through the sewerage system and could be removed from the transporting water as readily as they are added, a sewage treatment plant would be a relatively simple unloading station at which the wastes would be separated from the carrying medium for disposal in concentrated form. Unfortunately, the physical condition in which many of the waste products occur in sewage makes simple unloading impossible, and the obnoxious nature of the matter that finds its way into sewage renders it undesirable. Toward the end of the last century it was recognized that sewage treatment must rely upon physical separation of some of the objectionable waste matters and upon biological modification of the remainder in much the same way as this is accomplished in Nature's household by the self-purification of a polluted stream. Someone, indeed, has compared a sewage treatment plant to a river wound up at one spot to localize the area in which purification is accomplished. Activity is controlled and intensified, and many of the reactions proceeding slowly and fortuitously in the waters of polluted streams are accomplished more quickly in sewage treatment works by creating conditions that will induce, develop, or stimulate the forces of natural purification.

The fundamental processes of sewage treatment are: (1) separation of the suspended matter from the liquid sewage; (2) destruction of the putrescible organic matter in the liquid sewage looking to final mineralization by the processes of biological action; (3) transformation of the sewage sludge to a condition of stability and inertness by biological action; and (4) destruction of the bacteria and other micro-organisms in the liquid effluent or their removal from it.

The processes involved may be classified as follows: (1) **primary processes** such as screening, skimming, sedimentation, and chemical precipitation; (2) **sec**

ary processes, such as subsurface irrigation, broad irrigation, intermittent filtration, contact and trickling filter treatment, and activated sludge treatment; (3) finishing processes, such as disinfection and disposal of the effluent in water or on land; and (4) sludge treatment and disposal, such as digestion, air drying, mechanical dewatering, incineration, and disposal of the sludge on land or in water.

The processes are by no means clear-cut. They overlap at many points; they are used singly or in many different combinations.

**Primary Treatment.** The object of primary treatment is the removal of those suspended solids that are readily separated from the sewage by physical means alone, namely, screening or settling. The unloaded material is often subjected to further treatment in order to secure its safe and economic disposal.

**SCREENING.** There are two types of sewage screens: coarse screens and fine screens, including comminuting screens.

*Coarse Screens.* These consist of gratings of iron bars seldom less than an inch apart which hold back only the largest floating objects found in sewage, such as sticks, paper, and rags. They are used chiefly in connection with sewage pumping stations in order to prevent injury to the pumps, but they are also employed in treatment works and on outfalls to accomplish in a rough way what is done with a greater degree of effectiveness by fine screens.

Two types of coarse screens are widely used: racks placed in an inclined position in the channel of sewage flow, and cages lowered in duplicate vertically into the sewage, one being removed while the other is being cleaned. Racks may be cleaned by hand or by mechanical means.

*Fine Screens.* Fine screens are made of wire mesh or perforated metal plates with openings seldom more than  $\frac{3}{8}$  inch and often less than  $\frac{1}{16}$  inch in their smallest dimensions. They retain many of the finer sewage particles, including some solid matter. Fine screens clog rapidly and require special mechanisms to keep them clean. A great many different types of screens have been devised. They generally operate through the sewage in the form of disks, drums, or endless chains that usually are cleaned by brushes, sometimes by air or water jets, or by the water pressure created by the motion of the screen.

The amount of material screened from sewage varies from 1 to 30 cubic feet per million gallons of sewage, according to the size of rack and screen openings and the composition of the sewage. Fine screens remove from 2 to 20 per cent of the suspended matter and from 5 to 20 per cent of the biochemical oxygen demand. These are relatively low efficiencies. The use of fine screens, therefore, is generally restricted to special circumstances, such as the protection of water courses against unsightly sewage matters. In this case screening may be supplemented by chlorination. Screenings may be pressed to remove much of the entrained water. They may then be disposed of by being burned under a boiler or in an incinerator provided for that purpose, buried in land, or turned over to the local garbage and refuse department for disposal. Since they are so small a portion of the removable matter, at the same time, so unsightly and obnoxious to handle, it has become common practice to comminute the screenings and return them to the sewage. The screenings are generally comminuted in place by rotating the screen against a cutting device. This combination is called a comminuter. If screenings are disposed of on land, they should be covered sufficiently to prevent odors and fly-breeding.

When screens are operated in connection with grit chambers, the screenings are usually covered with grit to fill low-lying areas near the treatment works.

**SEDIMENTATION.** It was pointed out in connection with the design of sewerage systems that the velocities of flow in the sewers had to be maintained sufficiently high to prevent deposition of part of the burden of solid matter carried by the sewage. This tendency of sewage solids to settle out under the influence of gravity is the most generally useful process of sewage treatment. Some of the larger and heavier solids, such as sand, gravel, and other gritty mineral matter, settle out promptly when the velocity of flow is reduced below that commonly maintained in the sewers; other solids, constituting the bulk of the settling solids and including much of the suspended organic matter, require low velocities and long periods of time to settle through the depth of settling tanks; still others, fine suspended matter and matter in the colloidal state, will not settle even during protracted quiescence, but they can be removed in substantial amount by the addition of coagulating chemicals. Substances lighter than water, oil, grease, and floating matters, will rise to the surface when the velocity of flow is reduced and can then be skimmed off.

This behavior of sewage solids during relative quiescence is made use of for the following purposes: removal of grit or detritus; removal of oil and grease; and removal of settling solids. Related to these processes are the disposal of the materials removed and sometimes the further treatment of these materials prior to disposal.

*Removal of Grit or Detritus.* Most of the heavy mineral or gritty solids suspended in sewage have their origin in street wash and occur, therefore, chiefly in combined sewerage systems. Their removal becomes important when the grit subjects pumps and screens to excessive wear, makes the removal of sludge from settling tanks difficult, or interferes with other treatment processes. Grit may be separated from the flowing sewage by reducing the velocity of flow to about a foot a second for a minute or two. The structures in which this is accomplished are called grit chambers. They generally take the form of elongated channels of somewhat greater cross-sectional area than the outfall sewer to bring the velocity to the required value and to provide for the requisite detention period and grit storage. Since storm-flows are extremely variable, flexibility of control is usually obtained by constructing a number of parallel channels that can be thrown into operation as needed. The grit is removed from time to time by hand, by mechanical sludge elevators, or by hydraulic means. It is then used for fill or is buried. If the velocities of flow are well controlled, the grit will be relatively clean mineral matter; if not, it may contain sufficient organic matter to render the resulting sludge offensive. More or less continuous grit removal by mechanical scrapers and the washing out of the organic matter as the grit is brought to the surface of the chamber permit the use of a single grit chamber and yield a relatively clean grit.

Periods of detention of 15 minutes or more have been employed to separate from sewage the most readily removable suspended matter irrespective of its character. The resulting sludge is called detritus and is often offensive. The amount of grit collected varies with the character of the district drained and the frequency and intensity of storms as well as with the conditions of flow in the chambers. At velocities of one foot per second and detention periods of one or one and one-half

minutes, from 1 to 12 cubic feet of grit may be expected per million gallons of sewage treated.

*Removal of Oil and Grease.* Oil and grease find their way into sewage from household and industry, more particularly from garages. When discharged into waters receiving untreated sewage, these substances, together with other light or floating solids, form unsightly scum or "sleek" on the water surface. In sewage treatment plants, they produce similar conditions on settling tanks and may interfere with some of the treatment processes. For these reasons it may be desirable to provide skimming tanks which will permit the floating matter to rise to the surface of the sewage whence it may be removed intermittently or continuously by hand or by mechanical devices. Detention periods in excess of one minute, but less than 15 minutes, are generally provided and the flow may be horizontal or vertical. To prevent deposition of solids and to aid the separation of the oil and grease from the sewage, air may be blown into the tank from below. Skimmings are generally small in bulk but are often drawn from the tanks together with much water. Some water can be removed by placing the material in a separating tank whence the water is drawn off or by running it onto drying beds similar to sludge-drying beds to be discussed later. The drained material is generally added to sludge-digestion tanks. Sometimes it is burned or buried. The amounts collected vary greatly depending upon the enforcement of regulations governing the discharge of waste oil into the sewers.

*Removal of Settling Solids.* The proportion of solid material removed in grit chambers and skimming tanks is relatively small. The bulk of the settling solids, including most of the organic settling solids, is carried through such treatment devices and requires prolonged sedimentation with or without chemical treatment. Sedimentation tanks are commonly used in advance of the biological processes of sewage treatment to decrease the load on these or to remove substances that will interfere with their proper operation. They are also employed after biological treatment to retain the settleable solids produced in, or unloaded from, these processes. Finally, they are often used without other treatment methods to lessen the amounts of suspended solids discharged into bodies of water. Used in this way, sedimentation is of great importance, not only because it reduces the load placed on a receiving water, but also because it prevents the formation of sludge deposits that accumulate to localize and often intensify the biochemical oxygen demand of sewage matters.

The efficiency of sedimentation processes varies chiefly with the time permitted for settling to take place, the strength of the sewage, and the character of chemical treatment, if any. The greatest proportion of sedimentation takes place at the beginning; little added clarification is obtained beyond the second hour. When chemicals are used to improve settling, the detention period that will produce the most advantageous clarification is influenced by the time it takes for the necessary chemical reactions and floc-formation to be completed before sedimentation becomes fully effective. Stirring and flocculating devices and tanks are, therefore, often introduced to prepare the sewage for sedimentation. The stronger the sewage, the greater the rate of removal of suspended matter by sedimentation; but it will take longer to reduce the suspended matter to the same absolute effluent value in a strong sewage than in a weak one. Unaided by chemicals, sedimentation will remove in

from one to four hours between 40 and 70 per cent of the suspended matter and between 25 and 40 per cent of the five-day biochemical oxygen demand from sewage of medium strength. Average values are 60 per cent for suspended matter and 35 per cent for biochemical oxygen demand. Chemical precipitation, if well conducted, may reduce the suspended matter by 70 to 90 per cent and the biochemical oxygen demand by 50 to 85 per cent. To attain such high efficiencies, however, large quantities of chemicals may have to be applied, and the cost will be relatively high.

We may classify the various tanks employed for the removal of settling solids as follows: plain sedimentation tanks arranged as single or two-story units, septic tanks, and chemical precipitation tanks.

**PLAIN SEDIMENTATION TANKS.** Settling tanks are called plain when the force of gravity alone produces the clarifying of the sewage. In order to permit this force to operate to greatest advantage, the velocity of flow must be checked. Longitudinal displacement velocities less than 10 inches per minute are employed, and the detention time varies from 30 minutes to many hours. Periods greater than two hours are unusual and seldom economical. In modern works, fill-and-draw operation of the tanks has given way to continuous flow. The path of the sewage is generally horizontal in primary units, i.e., tanks preceding biological treatment or operating in plants having no further treatment except perhaps disinfection (Figure 41-8, A). Tanks in which the flocculent sludge produced by biological treatment is settled are often arranged to pass the sewage in downward, upward, and radial flow. In such units the flocculent solids settling from the sewage travel in opposite direction to the liquid and assist in sweeping out the lighter flocculent materials by aggregation. Vertical displacement is generally held below one inch per minute (Fig. 41-8, B).

It is essential for satisfactory operation of plain sedimentation units that the sludge be removed before it becomes septic and gas ebullition lifts the settled solids back into the flowing sewage. For this reason mechanical sludge-removal devices have come into use. These can be operated intermittently or continuously, as required. In principle they consist of scrapers that move the sludge to an outlet sump, whence the sludge is drawn off under the influence of hydrostatic pressure or by pumping (Figs. 41-8, C and D).

Continuous removal of the solids settling from the flowing sewage is accomplished without the aid of mechanical devices in two-story tanks in which the upper compartment serves as a settling chamber and the lower compartment as a storage chamber in which the settled solids may be carried to partial or complete digestion. The best known tank of this type is the Imhoff or Emscher tank (Fig. 41-8, E). The processes obtaining in the settling compartment are those of plain sedimentation; the ones acting in the sludge compartment are those of anaerobic sludge decomposition, called digestion. This treatment of sludge will be discussed later. It can also be accomplished in separate digestion tanks into which the sludge is pumped from the sedimentation units (see Fig. 41-8, F). The gases and scum rising in the digestion chamber of Imhoff tanks are not permitted to enter the sewage but pass into gas vents or collecting chambers that may occupy up to 20 per cent of the tank surface. The gases include methane of high fuel value. Hence

Fig. 41-8. Types of sedimentation and sludge digestion tanks.

*A*, rectangular settling tank with hopper bottom; *B*, circular or Dortmund settling tank with vertical flow; *C*, round settling tank with revolving scraper; *D*, rectangular settling tank with longitudinal scraper; *E*, rectangular two-story or Imhoff tank (transverse section); *F*, circular separate sludge digestion tank with floating cover.

The gases from both two-story and separate digestion tanks are generally captured and utilized in the treatment plants of larger communities. The sludge storage capacity of Imhoff tanks varies with the magnitude and duration of winter temperatures. For technically complete digestion, two cubic feet of sludge storage per capita are commonly provided in the northern United States.

Settling tank loadings are generally expressed in terms of the volume of sewage treated per unit of tank area per unit of time. A value of 900 gallons daily per square foot of tank surface is common for ordinary sewage solids. This figure is sometimes increased for secondary settling tanks for activated sludge and trickling filter humus.

**SEPTIC TANKS.** Septic tanks hold the sewage from 8 to 24 hours or longer and retain the sludge for such long periods of time that it becomes septic. Liquefaction and gasification of the organic matter take place and the sludge is reduced in volume. Gas-lifted solids may form a heavy scum on the tank surface. The effluent from single-story septic tanks frequently contains much gas-lifted suspended matter and may have a high biochemical oxygen demand; the sludge removed is usually incompletely digested and hence offensive; and the use of other sedimentation and digestion devices is generally more economical. Except for smaller installations, usually for isolated dwellings, septic tanks have, therefore, generally been displaced by Imhoff tanks or by plain-sedimentation units in combination with separate sludge digestion tanks.

**CHEMICAL PRECIPITATION.** Sedimentation may be hastened and increased by the use of chemicals. Lime (calcium oxide), copperas (ferrous sulfate), chlorinated copperas (containing ferric chloride), aluminum sulfate, ferric sulfate, and ferric chloride singly or in combination may be used to coagulate the suspended matter by forming flocculent masses of iron or aluminum hydroxides. The process is similar to the removal of color and turbidity from drinking water by coagulation. When the sewage itself contains the necessary amount of iron—often derived from the waste liquors of iron pickling processes—lime only may be needed. Several hundred pounds of chemicals are required per million gallons of sewage treated and from 50 to 85 per cent of the biochemical oxygen demand of the sewage is removed by this treatment process.

Clarification of the coagulated sewage by rapid filtration of the settled sewage through quartz sand or crushed magnetite which is cleaned periodically by backwashing has not established itself because of many operating difficulties. The acidifying of sewage with sulfuric acid or sulfurous acid fumes obtained by burning sulfur or roasting pyrite has been employed successfully for recovering grease from the sewage of wool-scouring plants and towns.

The relative incompleteness of purification and cost of chemical precipitation in comparison with biological treatment methods has generally confined its application to special conditions, such as the needs of resort communities in which seasonal requirements and populations vary widely. The small amount of equipment needed to convert plain sedimentation tanks into chemical precipitation units is then in favor of the process.

**Biological Treatment.** The effluent from sedimentation tanks still contains relatively large quantities of putrescible organic matter in suspension and solution. The removal of this putrescible matter by converting it to a settleable state or by transforming it into relatively stable compounds, is the object of biological sewage treatment. The methods developed can be arranged in the following historical order: irrigation, intermittent sand filtration, contact beds, trickling filters, and activated sludge. Each of these processes represents an attempt to simplify procedures and decrease the size of the treatment plant required to accomplish the desired results.

The results of biological treatment are closely associated with the development upon a supporting medium, such as a filter of soil, sand, or broken stone, or such as flocculent sewage solids, of gelatinous growths of bacteria (*zooglea*) and other organisms, including fungi, protozoa, and higher forms of life. Sewage in contact

with the active surfaces of the supporting medium is exposed to numerous physical, chemical, and biological forces, including adsorption, the life activities of microorganisms, the action of enzymes, chemical coagulation, and the tendency of dissolved and colloidal substances to move to or away from an interface. Maintenance of areobic conditions is essential to the success of all normal biological sewage-treatment processes, and the result attained is sometimes referred to as oxidation, or "moist combustion." It is well to remember that the principal result of the most advanced treatment methods is the conversion of dissolved and finely divided solids into settleable solids. These form a secondary sludge which is called "humus" when it is derived from trickling filters and "excess" or "waste" sludge when it comes from activated-sludge tanks. Both of these secondary sludges are highly putrescible.

For comparative purposes we may summarize the normal loading and efficiency of common biological processes as shown in Table 41-6.

Table 41-6. Normal loading and efficiencies of biological sewage treatment plants

Process	LOADING		PER CENT REMOVAL OF	
	Thousands of Gallons per Acre Daily	Persons per Acre	Suspended Matter	Biochemical Oxygen Demand
Surface irrigation	0.75-20	10-2,000	...	...
Subsurface irrigation of settled sewage	5-10	100-200	...	...
Intermittent sand filtration				
Raw sewage	20-80	250-1,000	85-95	90-95
Settled sewage	50-125	500-1,500		
Biologically treated sewage	up to 500	up to 500		
Trickling filter treatment of settled sewage in 6- to 10-foot beds *				
Low-rate operation	1,000-4,000	12,500-50,000	70-92	80-95
High-rate operation	20,000-25,000	250,000-300,000	65-92	65-95
Activated sludge treatment of settled sewage in 15-foot tanks * †	10,000-20,000	125,000-250,000	85-95	75-95

\* Including final sedimentation of effluent.

† Removal reduced in high-rate treatment.

**IRRIGATION.** There are two types of irrigation projects: surface irrigation, also known as sewage farming, and subsurface irrigation.

In surface irrigation, raw, settled, or more completely treated sewage is applied intermittently to land, where it serves as food for crops. The principal value of the applied sewage, however, is the water itself. The sewage is distributed by ditches and other channels as in ordinary irrigation. It is applied to the land of crops by flowing over sloping fields from an upper to a lower ditch (ridge, surface, or broad irrigation), by passing through numerous furrows between beds (bed, or ridge and furrow irrigation, or land filtration), or by flooding underdrained fields surrounded by banks (flood irrigation). The sewage may also be sprayed upon the land from a system of movable pipes. A great variety of crops is raised on sewage farms. Among them are: grasses, beets, and other fodder, garden truck, corn, and

wheat; and walnuts and oranges. Considerations of hygiene demand that direct pasturage of dairy animals and the raising of produce that is to be consumed raw, even though sewage does not come into direct contact with it, as in bed irrigation, should not be permitted on sewage farms. The crops harvested from sewage farms frequently pay the expenses of operation, but they seldom return the interest on the investment. Only in arid regions is irrigation profitable. Surface irrigation is not successful with clayey soils. The degree of purification obtained by irrigation is usually satisfactory, both chemically and bacteriologically.

For small installations a satisfactory method of disposing of sewage by irrigation after sedimentation is to discharge it through three-inch or four-inch open-jointed tile pipes that are laid in the ground 18 to 36 inches deep in rows 5 to 10 feet apart. In tight soils the tile drains may have to be surrounded with gravel and sand. Subsurface irrigation is particularly applicable to suburban and rural conditions (see Fig. 41-4).

**INTERMITTENT SAND FILTRATION.** With this method the sewage is flowed intermittently onto beds of sand, especially prepared for the purpose. The quantities are such that the sewage quickly seeps into the sand and draws air behind it into the bed. A resting period of many hours then affords an opportunity for aeration and oxidation or stabilization of the organic matter. The filtration area is usually divided into beds that are surrounded by earth embankments which cover the distributing pipes. The beds are generally underdrained with tiles laid about 10 feet apart in fine material, or as much as 100 feet apart in coarse material, their depth below the surface varying from two to eight feet. After a few weeks or months the beds become clogged and must be raked to loosen the surface, the accumulated deposit on the sand being scraped off. In winter the beds may be plowed into ridges that will support a sheet of ice above furrows through which the sewage will flow. The bed is thereby kept from freezing and cracking (see Fig. 41-9).

Fig. 41-9. Cross section of intermittent sand filter.

The efficiency of intermittent sand filtration is higher than that of any other process; the effluent is quite clear and nonputrescible. Economy limits the method, however, to regions where suitable, convenient, and adequate areas of sandy soil exist. Intermittent filtration may be employed to advantage also following other biological processes of treatment where an effluent of especially high quality is to be secured to protect water supplies. After biological treatment the rates of filtration may be stepped up to values that are limited only by the permeability of the sand.

**TRICKLING FILTERS.** Trickling filters, also called "sprinkling filters" and "percolating filters," consist of beds of coarse material such as broken stone, coke, or clinkers over which the sewage is sprinkled and through which it percolates to

nderdrains laid on a tight floor beneath. The entire bed is arranged to ensure adequate ventilation in order that the oxygen requirements of the biological slimes that cover the contact material may be met at all times. The sewage solids transferred to the slime are not permanently retained in the bed but are unloaded more or less intermittently in the effluent, from which they must be removed by secondary sedimentation. As shown in Table 41-6, trickling filters are operated at low or high rates. At low rates of operation solids are stored in the filter for considerable periods of time; at high rates "unloading" is more or less continuous. The seasonal unloading of low-rate filters produces solids that have served as abulum for vast numbers of living things and are often quite well stabilized and humus-like. The sludge from high-rate filters is relatively more putrescible.

The sewage is sprayed onto the beds as continuously as possible through fixed nozzles or by rotating or traveling sprinklers that are operated by the discharging sewage or by power (see Fig. 41-10, A). The beds vary in depth from 3 to 10

Fig. 41-10. Trickling filter.

A, transverse section of circular filter with rotary distributor of sewage; B, schematic illustration of recirculation of effluent through filter.

et, coarser material sometimes being used for the deeper beds, and shallow beds often being arranged serially in pairs. Formerly, trickling filters were operated intermittently because it was believed that a resting period was needed as for sand filters. To ensure proper hydraulic performance of the nozzles, the filters may have to be preceded by specially designed dosing chambers.

The efficiency of trickling filters varies with the strength of the sewage and the rate of operation. The efficiency of high-rate filters can be increased by recirculat-

ing the effluent through the bed. Recirculation is employed also to keep up the flow through the bed during periods of low sewage discharge to the treatment plant (see Fig. 41-10, B). In a sense, recirculation exposes the entire depth of filter to approximately the same concentration of sewage. The filters of small plants may be covered to prevent odor and fly nuisance and to keep the filters warm during cold weather. The occurrence and control of trickling filter flies are discussed later.

**ACTIVATED SLUDGE.** If air is blown into sewage standing in a tank, the particles of colloidal and suspended matter will flocculate and form an anchorage and source of food for zoogeleal biological growths much like the slimes covering the contact medium of sewage filters. The resultant flocs are known as "activated sludge"; once formed, they will persist and grow in bulk so long as they are brought into contact with new sewage and the oxygen requirements of the activating organisms are satisfied. In principle, the process resembles that of filtration, the sand grains or stones of sewage filters being replaced by sludge particles suspended in the liquid.

Aerobic conditions and mixture can be obtained in two ways. Finely divided air can be forced through the tank by the use of perforated pipes, diffusers, and other devices, or the sewage can be agitated mechanically, new surfaces of liquid being brought into contact with the atmosphere from which they absorb the required amount of oxygen. The first is termed *bubble aeration*, the second *mechanical aeration*. In both methods the sludge is kept in suspension throughout the liquid. Combinations of diffused air and mechanical agitation can also be employed. Ordinarily the volume of activated sludge is about 20 per cent of the

Fig. 41-11. Activated sludge aeration units.

A, transverse section of rectangular battery of diffused air units producing spiral flow.  
B, transverse section of rectangular unit employing mechanical agitation by paddles, aeration being aided by diffused air.

volume of the incoming sewage and the time of aeration varies from four to six hours. An aeration tank is shown in Figure 41-11. In activation by aeration, the amount of air used varies from 0.5 to 1.5 cubic feet per gallon of sewage. In all types of tanks a velocity of 1.5 feet per second is sufficient to keep the sludge in suspension and will permit surface aeration provided that the tanks are so designed that the sewage is well mixed during travel. The activated sludge is permitted to pass out of the tanks together with the treated sewage and is then separated from it by sedimentation. Vertical or mechanically cleansed secondary settling tanks are used quite commonly (see Figs. 41-8, B, C and D).

The sludge collected from the sewage is in part returned to the influent to the aeration units (about 94 per cent), and in part wasted as excess sludge (6 per cent). Modifications of the conventional process include: *reaeration* of the sludge after minimal aeration of the sewage; *step aeration* by adding sewage at two or more points along the aeration channel; *two-stage aeration* by dividing treatment between two similar units and by return and wasting of the sludge within each stage or the return of second-stage excess sludge to the first stage; and *high-rate treatment* by short-period aeration and either very high or very low sludge return.

**Disinfection of Sewage.** None of the processes so far described can be relied upon to furnish an effluent free from pathogenic organisms, despite the relatively high degree of purification obtained by the best processes. In order to protect oyster beds, waterworks, or bathing beaches, therefore, sewage is sometimes disinfected.

Disinfection is obtained by means similar to those used in water purification. Gaseous chlorine and chloride of lime are most commonly used. The quantities of chlorine required per million gallons of fresh sewage are approximately 50 to 100 pounds for raw sewage, 40 to 80 pounds for settled sewage, 25 to 50 pounds for chemically precipitated sewage, and 20 to 40 pounds for biologically treated sewage. For stale or septic sewage these values may have to be doubled. To secure satisfactory disinfection a chlorine "residual" must be maintained during an adequate contact period. A residual of 0.5 parts per million after 15 minutes of contact is often specified, but the required time of contact may be up to two hours.

In addition to a reduction of 95 to 99 per cent of the bacteria, the biochemical oxygen demand of chlorinated sewage is reduced, the decrease varying with the condition of the sewage treated. This is of importance in connection with the disposal of sewage and in keeping sewage fresh in extensive collection systems or long outfalls. Chlorine will also control odors about sewage treatment works.

**Bacterial Efficiency of Sewage Treatment Processes.** By way of recapitulation, the following average figures show the relative bacterial efficiency of the common processes of sewage treatment:

PROCESS	PERCENTAGE REMOVAL OF BACTERIA
Coarse screens . . . . .	0 to 5
Fine screens . . . . .	10 to 20
Grit chambers . . . . .	10 to 25
Sedimentation . . . . .	25 to 75
Chemical precipitation . . . . .	40 to 80
High-rate trickling filters . . . . .	80 to 90
Low-rate trickling filters . . . . .	90 to 95
Activated sludge process (less in high-rate operation) . . . . .	90 to 98
Intermittent sand filters . . . . .	95 to 98
Chlorination of raw or settled sewage . . . . .	90 to 95
Chlorination of biologically treated sewage . . . . .	98 to 99

**Choice of Sewage Treatment Methods.** The choice of treatment methods depends upon numerous considerations, including the nature of the sewage to be treated, the allowable character of the effluent with reference to the use made of the water into which it is to be discharged, the availability of suitable areas of land at proper elevation, and the costs of construction and operation.

The most common combinations of sewage treatment methods employed in the United States are:

*Primary treatment*—coarse screens (combined systems); grit chambers (combined systems); skimming tanks (sometimes); plain settling tanks with separate sludge digestion; pre-aeration tanks in advance of biological treatment (sometimes).

*Biological treatment*—trickling filters, or activated sludge tanks, both followed by secondary settling tanks.

## SEWAGE SLUDGE

The solids removed by the different treatment processes constitute the principal by-product of sewage treatment. Excepting screenings and the deposits obtained in grit chambers, the solids removed are called sludge. If the daily volume of sewage treated runs into millions of gallons, the amount of sludge to be disposed of will run into thousands of gallons daily. Because of its bulk, putrescibility, and potential inclusion of organisms of disease, the sanitary disposal or utilization of sewage sludge presents one of the most troublesome problems associated with the management of sewage works. The sludge obtained by different sewage treatment methods varies greatly in amount, chemical composition, and physical characteristics. Table 41-7 presents a general statement of these variations.

The relatively large volumes of sludge produced by the activated sludge process are due not only to the removal from liquid sewage, as by the trickling filter, of colloidal as well as finely divided suspended matters, but also to the watery consistency of the sludge produced. In this connection it should be realized that decreasing the water content of a sludge from 98 per cent (2 per cent solids) to 96 per cent (4 per cent solids), i.e., doubling the content of solid matter, decreases the volume of the sludge by about 50 per cent. The high weight of chemically precipitated sludge is accounted for by the inclusion of the precipitated chemicals and constitutes an inherent disadvantage of this treatment process. Drying renders undigested sludges relatively stable by depriving the saprophytic organisms of the moisture necessary to the free function of their life processes. Digestion or anaerobic decomposition not only reduces the bulk of the sludge by producing a less watery sludge, but results also in a loss of solid material by liquefaction and gasification.

**Sludge Treatment.** Treatment of the sludge produced by different sewage treatment processes is undertaken with a view to rendering the final disposal of the sludge economical and inoffensive. Utilization of the sludge solids as fertilizer and of combustible gases produced by the sludge during digestion is generally of secondary importance. The treatment processes commonly employed are: digestion, air drying; vacuum filtration; and heat drying with or without incineration. These processes may be used singly or in combination.

**DIGESTION.** Saprophytic bacteria and other organisms find in sewage solids an abundant source of food, different groups of organisms utilizing different types of food substances originally contained in the sludge or produced in the course of decomposition. As the nutritive elements are used up, the sludge becomes more stable and, in its final state, inoffensive to sight and smell. It is then said to be well digested. The end-products of digestion are gases, liquids, and a residue of mineral and relatively undecomposable organic matter. Losses by gasification and liquefaction of solid materials, as well as increased density and compaction of the

Table 41-7. Normal \* amount and character of sludge produced by different processes of sewage treatment

TREATMENT PROCESS	GALLONS OF SLUDGE PER MILLION OF SEWAGE	POUNDS OF DRY SOLIDS PER MILLION GALLONS OF SEWAGE	PER CENT SOLIDS IN SLUDGE	PER CENT ORGANIC MATTER IN DRY SOLIDS	APPEARANCE	ODOR WHEN FRESH	PUTRESCIBILITY AND DIGESTIBILITY	RESPONSE TO AIR DRYING

† Varying with types and degree of treatment.

†† Varying with rate of filter operation.

solid particles, reduce the bulk of the sludge to a marked extent. Sludge digestion is an anaerobic process as oxygen cannot diffuse sufficiently rapidly into sludge from water or atmosphere to satisfy the demand of the living organisms. The gases of decomposition, therefore, are substances such as methane, carbon dioxide, hydrogen, hydrogen sulphide and nitrogen; chiefly methane (65 to 80 per cent by volume) and carbon dioxide. The normal daily volume of gas produced on a per capita basis is about 1.0 cubic foot from plain sedimentation sludge and 1.1 to 1.5 cubic feet when trickling filter humus or excess activated sludge is digested together with the solids resulting from primary sedimentation or when sedimentation is increased by chemical precipitation. Industrial wastes, rich in organic matter, may increase the gas yield appreciably. The high methane content of sludge gas makes its fuel value (670 British thermal units per cubic foot) equal to or greater than that of most illuminating gases and renders it possible to utilize the gases of decomposition for various treatment plant purposes, such as the heating of buildings and digestion tanks and the production of power for pumping, air compressing, or other mechanical work.

Sludge digestion proceeds best when the raw solids are seeded with well-digested material and when the temperature of digestion is kept uniform and high. Seeding inoculates the raw solids with the proper bacterial flora and, by the strong buffering action of well-digested sludge, serves also to keep the hydrogen ion concentration of the digesting sludge close to the favorable neutral point. Artificial reduction of acidity by lime may have to be resorted to in the absence of seeding. Digestion is hastened by heating digestion units to favorable temperatures. Sludge held at 90° F. for example, will digest in about half the time that is required at 60° F. Heat is provided by the sludge gas. This is either burnt under a hot-water or steam boiler, in a heat exchanger within the tank itself, or in a gas engine the cooling water and exhaust gases of which serve as the heating medium. Optimum temperatures are 95° F (mesophilic) and 130° F (thermophilic). Values just below the lower optimum are commonly employed in practice.

The sludge digestion compartment of Imhoff tanks cannot be heated successfully, because most of the heat is lost to the sewage flowing through the settling compartment. Where digestion is to be speeded up by heating, therefore, separate digestion tanks are employed. These tanks are covered to capture the sludge gases and are usually heated by hot-water coils (see Fig. 41 8, F). The sludge storage capacity of digestion tanks for plain-sedimentation solids is generally about 1 cubic foot when the normal digestion temperature is 60° F, and the required capacity should be doubled or halved for a fall or rise of 30° F, respectively. When trickling-filter humus or excess activated sludge are to be digested with plain-sedimentation sludge, they are generally returned to the influent of the primary settling tanks and permitted to settle with the primary solids before being digested. Digester capacity must then be increased by 30 to 60 per cent for trickling filter humus and by 70 to 130 per cent for excess activated sludge. Thickening the sludge before digestion reduces the digester volume. The overflow liquor from separate digestion tanks is usually foul and is returned for treatment to the sewage entering the plant, in general without ill effects.

Utilization of the gases of decomposition requires a thorough appreciation of the explosion hazards involved.

**AIR DRYING.** The most common method of dewatering sludge is its air drying by flowing it in layers 1 to 12 inches thick onto underdrained sand, gravel, or under beds. Part of the moisture retained in the sludge is evaporated, and part percolates through the bed into the underdrains. The time required for drying varies with climatic conditions and the character of the sludge. Well-digested sludge is less offensive and dries more readily than relatively fresh sludge. In northern climates the drying area required varies from one to three square feet per capita for well-digested sludges; in southern climates the area required can be reduced. The lower figure is for primary sludge, the higher for mixtures of primary and activated sludge. Trickling filters add 0.6 square foot of drying area to the lower figure, and chemical precipitation adds 1.0 square foot. Glass-covered drying beds may require but half the area of open beds. When the sludge has dried sufficiently to become spadable it is removed from the beds.

**VACUUM FILTRATION.** Attempts to dewater sludge in filter presses and centrifuges in which the excess liquid is either pressed or thrown out of the sludge have given way to continuous vacuum filtration in which the sludge is dewatered by suction and forms a sludge cake. The waste liquor is highly offensive. The sludge is generally coagulated with chemicals in advance of filtration, ferric chloride being commonly employed as the conditioning agent. The amount of ferric chloride needed to coagulate digested sludge, which is highly alkaline, can be greatly reduced by washing the alkalinity out of the sludge with clarified sewage. This is called *striation*.

**HEAT DRYING.** The sludge cake produced by air or mechanical drying is sometimes further dewatered to commercial dryness (not more than 10 per cent moisture) by driving off excess water by heat. This is an expensive process. To offset its cost, the dry sludge may be ground and sold as fertilizer. Instead of recovering the sludge as fertilizer, the drying temperature may be raised to the point of ignition of the sludge which is then incinerated and provides the heat necessary to maintain the drying process. Direct recovery of heat by incineration of the sewage solids makes sludge digestion less advantageous. Fresh sludge in the dry state has a calorific value equal to that of lignite or peat, while digested sludge has but half its value. The fuel value lost from the sludge by digestion is more or less recovered as combustible gas.

**Sludge Disposal.** Among the ways for the final disposal of sewage sludge are: pumping into water, lagooning and trenching, filling and fertilizing.

**DUMPING.** Some of the larger seacoast towns discharge the wet or dewatered, fresh or digested sludge into the sea, either by direct pumping or by loading it into sludge vessels or barges in which it is carried out to sea and dumped in deep water. This method of sludge disposal is also used by some of the cities situated on great lakes or large rivers.

**LAGOONING AND TRENCHING.** Where there is much low-lying land in the vicinity of the disposal plant, it is a relatively simple matter to throw up dikes or utilize natural depressions in the ground to receive the wet sludge, which then forms a sludge lagoon. In these the sludge dries slowly. Where much land is available, the sludge is left in place until the lagoon is filled; where land is scarce, the sludge is moved after drying and disposed of in other ways. The odors rising from sludge lagoons that receive undigested or partially digested solids may be troublesome.

Sometimes the sludge is run into trenches which are covered with earth. After the sludge dries it is worked into the soil by plowing. The disposal area required then naturally large.

**FILLING.** Dried sludge is well suited to fill low-lying land, and much waste land can be reclaimed in the neighborhood of treatment works by careful filling.

**USE AS A FERTILIZER.** The use of sewage sludge as a fertilizer continues to be advocated as a measure of conservation. All sewage sludges contain nitrogen and some phosphorus and potash. Digested sludges, furthermore, are humus-like and possess soil-building properties. Municipalities are sometimes able to dispose of wet sludge or sludge cake to farmers who use it for fertilizing purposes. A charge is often made for the material. Dried activated sludge has excellent fertilizing qualities and is especially useful on lawns and golf greens. The revenue derived from the sale of dry sludge may, under favorable conditions, offset the expense of dewatering.

**Hygienic Aspects of Sludge Utilization.** A number of sanitary hazards are involved in the use of sewage sludge for the fertilizing of crops. These are not confined to the transmission of bacterial diseases, such as typhoid fever and dysentery through contaminated vegetables or other agricultural products that are consumed raw, but include the possible spread of virus diseases such as infectious hepatitis and of amebic dysentery and worm infections, notably ascariasis. Under favoring conditions, furthermore, sewage sludge may pollute the soil and contribute to the transmission of hookworm infection.

In a general way, fresh solids are more dangerous than well-digested sludge and wet solids more so than partly dry solids. Air-dried solids are relatively safe and heat-dried solids distinctly safe. Although the survival of pathogenic bacteria in digesting and air-dried sludge may be short, Cram (1943) has reported that the cysts of *E. histolytica* survive in sludge for 10 days at 30° C; the eggs of *Ascaris* for six months (10 per cent survival); and the eggs of hookworm for 4 days at 30° C. She has also found *Ascaris* and hookworm ova to be very resistant to air drying. The heating of pulverized sludge to 103° C for three minutes, on the other hand, destroyed all *Ascaris* eggs.

**Choice of Sludge Disposal Methods.** The choice of sludge disposal method like that of sewage disposal depends upon numerous factors, such as the general location of the community, the demand for sludge as a fertilizer, the economics of sludge treatment, and the availability of land for disposal.

**Management of Sewage-Treatment Works.** Proper management of sewage treatment works is as important as proper design, and is more difficult to secure. Neglect not only makes the effluent unsatisfactory but leaves the works themselves in an offensive condition. Neglect of small plants is more common than of plants large enough to require full-time employment of one or more trained attendants.

Another frequent cause of failure is that treatment works are allowed to become outgrown, so that the plant becomes overloaded. The sewers of a city are usually designed for a long period in advance—40 or 50 years—but this is not the custom with treatment works, for the reason that such works can ordinarily be enlarged when necessary. If they are enlarged at the required time, this is sound policy because methods of treatment are constantly improving and it is desirable to take advantage of these improvements.

The treatment of sewage is a highly technical matter, and it is desirable to have the works in charge of qualified personnel with a laboratory at their disposal. Tests of the sewage before and after treatment should be made regularly in order to ascertain the efficiency of the process. Tests should also be made of the water into which the sewage is discharged. Where plants are of large size, such tests are made daily; but where plants are too small for the employment of a full-time chemist, tests should be made regularly by some controlling authority. Herein lies one of the functions of health departments.

**Treatment Plants as Nuisances.** If sewage treatment works are properly designed and carefully operated, and if they are enlarged from time to time to meet the needs of the growing community and changing demands upon the receiving bodies of water, they will not cause offensive conditions. Opprobrium is, nevertheless, generally attached to the areas in which such works lie and results in a recognized deterioration of property values. If the sewage reaching the treatment works is stale, odors may arise and reach distances up to perhaps half a mile from the plant, depending upon the amount and character of sewage treatment, the local topography, prevailing direction of the wind, humidity in the atmosphere, and other conditions. Modern treatment works, however, can be designed and operated to keep complaints within reason.

High winds will carry the spray from trickling filters or activated sludge tanks for several hundred feet with inevitable pollution of the air. Little hygienic significance seems to attach to this phenomenon, however. At certain seasons of the year swarms of minute flies (*Psychoda*) breed in trickling filters. These flies are troublesome in the immediate vicinity of such works because they enter the mouth, nose, ears, and eyes of plant personnel. Too small to be kept out of habitations by ordinary window screens, their radius of flight fortunately is small. Filter flies can be kept in check by DDT residual spray on walls of the bed and adjacent buildings and other shelters.

## COOPERATIVE SANITATION

What appears to be needed for the most effective utilization of water resources is some method of cooperation by which needed sanitary controls can be exerted at least expense. It is unbusinesslike to compel the treatment of the sewage of a large upstream city in order to protect the water supply of a small city lower down, when pure water can be furnished the latter in some better and cheaper way. Legislation that clothes water authorities with power to prevent the pollution of streams with sewage, but does not give them power to compel the purification of water or to control pollution by industrial wastes, is unfortunate. It naturally leads to litigation rather than cooperation, and it may retard rather than hasten necessary sanitary reform. State authorities are ordinarily entrusted with this matter and may in with the authorities of neighboring states to create interstate authorities that can deal with natural hydrographic areas that overlap state boundaries. Interstate waters and the boundary waters of the country are also the concern of the national government. In whatever form the authority is constituted, the idea of cooperation should prevail. There should be, in particular, a rational distribution of the burden of water purification and sewage treatment, and an equitable adjustment of cost

between the parties interested, thus decreasing the total expense of sanitary measures required and utilizing natural resources to greatest advantage.

## REFUSE DISPOSAL

GORDON M. FAIR, M.S., DR.ING.

The refuse disposal problem is one of economy, convenience, and general cleanliness rather than hygiene. Odors rising from fermenting garbage or the processes connected with garbage disposal do not injure the public health directly, yet they are offensive to the sense of smell and interfere with the enjoyment of an otherwise healthy environment. From this standpoint their elimination is an important matter. Garbage attracts numerous insects, particularly flies which feed in unprotected garbage receptacles and sometimes rise in swarms from dumps in which garbage, manure, or other organic wastes are permitted to accumulate. These places also provide food for rats and other vermin, and may support large rodent and insect populations. As shown later, the feeding of garbage to hogs increases the incidence of trichinosis both in the swine and human population. Accumulating rubbish creates a fire hazard as well as being offensive to the olfactory senses and affording an opportunity for mosquito breeding in tin cans and other discarded receptacles that become filled with rain water and that shelter the insect larvae and pupae until maturity. Ashes and street dust are easily lifted by wind and when blown about may irritate eyes, nose, and throat. The indirect effects of refuse disposal on the public health are, therefore, many, and the sanitary disposal of wastes, more particularly garbage, is of concern to health departments, although needed operations are left to other municipal departments.

**Composition and Quantities of Refuse.** The general term "refuse" is applied to all of the solid waste material from human habitations not carried by the sewers. Such it includes ashes, rubbish, garbage, street sweepings, and dead animals, as shown in the classification following. Excreta, which form part of the solid wastes of a community, although included in this classification, are considered in Chapter 41.

- A. Public Refuse—municipal responsibility for collection and disposal.
  1. Originating in homes, hotels, institutions, markets, stores.
    - a. Garbage: Wastes from the handling, storage, sale, preparation, and consumption of food.
    - b. Rubbish:
      - (1) Combustible: Packaging materials, yard trimmings, discarded home furnishings.
      - (2) Noncombustible: Metallic and ceramic waste materials, and dirt.
    - c. Ashes: Residue from fires.
  2. Originating in public ways and vacant lots.
    - a. Street refuse: Sweepings, leaves, dirt.
    - b. Dead animals.

**B. Industrial Refuse**—private responsibility for disposal.  
Solid wastes from industrial operations.

The quantity of waste material that must be removed from cities is very large. The total amount of refuse is, roughly, half a ton per capita per year, and it varies with the size of the community, its industrial and mercantile activity, and its geographical situation. The amount of garbage varies from less than 100 to upward of 500 pounds per capita per year; the weight of rubbish from less than 200 to more than 500 pounds per capita per year; and the amount of ashes from less than 400 to more than 600 pounds per capita per year. In addition, from 20 to 80 dead animals must be disposed of annually per 1,000 population. Both the quantity and character of the refuse vary with the seasons, the maximum amount of ashes being produced in the winter and the maximum amount of garbage in the summer, keeping the total weight of refuse about the same in all months of the year.

Ashes weigh from 1,150 to 1,400 pounds per cubic yard; garbage, from 800 to 1,500 pounds; street sweepings, from 700 to 1,800 pounds; and rubbish, from 200 to 700 pounds.

**Collection of Refuse.** There are two general methods of refuse collection: the mixed system and the separate system. The choice of the system depends to a large degree upon economic considerations and the type of ultimate disposal. With the *mixed system*, all of the wastes are placed in a single receptacle by the householder. They are then collected in single conveyances and transported to the point of disposal where they are disposed of jointly. With the *separate system*, garbage, ashes, rubbish and other wastes are placed in separate containers by the householder and collected in separate wagons or trucks to be separately disposed of, usually in different ways.

The proper choice of receptacle for the storage of the various types of refuse will keep down nuisances in the neighborhood of human habitations. Garbage should be placed in covered metallic containers that render the contents inaccessible to dogs and other animals and do not permit the breeding of flies. Cities in which garbage is incinerated may require that all garbage be wrapped in paper before being deposited in the container. This keeps the can clean, prevents rapid fermentation in summer and freezing in winter, causes the householder to drain the garbage before wrapping it and placing it in the can, avoids the transportation of unnecessary amounts of water, and permits collection of the garbage in uncovered vehicles. Garbage cans should be thoroughly scoured from time to time. Ashes are commonly placed in covered metal containers. Rubbish is usually stored in barrels or tied into bundles. Because of its high market value as a fertilizer, stable manure, no longer an important element of municipal refuse, is usually removed by private individuals. Stable manure is a favorite breeding medium for flies and should be stored in well-drained receptacles that are as nearly fly-tight as possible. A concrete floor will make it impossible for the larvae to pupate in the ground. Storage of manure on a slotted platform above a concrete floor covered with a few inches of water, will cause the downward burrowing larvae to drown. Compacting of manure raises its temperature and kills fly maggots as well as intestinal parasites. The use of insecticides for the destruction of fly maggots is not an efficient measure because of the large quantities of organic matter in the manure, but a solution of borax in water is useful for controlling the development of fly larvae in the surface.

yers of compacted manure. Adult flies are destroyed by residual sprays (see page 458).

The frequency of refuse collection varies with the season of the year. Garbage produced in greater bulk during the summer and ferments more rapidly in hot weather. This is also the time in which the breeding cycle of flies is shortest (about 10 days). It is, therefore, commonly collected at shorter intervals of time during the summer months (two to four days) than in winter (three to seven days). The garbage of hotels, restaurants, and markets is generally collected daily. Ash and rubbish collection is more frequent in winter than in summer.

**Disposal of Refuse.** In rural or sparsely settled communities the disposal of refuse is a simple matter. Garbage is fed to domestic animals, notably chickens and pigs. Failing this, it is either buried in field or garden or burned together with rubbish. Incineration is readily accomplished in suitable wire baskets. For large dwellings, isolated hotels, or camps, stone or brick incinerators are sometimes built. As shown in Figure 42-1, A, the damp refuse is thrown onto the drying

Fig. 42-1. Incinerators.

*A*, destructor suitable for camps, isolated dwellings, and small communities; *B*, cross section of a Decarie incinerator.

shelf of this incinerator, whence it slides or is pushed into the fire. If fly proof, this pattern may be used for the incineration of feces. In temporary camps the refuse can either be buried, or burned in open pits lined with rubble. In the circular rock pile crematory, the fire is built in one quadrant and the solid wastes are thrown into it. A central pile of rocks assists in creating a draft and offers a large surface for the evaporation of liquids which are poured into neighboring quadrants. When fuel is scarce and stones few, the Caldwell or English crematory can be used. It consists of a trench 10 feet long and 1 foot wide. It slopes from the surface at either end to the center where it is about 15 inches deep. A barrel is placed over the deep portion and a chimney of clay, earth, or sand properly tamped is built around it. A fire is made in the pit and the barrel is burned out, after which the solid cone of earth remains. Fuel and garbage are dropped through the chimney. The leeward opening is closed and a bed of tin cans is provided to take the place of a grate.

In urban communities refuse disposal becomes an important and sometimes vexing sanitary problem. A number of different methods are in use, as illustrated in Table 42-1. Composting of garbage and other refuse for conversion into fertilizer has not established itself in American practice.

Table 42-1. Methods of municipal refuse disposal

DUMPING AT SEA	SANITARY FILL	INCINERATION	FEEDING	REDUCTION	GRINDING
Garbage	Garbage	Garbage	Garbage	Garbage	Garbage
Animals	Ashes	Animals		Animals	
Ashes	Rubbish	Rubbish			
Rubbish	Street	Excreta			
Excreta	sweepings	Street			
Street		sweepings			
sweepings					

The choice of the system of disposal depends upon local conditions and must be decided by economic as well as sanitary considerations. Reasonable sanitation at a reasonable cost is the most that can be expected.

DUMPING AT SEA. In many seacoast towns, some of the municipal refuse, particularly garbage, is disposed of by placing it in scows that are towed out to sea and dumped. It is probably the cheapest method of refuse disposal, but may result in the ultimate stranding of sometimes putrid waste materials along the water-line of beaches and banks. Dumping of refuse into inland waters is no longer countenanced.

SANITARY FILL. Some of the refuse materials, notably ashes, are well suited for filling low-lying lands, abandoned clay pits and tidal marshes. Many communities have made profitable use of this method for the disposal of their mineral, non-putrefying wastes, and large tracts of so-called "made land" have thus been created. The only objection to this method is the blowing about of fine ash dust during windy weather. In the "sanitary fill" the method is expanded to include all of the refuse produced by the community.

If, as shown in Figure 42-2, the mixed refuse is properly placed, compacted, and covered, fermentation cells are created in which the temperature at the three-foot level rises to 130 to 150° F in about four days, remains at this magnitude up to about 60 days, and returns to normal in just under a year. To be successful, the fill must be kept less than six feet deep, the area normally required annually being three quarters of an acre to an acre and a half for 10,000 people. A well-compacted fill will settle from 25 to 40 per cent in the course of time. It will not give rise to odors or harbor rats and insects. Fires will not be produced spontaneously, but the hazard of their being set must be guarded against. Dump fires will smolder for years, producing acrid smoke and foul stenches that are carried long distances by the winds. Unlike the selected fill of inert refuse, areas that have been devoted to sanitary-fill operations cannot be developed as building sites for many years, but they can serve as parks and playgrounds almost as soon as they are completed.

INCINERATION. Incineration is the destruction of wastes by fire. The mixed refuse of cities and towns contains much combustible material and is readily dis-

posed of by incineration. In the United States it is customary to exclude all or most of the ashes, although the latter sometimes contain as much as 30 per cent of unburned coal. Ashes, however, are large in bulk and increase the operating difficulties of incinerator plants.

From Recommended Wartime Refuse Disposal Practice, U. S. Public Health Service, 1942.

Fig. 42-2. Sanitary fill operation on level ground.

1, dragline excavates trench; 2, truck discharges mixed refuse; 3, bulldozer places and compacts refuse; 4, cover material from trench is placed over refuse by bulldozer; 5, finished fill is impacted by trucks and bulldozer.

From the sanitary standpoint incineration affords an excellent method of refuse destruction, because the solids remaining after incineration are stable materials that can be used to fill lands adjacent to the incinerator. In order to prevent flours from the flue gases in the vicinity of incinerator plants, the temperature of the gases must be raised above  $1250^{\circ}\text{F}$ . Auxiliary fuel is frequently required to start the furnace. The steam generated by incineration can sometimes be usefully employed in operating the plant equipment and producing electric power, but steam generation requires incinerator temperatures of  $1800^{\circ}\text{F}$  or more.

Most incineration plants possess patented features that are intended to make them more economical or to secure speedier or surer operation. In some plants the refuse is first dried or heated before passing onto the incineration grates; in others it is deposited directly in the furnace. The hourly amount of mixed refuse burned varies from 50 to 80 pounds per square foot of grate area. The ashes produced equal from 15 to 50 per cent of the material burned. Incinerators are sometimes built into apartment buildings and residences, a chute carrying the wastes into the furnace (see Fig. 42-1, B).

**GRINDING.** The employment of sewers for the water-carriage of garbage from kitchens and markets is a logical expansion of this transportation system for household and industrial wastes. The garbage must be comminuted before it is discharged into the sewers. Otherwise it will cause stoppages. Individual household grinding units, or central grinding stations are provided for this purpose. The increased load of putrescible matter received by the sewage treatment and disposal

works must be given due consideration. The discharge of excreta into sewers is discussed in Chapter 41.

**Management.** The sanitary collection and disposal of refuse is a proper governmental function justifiable under the police power. In many small communities, however, refuse disposal continues to be undertaken by private enterprise without systematic governmental supervision. In some of the larger communities both the collection and disposal are entirely in the hands of the local authorities. In others the refuse is collected by the municipality but disposed of by private parties. In still others collection as well as disposal is contracted for. It is possible to obtain satisfactory results both with the municipal system and the contract system, but the latter is generally the more economical one. Salvaging operations for the recovery of paper, rags, bottles, and cans are sometimes included in the disposal of municipal refuse.

## Section Eight

# METHODOLOGY

## 43

### EPIDEMIOLOGY

**Introduction.** Epidemic is a very old word, dating back at least to the third century, B. C. in the writings of Hippocrates. Epidemiology as a field of medical science is a concept which has been gradually formulated during the past century. By derivation, it is concerned with the explanation of epidemics of disease in human populations. While this definition still obtains in part, with the advance of biologic and medical science, usage of the term epidemiology has become more inclusive. An epidemic is commonly a sudden increase in the prevalence of a disease which is more or less constantly present, or endemic, in a community. To explain the sudden increase it is necessary to understand the factors and conditions which determine the usual or interepidemic levels of prevalence and the characteristic distribution which the disease ordinarily manifests in human population.

The widening horizon of the biological universe has extended use of the term epidemiology to the study of disease in animal populations and plant life. Although "epizootic" and "epizootic" have been used by veterinarians to describe the level of prevalence of diseases in animal populations, it is now considered good usage to refer to the epidemiology of cattle plague or of foot and mouth disease. While it is etymologically correct to use "epiphytic" to refer to an outbreak of infectious disease in plants, a modern plant pathologist may prefer to describe his observations on the stem rust of wheat under the title of epidemiology. Such usages are justified by the derivation of the word epidemic, which literally translated from the Greek means "upon the population." The population may be composed of people, animals, birds, fish, plants, or whatnot. Moreover, while in its early history epidemiology was largely concerned with infectious diseases, it has been found profitable to make a similar approach to the understanding of diseases of unknown origin, conditions due to nutritional deficiencies, to senescence, to abnormal cell growth, and even to casualties caused by physical or chemical agents, accidents, etc. Thus, usage has extended the meaning of epidemiology beyond its original limits to designate not merely the doctrine of epidemics but a science of broader scope in relation to the mass-phenomena of diseases in their usual as well as their epidemic occurrences. The subject is pursued here with a homocentric bias, since the concern is primarily with human welfare. For present purposes, therefore, *epidemiology is defined as that field of medical science which is concerned with the relationships of the various factors and conditions which determine the frequencies and distributions of an infectious process, a disease, or a physiological change in a human community.* It seeks to advance rational conceptual schemes of causation of the various ills that afflict mankind medically speaking. To the extent that this body of knowledge is advanced and valid, it becomes possible for appro-

priate community agencies to take effective measures directed toward prevention, control or eradication. As defined the field is a broad one.

Consideration of the principles and methods of epidemiology can be developed with advantage if the discussion is limited at first to the infectious diseases. In previous chapters, infectious diseases have been individually treated. For each there has been presented some account of the identifying clinical syndrome, the more important attributes of the causative agent, and the manner of its occurrence in human populations in terms of its geographical and seasonal distribution, selectivity for various population groupings, such as sex, age, race, and occupation, endemic and epidemic prevalence, etc. It has become apparent that each has a characteristic epidemiological pattern as well as clinical pattern. There is an endless variety and it would appear on the surface that each is a law unto itself. Yet there are generalizations which can be applied to the behavior of all infectious diseases in human populations. The conceptual scheme upon which these generalizations depend was comprehensively formulated by Theobald Smith in 1934.

*Infectious disease is a manifestation of parasitism.* Acceptance of this concept marked an important transition. The medical explanation of disease broadened to become a biologic one. Infection was no longer set apart as a phenomenon peculiarly within the province of human medicine but was viewed in its natural relationships as an expression of the eternal struggle of living things for food by predation or parasitism, for shelter and for propagation of their kind. More particularly, it is the reaction between one of the higher forms of life to the invasion of its tissues by some species of microparasite. This conception carries with it implications that are fundamental and far-reaching. It affords a framework or pattern into which endless scattered observations can be fitted. Explanation of epidemics can then be sought in host-parasite relationships and the environmental factors which modify them.

As a result of centuries of host wanderings, mutation and selective adaptation, certain worms, protozoa, fungi, bacteria, rickettsia, and viruses have in some degree become established in the biologic orbit of man, and are responsible for some of his ills. Their potentialities range from those which only rarely and inadvertently invade his tissues to cause an occasional sporadic case of a rare disease, to those which are dependent upon human tissues for their continuous propagation, sometimes giving rise to epidemics which decimate tribes or nations and change the course of history. The importance of each parasite species to man has been determined by a few biological conditions to which only brief reference can be made.

Man may be an obligate, a principal or an occasional host species, according to the degree of success which a particular species of parasite has in passing through four critical stages in relationship to him. A micro-organism may become completely dependent upon man for its survival if it is continuously successful (1) in finding entrance into his body through its proper portal of entry, whether it be the mucous membrane of the respiratory, the alimentary or the genito-urinary tracts, or the skin by means of trauma or insect bite; (2) in reaching the particular organ, tissue or cells in which the nutritive conditions are most favorable for multiplication; (3) in making an exit from the body in excretions, secretions, or by blood-sucking arthropods; (4) in surviving under the conditions of the external

environment, or in an arthropod vector, a sufficient time to reach a new susceptible host. To the extent that it is unsuccessful in continuously maintaining progressive passage through these four critical stages in human populations and their environment it must be able to utilize other host species or survival mechanisms. Thus, one of the first requisites of a rational explanation of the behavior of an infectious disease in a human population is to understand *to what extent man as a host shares responsibility for the continuous propagation of the causative microparasite with other species—animal, bird or arthropod.*

**Incubation Period.** The first stage in infection is the incubation period, that is, the interval of time from primary invasion through skin or mucous membrane to the onset of symptoms of the disease. Its length depends upon the peculiarities of each particular host-parasite relationship. It is extremely short, a matter of hours, when the symptoms are due to preformed growth products or to large numbers of micro-organisms which have already had opportunity to multiply in the ingested foodstuff, as in some *Salmonella* infections. It is short, a matter of days, when the microparasite has more or less direct access to the tissue in which primary multiplication takes place, as in certain air-borne infections with microparasites which multiply in the epithelial cells lining the respiratory tract, as in influenza. It is longer in those infections in which the microparasite is unable to multiply at the site of entrance into the body but must make its way through lymph channels to regional lymph nodes by the lymphatics to the blood stream, in a stepwise multiplication and invasion, bypassing the defensive barriers and the phagocytic activity of the host tissues, ultimately gaining admission to the general circulation and affecting the organs or tissue cells for which it has a predilection and in which it can multiply, as with such diseases as typhoid. Thus, the incubation period may be a matter of hours, days, weeks or even months, but for any particular disease its length is relatively constant and predictable.

However, as with any other measurable biologic attribute, *the incubation period of a specific infectious disease manifests a constant range of variation.* Most frequency distributions of incubation periods bear a resemblance to the normal curve with slight skewness, rising more abruptly on the short side of the mean; examples are shown in Figure 43-1. As Sartwell (1950) points out, the degree of variation in relation to the magnitude of the mean has a constant statistical pattern, no matter whether the unit of time be hours, days, weeks or months. The range of the incubation period is an important epidemiological characteristic for each disease.

**Host Reaction.** Multiplication of the microparasite within the host organism up to the threshold point at which it disturbs the physiological state gives rise to the symptoms and signs of illness by which the disease is recognized. The second critical stage in the host-parasite relationship mentioned above ensues. The host reaction or, properly speaking, the host-parasite interaction may vary greatly, both in severity and duration. A case of an infectious disease is a host reaction of sufficiently characteristic intensity and duration to permit clinical diagnosis. Reactions which are less intense and of shorter duration are called *abortive* or *suspected* cases, the pattern being too definitive or protean in nature to permit clinical diagnosis, except in association with *frank* cases. When the subjective and objective symptoms are so slight as to pass unnoticed, the host is said to suffer an *inapparent* infection. Infections which are below the threshold of clinical recognition are

grouped together as *subclinical*. They can be identified only by such procedures as cultural recovery of the infecting micro-organism from the host's tissues, as, for example, by nose and throat cultures for diphtheria bacilli; change in the response of the skin to specific antigenic material, as in the tuberculin test; or change in a serologic reaction from a negative to a positive, as in a serum neutralization test

From Sartwell, P. E., Am. J. Hyg., 51: 311

Fig. 43-1. Frequency distributions of incubation periods. Left, epidemic of food-borne streptococcal sore throat (scarlet fever) (in hours); right, a series of cases of serum hepatitis following administration of icterogenic lots of yellow fever vaccine (in weeks).

with the virus of influenza. It is at least theoretically possible that an infection may occur without demonstrable reaction on the part of the host, i.e., a symbiotic or a saprophytic relationship, but there is a difference of opinion as to whether the word infection should be used to describe such a condition.

**Infectious Period.** In clinical medicine, interest is centered upon a patient during the period that he or she is more or less incapacitated by the disturbance of physiologic functions caused by the invasion of a pathogenic micro-organism, i.e., from the onset of symptoms to clinical recovery or to a fatal issue. In epidemiology, interest must be broadened to include the whole duration of the host-parasite relationship, i.e., from the time of the infective exposure until the microparasite is suppressed or eliminated from the host's body. This includes the incubation period, clinical manifestation, convalescence, latent periods, relapses, to death or final elimination of the microparasite from the body. Of particular importance is the *infectious period*, the time or times during which the *microparasite progeny* are making an exit or are potentially available for transfer to a new host.

**Carriers and Inapparent Infections.** As early as 1890, Escherich noted that the infectious period of diphtheria was not necessarily coincident with the clinical course but that diphtheria bacilli might persist in the throats of patients during convalescence. In 1892, Guttman, Rommelaere and Simonds noted that cholera

prios might be recovered from the feces during convalescence. Credit probably longs to Koch (Winslow, 1943) for grasping the important fact that cases which could be clinically diagnosed were not alone responsible for the spread of contagious diseases. In his studies of cholera in Germany, during the winter of 1892-93, he noted that some cases were so mild that they escaped recognition, and indeed could be detected only with the aid of bacteriological investigation. The term carrier thus includes two classes. First, there are those who are about to have or have already had a clinical attack; they are designated as *incubatory*, *convalescent* or *chronic* carriers. Second, there are those who are suffering from a subclinical or asymptomatic infection, the so-called *healthy* carriers. It is important to distinguish between these two classes; for the purpose of this discussion, the second class of carriers will be included in the designation *subclinical* or *inapparent* infections.

**Pathogenicity.** The characteristics of the clinical reaction and the ultimate issue of the infectious process is determined by the balance between the devices of aggression of the specific species of microparasites and the mechanisms of defense of the host species, capacities for both of which are genetically transmitted. The attributes of the parasite which determine the outcome of the reaction are described by such words as infectivity, pathogenicity, virulence, antigenic power. These attributes, however, cannot be considered apart from those of the host which are opposed. These host attributes are described by such words as susceptibility and resistance. Resistance, in turn, is broken down into such concepts as genetic resistance, maternal immunity, naturally and artificially acquired immunity, antibody response, interference phenomenon, etc. These attributes, both of the microparasitic species and of the human host, are mutually relative and subject potentially to all degrees of quantitative variation, not only as between different species of microparasites and different broad population groups, but also between strains of the same microparasitic species and individuals in the same general group. For the sake of simplicity, in this discussion they will be included under a broad definition of the term pathogenicity.

In this sense, the *pathogenicity of a given microparasitic species for a human host population cannot be measured experimentally on animals*. It is indicated only by observations on the experience of human beings exposed to this particular infection under natural conditions. To the extent that infection may result in recovery or death, pathogenicity is roughly indicated by the proportion of attacks which are fatal. Stated in different words, it is a ratio between cases and deaths (usually the percentage of cases which are fatal) or the *case fatality ratio* of a disease. This ratio, however, may be affected in a considerable measure by non-specific conditions which affect the host population, such as starvation, lack of proper medical care, secondary invasion by other micro-organisms, or other factors.

To the extent that the infection may result in a residual of impaired function, pathogenicity may be indicated by the proportion of cases which exhibit paralysis or other defect. Finally, and more important, it is possible with many infectious diseases to estimate the proportion of the total number of individuals infected with a particular microparasite who manifest a characteristic clinical reaction, i.e., the ratio of subclinical to clinical infections. For example, in measles it is of the order 1:19; in diphtheria, in the age group 10 to 14, at the time of a particular study, it was 15:1. Such ratios vary not only with the species of microparasites but fre-

quently with different strains or types of the same species, as with streptococci and pneumococci.

**Successful Parasitism.** Successful adaptation of a species of microparasite to the human host does not imply a high order of pathogenicity. Rather the contrary is true. Success for a parasite, as for any other living organisms, can only be measured by the size of the population of its kind and its ability to survive and maintain these numbers in a constantly changing natural universe. There is no advantage if its host sickens and dies, since dissemination of its progeny accordingly becomes limited and soon ceases. The opportunities for scatter and chance of productive contact are increased in proportion to the length of time it can continue to multiply and find easy egress in large numbers from a host which is ambulatory and gregarious. Accordingly, a high case-fatality ratio may be a disadvantage to survival of a parasitic agent. Conversely, a low ratio of clinical to subclinical infections and a long duration of the infectious period tends to insure wide dissemination. The microparasites best adapted for survival are those which cause infection with the least inconvenience and injury to the host species, and create only a low grade immunity of short duration. A notable exception to this generalization is canine rabies.

Those infectious diseases which are continuously maintained by person-to-person transfer, in other words the *contagious diseases*, are caused by microscopic species which have been successful in their relationships with the human host. Those diseases which are not directly transmissible from man to man, or transmissible only occasionally under unusual circumstances, as in pneumonic plague (*noncontagious diseases*), are caused by microparasitic species which are unsuccessful in their relationships with the human host. In man, they represent aberrant parasitism. They succeed occasionally in making effective contact, multiplying and causing human disease but the pathology which they generate does not permit their exit from the body in sufficient numbers to make effective contact with a new human host. They must be maintained by and come from extrahuman sources. They have been successful in adapting themselves to survival in some host species, animal, bird or arthropod (as in human plague or tularemia); or by an alternation of human species by the intermediation of a vector (as in malaria); or they have found conditions under which they can survive, multiply and propagate in the environment outside the human body as, for example, such fungi as *Coccidioides immitis*. Obviously, the factors and conditions which determine the frequency and distribution of the first class of diseases are relatively simple and much more easily understood than are those that relate to the latter classes.

**The Dynamics of Contagious Disease.** The forces which create the dynamic phenomena of contagious disease are, in the ultimate analysis, population pressures, i.e., the innate impulse of living micro-organisms to multiply and survive by parasitism upon homo sapiens, and the efforts of this host to preserve its own integrity. The balance between these two forces is constantly fluctuating, just as are the interactions between all living species. When the balance is relatively stable, it is manifested by an *endemic* prevalence. When the balance is subject to sudden or violent disturbance it is manifested by *epidemics*. If the balance is in favor of the host, the disease shows a downward trend and tends to disappear. If the balance is in favor of the microparasite, the disease tends to increase in prevalence.

To represent these phenomena, and to facilitate reasoning with regard to them, is necessary to use quantitative indices. The conventional rates and ratios which are commonly used for this purpose are described in detail in the succeeding chapters. Reference here is made particularly to: (1) case, attack or morbidity rates; (2) mortality rates; (3) prevalence rates. Indirectly they express the relationship of the number of the parasitic population (numerator) to the number of the host population (denominator). The denominator (the number of individuals of the host population who are at risk of attack at any particular time or during any particular calendar period) can, in many situations, be counted or estimated with considerable accuracy. The numerator (number of parasitic micro-organisms in the same universe of time, place and persons) can only be indirectly represented. It is correlated in a rough way with the number of deaths, or cases, or infections caused by a specific microparasitic population. It must be constantly borne in mind that these quantitative expressions are not measurements but are indices of these biologic phenomena.

To represent the shifts in balance or changes in equilibrium between a micro-parasite and the host population, the expression of choice is, ordinarily, an attack rate based upon cases by date of report, onset, discovery, or admission to a clinic on successive days, weeks, months or years. If interest is limited to the frequency of the occurrence of such cases, and the population at risk is relatively constant during the period under consideration, it is unnecessary to calculate the rates. The time sequence of the number of cases reflects changes in the frequency with which the microparasite is spreading and gaining access to new susceptible individuals and, accordingly, the increase or decrease in the microparasitic population. This is well illustrated by the account which is given of the spread of measles (see measles, Chapter 1).

**Progressive or Contact Epidemics.** Frequently, the term epidemic refers only to a peak in the oscillating incidence of a disease more or less constantly present in a community. How great the increase in incidence must be before it is regarded as an epidemic is a matter of judgment, and is influenced by psychologic attitudes. The greater the fear of a disease, or the more unusual it is in a community, the smaller the increase needs to be to justify the use of the descriptive term. Many statistical devices have been suggested for making the definition more objective and precise (Rich and Terry, 1946), but no definition has yet received general sanction. Dependence is placed in general upon comparing the current incidence of a disease with its incidence in the past in the same population group and at the same time of the year. This expected number, or norm, is commonly expressed as a three-year or five-year median of reported cases. When current incidence exceeds this number, the disease shows the tendency, which if sustained and great enough, sooner or later merits the pronouncement of the presence of an epidemic.

Each contagious disease has a seasonal variation which follows a more or less regular pattern, reaching its maximal distribution about the same time each calendar year when conditions are most favorable for transmission. Each is subject also to an interannual variation, or secular trend, which may show slight or wide fluctuation, and some of which under limited conditions exhibit a more or less regular periodicity. For the common contagious diseases, most of the factors which affect the fluctuation in the rate of transmission are known and can be enumerated.

**CHANGES IN THE BIOLOGY OF THE MICROPARASITE.** Some species of microparasite are relatively stable in their biological attributes and show little capacity to vary toward higher or lower pathogenicity. Such, for example, is the case with the virus of measles. At the other extreme are species which are relatively unstable and show considerable ability to vary. Such, for example, is the case with the virus of influenza, which includes not only at least two immunologically distinct types (A and B) but which shows a considerable antigenic variability within each type. Type A is not immunologically homogeneous but includes a large number of strains which exhibit minor immunologic differences when measured by laboratory procedures. Between these two extreme examples are all gradations in the potentialities for strain variation. In general, those strains tend to propagate which are selectively best adapted to multiplication and survival in a human population at a particular time.

**GROUP OR HERD SUSCEPTIBILITY.** The human community is made up of a number of individuals who vary not only in their genetic capacity to react but nearly always in previous experience with the predominant strains of a particular species of microparasite or its close relatives. Some individuals have acquired a complete immunity, some a partial immunity, some none. The proportion of a population at any one time which has little or no immunity determines the theoretical level of a community, group or herd susceptibility for a particular contagious disease. If such a disease is commonly prevalent in a community, the proportion is a constantly changing one as susceptibles are infected, develop immunity and recover. If the immunity conferred by either subclinical or clinical infection is durable, then the group susceptibility decreases with advancing age as more and more of the population have had experience with this antigen, and the age distribution of cases consequently is that of a children's disease. If the immunity conferred is temporary, as with some acute respiratory infections, such as influenza, the same individual may be reinfected after a short interval, and consequently the disease may attack all ages, adults and old people, as well as infants and children. Thus, for each of the common contagious diseases there is a characteristic age distribution from which inferences may be drawn with regard to past experience and durability of specific immunity.

By means of a skin test or serological examination of a representative sample of persons, it is possible with some to establish the immunity status of a community. The age distribution of immunity may give information with regard to the time at which the disease was last present in the community. A good example of this type of observation is the report of Paul and Riordan (1950) on their findings with regard to the Lansing strain of poliomyelitis virus in sera from Alaskan Eskimos. In the belief that Eskimos have less exposure to poliomyelitis than do most other populations, serum samples from Eskimos living on the north coast of Alaska were collected and studied. Particular attention was paid to the presence or absence of neutralizing antibodies to the Lansing strain of poliomyelitis virus. Poliomyelitis is known to have been present along this north coast in 1930, but among the scanty and unreliable records available there is no note of its occurrence since that date. The neutralizing antibody test of this Lansing strain of poliomyelitis virus revealed that nearly all natives who were tested from the two villages, and who were below the age of 20 failed to have antibodies; whereas

in those who were age 20 and above about 80 per cent had these antibodies in their sera. The evidence suggested that there had been no exposure or infection to the causative strain in this remote community since 1930.

**POPULATION DENSITY AND MOVEMENT.** The critical level of susceptibility ("epidemic potential") required for the rapid passage or epidemic spread of a contagious agent varies from community to community, and even in the same community, at different times, depending upon population density and other factors. The degree of crowding or dispersal of a population may be indicated in many ways; the most common is the classification into urban and rural populations. Quantitative estimates are sometimes made of the number of persons per square mile, the number of individuals per house, or the number of persons per room. These expressions are intended to convey in a rough way an idea of the frequency with which one individual may meet or have contact with another individual under conditions which would permit the passage of infectious agents from one to the other. The association of the unusual prevalence of contagious diseases with crowding, in communities, in institutions, in jails, on ships, in barracks, in refugee camps, etc., is a very old one.

Opportunity for the dissemination of microparasites is obviously facilitated by the amount of population movement, travel and flow of people through a community. In isolated small communities, with a small natural turnover in population by births and deaths, many of the common communicable diseases are unable to maintain themselves over long periods of time; because of acquired immunity they tend to die out and must be reintroduced. Under modern conditions of travel, however, such communities are encountered only in the most remote parts of the world. Today there is a constant flow of people into and out of most communities. A sudden increase in the incidence of a disease may be precipitated by the arrival of a large number of susceptible individuals such as refugees, immigrants or recruits.

**HABITS OF LIVING AT HOME AND IN COMMUNITIES.** The customs and habits of the people are obviously important in affording opportunities for transmission. For respiratory diseases this relates to customs with regard to uncontrolled coughing, spitting, and sneezing. For enteric infections it relates to the habits of fecal disposal, hand washing, etc. For venereal diseases it relates to the habits with regard to promiscuous sexual intercourse. The general concept is expressed in terms of the level of household cleanliness and personal hygiene. In communal living, the potentialities of common water, milk and food supplies and of methods of sewage and refuse disposal for the dissemination of pathogenic microparasites are well known. Indeed, the downward trend on many of the contagious diseases, particularly of the enteric group, during the past half century is the result of sanitary measures designed to reduce to a minimum the stream of fecal micro-organisms through the human alimentary tract by common vehicles.

**CLIMATIC FACTORS.** Temperature, humidity, rainfall, and sunlight may influence the equilibrium between the microparasite and host population in a number of different ways. Such factors may directly influence survival of a microparasite in the external environment on objects, in soil, in dust, water, and in food. They may thus facilitate or retard the passage of the microparasite from one host to the next. On the other hand, these factors may affect the resistance or immunity of the host population. Less is known about the latter effect, but there is some reason

to believe that resistance to certain microparasites may be indirectly affected by changes which take place with season, and more particularly with sudden extreme changes in body temperature.

It is apparent from this brief summary that the host-parasite balance is determined by large numbers of factors and conditions, and is the resultant of a complex biological situation. While to a considerable degree *these factors and conditions may be recognized, described, and enumerated, their relative importance varies with each contagious disease and with local circumstances.* To assess their relative importance for a particular disease, in relation to a definite locality, population and time, is one of the principal objectives of an epidemiological investigation, because upon such knowledge effective control depends.

**Experimental Epidemiology.** One approach to the elucidation of these relationships is through observations made upon artificially induced epidemics in experimental animal colonies. Notable particularly in this connection are the studies of Webster and his associates (1932, 1946) on *Salmonella*, *Pasteurella*, pneumococcus and Friedlander bacillus infections, and the studies by Topley and his associates (Topley, 1942; Greenwood and others, 1936) on *Salmonella*, *Pasteurella* and ectromelia virus infections. These studies are too extensive to permit detailed review; it will be useful perhaps to comment briefly upon the methods used and the knowledge gained.

The general procedure was to assemble uninfected animals in unit cages, the arrangement of which could be altered to simulate a community of any desired size. A constant regime of cleaning and feeding was established, and appropriate measures taken to prevent the introduction of extraneous, pathogenic micro-organisms. An epidemic was started by introducing into an uninfected animal colony a certain number of animals infected with the microparasite selected for the experiment. The course of the subsequent epidemic was indicated by the occurrence of specific deaths, proved by necropsy and culture. *Effort was made to hold all of the important factors and conditions constant except the one under examination and to note the effect this variable had upon the course of an artificially produced epidemic.*

It became evident very early in this work that a constant genetic stock of experimental animals was fundamental to control of the host variable. As had long been known to the plant pathologists, it was found possible within certain limits by selective mating to breed out lines that were relatively susceptible to infection with a particular micro-organism, such as *S. enteriditis*, the cause of mouse typhoid. It was demonstrated, for example, that there may be selected promptly from a hybrid stock of mice, of which 40 or 50 per cent die, lines in which as high as 95 per cent and as low as 15 per cent succumb following a standard dose of *S. enteriditis*. This afforded experimental evidence of the importance of innate differences in resistance genetically transmitted in human families, lines of descent, races, to a particular microparasite, a phenomenon well illustrated by the differences in the host reaction of the white and Negro race to infection with *Mycobacterium tuberculosis*.

The possible importance of nutrition of the host to natural resistance to infection was appreciated. If a diet were so poor in quality or quantity as to bring about a state of debility, experimental animals whose lives were already in jeopardy

om the consequences of produced deficiency would have a higher death rate an well-nourished animals if subjected to the added insult of infection. Obviously, it was desirable to hold this factor constant by providing a uniform and well-balanced diet. It was noted, however, that a diet which was well balanced for normal growth and development, was not necessarily well balanced in its effects upon host resistance to infection with a specific micro-organism. This question has been explored extensively by many investigators in relation to various infections experimentally produced in animals. It has been demonstrated that specific "natural resistance" can be influenced by nutrition when the host stock is genetically heterogeneous and the pathogenic population to which it is exposed is heterologous in the sense that it contains an array of variation in terms of capacity to produce disease (Schneider, 1951). These studies have advanced the understanding of underlying mechanisms implied in the terms resistance and susceptibility, but diet was of very limited importance as one of the variables affecting the results of experimental epidemics produced by *Salmonella enteritidis*.

The variability in the biologic potentialities of the strains of infecting micro-organisms employed received considerable attention. A theory has been advanced by certain speculative epidemiologists that the rise and fall of an epidemic, such as the epidemic of influenza, are principally, if not wholly, due to a progressive increase and decrease, respectively, in pathogenicity of the specific agent, the increase being brought about by the rapid passage of the infecting agent in human beings during the early part of an epidemic and the decrease occurring because the infecting agent is subjected as the epidemic progresses to more resistance and less frequent passage as the result of increasing immunity in the host population. To test this theory, methods were devised by Webster for measuring the pathogenicity of a specific strain of micro-organism for groups of mice by administering a fixed dosage. Sample cultures were obtained from animals dying at various times during artificially produced epidemics. Comparative titrations were made on strains from epidemics of pasteurellosis in rabbits, chickens and mice. Similar titrations of two serologic types were made during the course of mouse typhoid infections in mouse populations. A total of 300 to 400 titrations were made under many conditions to test the theory of fluctuating pathogenicity. "The results were invariably negative and showed a constancy and fixity of disease-producing power of a given strain of organisms under all conditions of natural infection. . . ."

From his experience with experimental epidemiology, Webster was inclined to believe that in all instances changes in biologic potentialities of specific micro-parasitic species are of little or no importance in determining the rise and fall of epidemic waves. While this may be true for many parasitic species, there are some which are more unstable and have a greater capacity for selective variation in pathogenicity (Burnet, 1951).

Other highly suggestive experiments were conducted by Webster and associates. In one series of studies it was demonstrated that, when infected animals were introduced in a closed universe of susceptible animals, the ensuing epidemic quickly subsided as susceptibles died or became immune, although some escaped infection. An epidemic started in this manner could be maintained in an open universe if sufficient susceptible recruits were added at regular intervals. If the conditions were held relatively constant, the balance between the microparasites and the host popu-

lation tended to reach a stabilized equilibrium. This was violently disturbed by a major change in the contact rate, which was accomplished by bringing a large number of animals previously dispersed in small single cages into a single colony in a large cage.

These and other experiments added support to some of the generalizations derived from experiences with epidemics in human populations under natural conditions. They emphasized particularly the accelerating effect upon incidence of an inflow of susceptibles into an infected community, and of aggregation of individuals into large groups (crowding) and per contra the dampening effect upon incidence of accumulation of immunes. *But the relative importance of each of these factors and conditions varies with the disease, its mode of transmission, the host relationships involved and the local circumstances.*

**Common Vehicle Epidemics.** When in a *relatively* short time interval there is an abrupt increase in the incidence of a disease previously absent or occurring only endemically, in a particular population group and environment, investigation of the causative conditions and factors may be simple. The word *relative* implies a standard of comparison. In this case the comparison is between the distribution of cases by time of onset and the range of variation of the incubation period of the particular disease involved. Thus, if a considerable proportion of the cases occur within the approximate time limits of variation of the incubation period, it can be assumed a priori that these individuals were exposed to infection at or about the same time. The microparasitic population has suddenly found an opportunity and a vehicle by which it can be disseminated more or less simultaneously through a group of individuals. A certain proportion of the exposed persons is susceptible, and to that extent they come down with subclinical or clinical attacks characteristic of the specific infectious agent. The problem is resolved by searching for the single factor, usually contaminated water or milk or some other food supply.

For example, in early July, 1934, an unusual number of cases of streptococcal sore throat were reported in a village in northern New York State. An investigation conducted by the district health officer developed the fact that the persons affected lived in widely separated parts of the village and that all had attended a church picnic about 1 P. M. on June 29. Of the 251 persons attending the picnic, 62 were found to have been attacked by streptococcal sore throat (scarlet fever). The distribution of 51 of these cases by date of onset is shown in Figure 43-2. It will be noted that all occurred within the time period of one to six days following the picnic. This is within the range of variation in the incubation period of streptococcal sore throat (see Fig. 43-1). The conclusion was inescapable that these individuals had been exposed to infection upon a common occasion. Three secondary cases occurred among 81 household contacts of picnic cases who did not themselves attend this gathering. Time intervals between the onsets of primary and secondary cases were 3, 13 and 16 days, respectively. The inquiry was then resolved into ascertaining the article of food or drink served upon this occasion which acted as the vehicle of dissemination. The menu included various kinds of sandwiches, baked beans, potato salad, potato chips, pickles, ice cream, several varieties of cake, lemonade, and coffee with cream. A careful history was taken of the items of food and drink consumed by each person known to have attended

e picnic. From these data were tabulated first a comparison of attack rates from reptococcal sore throat among those individuals: (a) who did not, and (b) who d partake of each item. This was checked by a reverse comparison of the proportion of persons who had consumed each item among those who: (a) had

g. 43-2. Distribution by date of onset of 51 cases of streptococcal sore throat (scarlet fever) in a common vehicle epidemic.

reptococcal sore throat, and (b) did not have streptococcal sore throat. These comparisons, together with collateral considerations of the method of preparation, opportunities for contamination and multiplication of hemolytic streptococci, led to the conclusion that the outbreak was probably due to either ice cream or potato salad, the evidence in favor of the potato salad as the vehicle being slightly more suggestive than that in favor of the ice cream.

It is to be noted that the common vehicle may be effective in dissemination on a single occasion, as is usually the case in food poisoning, or it may be effective over a period of time, as is frequently the case with water-borne outbreaks. The termination of the epidemic depends upon the interval during which the contamination of the vehicle persisted and was consumed, or upon the exhaustion of susceptibles, and the extent to which the particular disease is transmitted by contagion to secondary cases.

**Investigation of an Epidemic.** In undertaking such an investigation, it is desirable to have an orderly procedure. The following outline is suggested as applicable, in general, to such situations:

A. Preliminary analysis on the basis of the information available at the time the investigation is begun.

1. *Verify the diagnosis.* This may require only a brief review of the clinical findings, or may necessitate getting laboratory tests under way.

2. *Verify that an epidemic exists,* by comparing the incidence of the disease with its usual incidence in the community.

3. Orient the epidemic as to *time* by determining the chronological distribution of dates of onset (the epidemic curve).

4. Orient as to *place* by determining the geographical distribution of cases.

5. Orient as to *persons* by determining age, sex, race, and when possible, other characteristics of the cases; determine attack rates according to these characteristics.

6. On the basis of a rapid preliminary analysis of the selection of the disease as to time, place and persons, formulate tentative hypotheses to guide further investigations. Attempt to classify the epidemic as to mode of transmission as follows:

transmission by a	{	single exposure
common vehicle		continued exposure

propagated by	{	person-to-person spread
		arthropod vector
		animal reservoir

#### B. Further investigation and analysis:

7. Search for additional cases which may not have been recognized or reported.

8. Determine what additional information is necessary to answer any questions formulated and to test tentative hypotheses. Plan and conduct a detailed epidemiological investigation of all the cases (or of a representative sample of cases), using a suitable epidemiological case card. Arrange for any special investigations needed to establish collateral circumstances, using laboratory facilities, engineering and other expert consultation.

9. Analyze detailed data derived from case investigation, comparing attack rates among various pertinent groupings. Try to identify the group selected for attack and discover the common source or vehicle to which they were exposed, if any. Assemble results of collateral investigations.

10. Test various hypotheses which have been suggested, to ascertain which one is consistent with all the known facts. Base conclusions on all pertinent evidence, not relying upon any single distribution or circumstance by itself. If more than one hypothesis fits all the known facts, seek further evidence until the sum total of evidence is consistent with only one hypothesis. Formulate conclusions as to the source, mode of transmission and all other features of the epidemic which require explanation.

A report of the investigation of an epidemic may be organized along the lines of the outline given above. In addition, it should usually include a discussion of factors leading to the occurrence of the epidemic, an evaluation of the measures employed for its control, and recommendations for the prevention of similar episodes in the future.

**Dynamics of Noncontagious Infections.** Up to this point, for the sake of simplicity in discussion, attention has been principally focused upon infections transmissible directly from one human being to another, i.e., contagious infections.

as has been pointed out previously, some of the most devastating diseases of mankind are due to microparasites: (a) which can make exit from the human body only through intermediation of the bite of an arthropod vector, or (b) cannot make an effective exit, human infection being a terminal event in transmission. In the former situation, man may share responsibility for continued propagation of a microparasite with an arthropod vector in a transmission chain, as in the "louse-man-louse" propagation of epidemic typhus fever. In the latter situation, survival of the parasitic species is entirely independent of its relationship to man. Thus, *Rickettsi mooseri*, the cause of murine typhus, is continuously propagated in the Norway rat and related rodent populations through the mediation of rat ectoparasites, particularly the flea *Xenopsylla cheopis*; the principal transmission chain is "rat-flea-rat." The infection of man by this flea is an accident which is of no importance in the continuous passage of *R. mooseri*.

To understand and effectively interfere with the spread of such diseases in a human community, it is necessary to take into account not only the factors and conditions which affect the human host and the microparasitic populations, but those which affect the vector and extrahuman vertebrate host populations and their relationships to the microparasite on one hand and to man on the other. If only man and an arthropod vector are involved in propagation, the biological relationships are not too complex for quantitative expression and comprehension, as in malaria. The internal relationships of the malaria plasmodia to the human host and to the mosquito host are approximately the same everywhere. However, the living conditions of the population, the habits of the particular anopheline vector species with regard to breeding places, resting places, feeding habits and blood meals, etc., and the climatological factors which affect these two are eternally changing from one locality to another and make necessary careful malaria surveys precedent to well-directed measures of control. When, on the other hand, the microparasitic species is gregarious in its host relationships, both as regards vertebrates and arthropods, and at the same time capable of surviving for considerable periods of time in the external environment as, for example, with such micro-organisms as *P. tularensis*, the biological complex responsible for its continued propagation is exceedingly involved.

It is a function of epidemiology to distinguish between relationships which are fundamental to survival of a microparasitic population and those which are only incidental, i.e., to distinguish between transient hosts and reservoir hosts. By the latter term is implied the host relationships upon which the microparasite depends chiefly for its continuous propagation. While usually applied to vertebrate hosts, it would seem entirely appropriate to apply this term to arthropod vector hosts to which the microparasite has become adapted and in which it is able to survive for long periods of time with stage-to-stage transfer from one generation to the next, as with *Dermacentroxenus rickettsi*, the causative agent of Rocky Mountain spotted fever in ticks.

The epidemiology of these diseases may involve a considerable part of the ecology of a region. Indeed, as pointed out by Burnet (1951), the ecological point of view is fundamental to an understanding of the manifestations of such diseases. As the latter in human populations, the occurrence of cases of which is a reflection

of the waxing and waning of microparasitic populations in their extrahuman reservoir multiplication.

One epidemiological characteristic which these diseases have in common is that none is world wide in distribution. They are limited in their geography to localities or foci where the highly specialized conditions required for maintaining

Prepared from data in Pub. Health Rep., 52:107, 1937.

Fig. 43-3. Seasonal prevalence of tularemia.

Transmitted by: *D. andersoni* ———; *D. variabilis* - - -; *Chrysops discalis* — · —; rabbit contact ·····.

transmission can be realized. The second characteristic is that the immunity status of the human population is seldom an important limiting factor. Usually, the incidence in seasonal variation and in population group selection is determined principally by exposure to the arthropod vectors, to extrahuman hosts, or to both.

Many examples of progressive development of knowledge of diseases of this type have been given in previous chapters. A classical illustration is afforded by the account of "The Conquest of Yellow Fever" by Strode and others (1951). Briefly stated, the successive steps which led to the elucidation of the biological mechanisms involved in the maintenance of yellow fever virus in nature were the following: (1) clinical and pathological differentiation of the disease yellow fever beginning in the seventeenth century; (2) description of the epidemiological features of the disease, accumulated principally during the latter part of the nineteenth century (before routinely collected morbidity and mortality statistics were available), i.e., crude quantitative estimates of frequency and distribution in human populations, geographic location of endemic and epidemic centers, transportation and introduction into new areas by sailing ships, tendency when introduced to spread radially from the water front, disappearance from communities in the tem-

erate zone with the frost in the fall, formulation of the hypothesis of mosquito transmission by Carlos Finlay in 1881, observations on the period of extrinsic incubation by Dr. Henry Rose Carter in 1898; (3) the human experiments of the Walter Reed Commission (about 1900), proving that yellow fever could be transmitted by a mosquito, *Aedes aegypti*, and that the causative agent is an ultra-microscopic filtrable virus, thus establishing the man-*aegypti*-man propagation as the principal chain of transmission of urban yellow fever; (4) the development in the field of practical methods for suppressing *Aedes aegypti* populations in urban communities below the threshold at which transmission can be maintained, beginning in Havana, Cuba, in 1902; (5) discovery in the experimental laboratory of the susceptibility of the monkey in 1927 and, three years later, of the white mouse, leading to confirmation of experimental transmission by *Aedes aegypti* and other species, and to the development of the mouse protection test for the detection of specific antibodies in sera; (6) epidemiological field observations, in 1932, describing the occurrence of cases of yellow fever in areas where *Aedes aegypti* were not found and the selection of the disease for adult males engaged in wood cutting; (7) epidemiological organization of the viscerotome service (liver puncture) in Brazil about 1934, leading to the finding of cases of yellow fever in areas from which *Aedes aegypti* were absent and extension of the use of the mouse neutralization test to sera gathered from populations in various geographic areas in South America and Africa, outlining the distribution of the virus infection; (8) laboratory demonstration (1940-1946) of the presence of neutralizing antibodies and recovery of the virus from certain species of monkeys in South America and later in Africa, recovery of the virus from mosquitoes captured in nature in these areas (*Haemagogus spegazzinii* in Brazil and of *Aedes simpsoni* and *Aedes africanus* in Africa) elucidating the mechanism of propagation of the virus in a jungle; (9) laboratory development (1936-1943) of a simple practical method of vaccination; and (10) field trial (1937-1943) of the vaccine on human populations to assess its safety and the protection which it afforded the vaccinated as compared with the unvaccinated under conditions of natural exposure.

It will be noted that after the disease had been clinically differentiated, the development of knowledge which achieved the virtual eradication of *Aedes aegypti* transmitted yellow fever from the Western Hemisphere, and which yielded a practical means of prevention of human infections with jungle yellow fever in South America and Africa, was a stepwise process resulting from the alternation of epidemiological observation and chains of inference with laboratory experiments and field applications. At the same time, the synthesis of these chains of inference into a biological pattern, gave rise to an adequately supported concept of the manner in which the virus of yellow fever is continuously propagated in the human reservoir of primate and mosquito life in the jungle ecology, from which it occasionally emerges into human experience as sporadic cases or as epidemics, propagated, at least temporarily, by a vector (*Aedes aegypti*) which is adapted to the domestic economy of man.

**Noninfectious Diseases and Abnormal Physiological States.** Similarly, observations and reasoning based upon the manner of occurrence of noninfectious diseases and abnormal physiological states in human populations have been of value in contributing to the understanding of the underlying pathology. One of the classical

studies in history of epidemiology (although the author was unacquainted with this word) was "an inquiry concerning the cause of endemial colic in Devonshire" presented by Sir George Baker before the College of Physicians in London, June 28, 1767. He identified the clinical condition with which he was dealing as lead poisoning. He studied its distribution and selection in the population of Devonshire and the adjoining counties. The condition was largely confined to Devonshire, selected "people not very elegant and careful in their diet," occurred in the autumn, and was associated with drinking cider. Baker sought a rational explanation of why some of the people drinking cider were made sick and others were not. He found it in a difference in use of lead in construction of cider mills, the use of lead for storing juice and the use of sugar of lead as an adulterant to stop fermentation and to sweeten the cider.

In 1914, Dr. Joseph Goldberger was assigned by the U. S. Public Health Service to a study of pellagra, which at times had become quite prevalent in certain villages and institutions in South Carolina, Georgia and Mississippi. His approach to the problem was to observe the conditions under which the disease was occurring. In insane asylums, he noted that, although the disease was of frequent occurrence among patients, the doctors, nurses, attendants and orderlies in these same institutions were never attacked. He reasoned that, since the attendants had to handle, wrestle, and sometimes even fight with these patients, the disease could not be readily transmitted by contagion. He noted among other things that there was a significant difference in food consumed by pellagrinous patients and that consumed by the staff. In particular, members of the staff had nice cuts of meat and glasses of milk, whereas many of the patients were unable to feed themselves adequately with the limited dietary that was served to them.

Further in the course of his travels, Goldberger found two orphanages in southern Mississippi in which a considerable proportion of the children had symptoms resembling those of pellagra. On more careful analysis, he discovered the surprising fact that the disease was limited to children between the ages of 6 and 12; there was none among the younger nor among the older children. Again, by close observation, he discovered that two mugs of fresh milk were served each day to children up to six, the diet for children from 6 to 12 consisted of plenty of cornbread, hominy grits, biscuits, molasses, and there was on gala days once a week, fresh meat. The older children, 12 to 15 years of age, were allowed to assist in the kitchen and had opportunity to supplement their diet by milk and meat obtained surreptitiously. Goldberger drew the inference that this difference in diet explained the difference in age selection of the sick children. To test this hypothesis, the ordinary diet of all the children was supplemented by feeding fresh meat four times each week, two seven-ounce cups of milk each day and every child under 12 had at least one egg a day. Within a few months symptoms of pellagra had disappeared from the whole orphanage population.

These observations led to the formulation of an hypothesis that pellagra is due to a deficiency of fresh meat, milk, eggs and other protein foods. This hypothesis was tested and confirmed by human experiment carried on at a Mississippi state prison. It was consistent with the findings of an extensive study in several cotton mill villages in South Carolina, correlating the prevalence of pellagra and its selective occurrence with economic, dietary, seasonal and other factors and

conditions. Finally, the hypothesis was put to experimental test in dogs, who were known to suffer from an analog of pellagra, known as "black tongue." This led to the subsequent work of many investigators which elucidated step by step the role of B vitamin complex in nutrition.

Other examples could be cited, but these will suffice to illustrate the manner in which the epidemiological method can be applied to the problems presented by diseases of unknown etiology, to deficiency states, to industrial hazards, to disturbances of growth and metabolism, etc. The essence of the method is to compare the frequency of occurrence of the disease or state in various groupings of persons in relation to time, place, and factors and conditions which appear to be, or may be, of causal significance according to the hypothesis which guides the investigation.

The study of the epidemiology of some thing or event—cancer, for example— involves a recognition of the event we are talking about, so that the population can be separated into those who have cancer and those who have not. Moreover, the study demands classification of the population on other axes to determine the important related factors that single out these particular people for attack. Are they different in inheritance, in nutrition, in occupation, and so forth, from the rest of the population?

Considerable imagination is required in seeking out the pertinent variables to study. We may search along one axis of classification assiduously and neglect some other more relevant one, and thus the real relationship may elude us. The study of cholera in London might be recalled, in which Farr showed that there was a diminishing proportion of people attacked as the altitude increased. This fitted beautifully with the miasma theory of disease. It happened also that the water supply got increasingly better with altitude, and that water was the relevant axis of classification, altitude being merely incidental. If we are able to separate our population with regard to an event whose epidemiology we are studying and if we are able to relate this classification to the factors which produce it, we will understand the epidemiology of an event.

**Biostatistical Approach.** Up to this time little has been said about the employment of biostatistical methods and technics in epidemiology. In many such investigations the requirements for quantitative statement and comparisons may be relatively simple, a matter of numbers, simple rates and ratios, to which reference has been previously made. Other investigations require the employment of extensive statistical data based upon reports of cases or deaths, sometimes systematically collected over long periods of time, related to the population composition of community or region, or are concerned with the evaluation of the effectiveness of measures of prevention, prophylaxis, or control requiring experimental design. While the validity of epidemiological inferences drawn from such studies depends primarily upon the accuracy of the original observations and biological concepts, it is affected to an equal degree by the soundness of the statistical methodology used.

## STATISTICAL REASONING

PAUL M. DENSEN, SC.D.

**Introduction.** "The black plague that ravaged Europe is all but gone. The yellow fever that made men pray for winter is all but gone. The malignant choking path that struck at children is all but gone. Purging fevers no longer haunt the water that cities drink. Cheeks that would once have been pitted with smallpox are smooth and fresh. Men and women die old.

"Are we then so wise that we have beaten our parasites? Sallow-faced farmers shivering and burning with malaria, bedside watchers listening to the anxious wheezing of pneumonia, jaded nurses tending the wrecks of syphilis, millions exasperated by the nagging misery of the common cold know the answer. We have not tamed the world entirely of any single infection known to man, and some we have not yet begun to fight. As for the premises for action, we do not yet know why one man sickens and the next goes free, why one pest seeks out the lungs and another the liver, how drugs cure the ills they seem to cure, how disease begins or how it ends" (Smith, 1948).

Thus Geddes Smith, concerned perhaps lest we rest on past laurels, reminds us that there is yet much to be done. One learns from past experience, however, as Smith himself demonstrates in the body of his book, and the lesson to be learned here is that such understanding as we have gained of health and disease has been through the patient study of many workers of the relationship between man and his environment, biological, physical, and social. The study of this relationship is essentially the study of variation and the exploration of this variation constitutes the avenue along which we may hope to find the "premises for action" which will tell us why "one man sickens and the next goes free." Because the statistical method is one of the most powerful tools available for the study of variation, this chapter is concerned with the nature of the reasoning process underlying the application of this method to the study of man and his responses to his total environment.

**Formulation of the Problem.** The first step toward answering such questions as why one person gets sick and another doesn't, whether penicillin is effective in the treatment of certain types of cardiovascular syphilis, why certain diseases such as rheumatic fever show a high familial concentration, and so on, is a careful statement of the question itself. The more sharply it is possible to focus the hypothesis to be tested, the more likely it is that an unequivocal answer will be forthcoming.

Suppose, for example, it is desirable to evaluate the effectiveness of a particular therapeutic or prophylactic procedure—operation, drug, x-ray, bed rest, immuni-

zation, etc. The question in its initial form might be as follows: Does the procedure cure the disease? Expressed in this way it is very difficult to judge the value of the procedure, for there may be any number of different interpretations of what is meant by "cure." However, the question may be restated in more specific terms. If by cure is meant to reduce the chances of dying within a specified period of time, then the question may be put somewhat as follows: Does the procedure reduce the mortality from this disease and how does this reduction vary with the time since the procedure was instituted? Still another interpretation of cure might be in terms of the frequency with which recurrences of certain manifestations occur after treatment. The question would then be worded accordingly. The more specifically the therapeutic objective is defined, the simpler it is to determine whether this objective is attained and to what extent such attainment is due to the particular therapy employed.

Analogous problems are equally frequent in the public health field. Consider the well-baby clinic. Does it do any good? It is not possible to answer the question in this form because it does not pose a hypothesis to be tested. However, if one hypothesizes that children who come to well-baby clinics have a lesser frequency of childhood diseases than those who do not attend, this contains the possibility of being tested if the necessary data can be obtained. A number of other hypotheses in relation to the activities of a well-baby clinic, such as those concerned with measures of growth, will suggest themselves.

The reader is referred to a paper by Whelpton and Kiser (1945) for an excellent example of the principle of developing specific hypotheses to be tested before undertaking collection of data.

**Planning the Collection of the Data.** The kind of data to be collected and the manner in which the collection is made are dependent upon the hypotheses to be tested or the way in which the basic questions are phrased. Suppose, for example, one wished to test the hypothesis that whooping cough immunization reduces the occurrence of the disease. This requires that information concerning the occurrence of the disease during a stated period of time be obtained from every child who received the vaccine. Some decision would have to be made as to what is to be counted as a case of whooping cough. Will history be sufficient? Will cough plates be required? The more objective the definition, within the practical limitations of the situation, the better. A decision must also be reached as to how the information is to be obtained. Is it to be by getting the history from the mother at the end of a period such as a year or is it to be by periodic visits at fairly frequent intervals so that the memory factor is reduced to a minimum?

A very important requirement dictated by the nature of the hypothesis is that information similar to that obtained on the inoculated group must also be obtained on a group of noninoculated individuals. Otherwise, it would not be possible to determine whether the frequency of attack among the inoculated group was reduced by the inoculation. In other words, a control is essential. Topley (1940), illustrating the point, speaks of Broussais, a French clinician of the early nineteenth century who believed that the way to treat infectious disease was to bleed the patient. Under his aegis, the consumption of leeches in France rose sharply until Pierre Louis decided to see what happened to the patients who had not been leeches. As Topley puts it, "the results lent no support to the leeches."

The purpose of a control is to permit the isolation of the factor responsible for the observed result in the study or experimental group. It is essential, therefore, that the control group be similar to the study group in every respect except the one which is the object of study. This is not an easy requirement to fulfill. In laboratory experiments, the investigator usually begins with a group of animals which he then divides into two subgroups, one of which is experimented upon, the other remaining as the control. The division into two subgroups is usually accomplished by some kind of randomizing process which will insure that the groups do meet the above requirement. In studies on man similar to that on the efficacy of whooping cough immunization, attempts to set up controls through a randomizing process often meet with difficulty, because if there is some chance that the treatment immunizing agent will be effective, it is hard for the physician to deny it to some individuals. However, "it is easy to fall into the error of assuming that a new drug (or other agent) must be good and, therefore, it is unethical to withhold it from a patient . . . It may well be that those from whom the drug (or other agent) is withheld are in fact the fortunate ones, and that by not setting up a control this fact is not immediately discovered" (Merrell, 1949). Excellent examples of well planned studies of therapeutic or prophylactic agents are reported by Merrell (1949), the Medical Research Council (1948), and Kendrick and Eldering (1939).

In studies concerning therapeutic or prophylactic agents of one sort or another, whether they be conducted in the laboratory or among population groups, the researcher usually makes the decision as to who shall receive the agent and who shall not. There is a whole class of studies, however, in which the separation into two groups to be compared has taken place prior to the time the material comes to the attention of the investigator. However, the problem of determining whether the study and control groups are alike in every respect except that under consideration still remains. For example, one may ask the question whether household contacts to cases of tuberculosis have a greater or lesser mortality than the population in general (Frost, 1933; Brailey, 1940; Puffer, 1946). Here the investigator is not in a position to decide which individuals shall be among the group, "household contacts of tuberculosis." He must accept the data as they come to him. It becomes his responsibility, however, to compare the study group (contacts) and the control group (population in general) with respect to characteristics other than mortality such as age, sex and race to see if they are the same, or, if they differ, to ascertain the effect of the difference on mortality. The reader will readily think of other situations in which this problem arises. Berkson (1946) discusses the issue with respect to the conclusions which may be drawn from certain kinds of hospital data and Puffer (1950) the general issue of designing studies as exemplified by certain psychological studies made during World War II.

Whenever the basic question or objective of a study is of the form: What is the relationship between A and B?, a control is a *sine qua non* of the study. For example, if, as in the previous paragraph, we raised the question of the relationship between contact with tuberculosis and mortality, a control will be necessary. There are many studies, however, in which a control is not required. In these studies, the basic question is of the form: How much is there of A? For example, what is the prevalence of cancer in the population, or any other question of this form.

Although a control is not a requirement of studies concerned with the second

type of question mentioned above, there are other points to be considered, chief among which is the representativeness of the material. For example, suppose one wishes to determine how much syphilis is present in the population of a city at a particular time. There are several ways of deciding what shall be counted as syphilis (Turner, 1943) but for the present purpose we shall be concerned with the frequency of infection as evidenced by a positive serological test. If it were possible to obtain a serological test on every person in the city, the prevalence of syphilitic infection could be established.\* Ordinarily, of course, this is not practicable and a sample of the population is obtained instead. It then becomes necessary to consider how representative the sample is of the entire population. If the city has a high proportion of nonwhite population, the sample should contain essentially the same proportion of nonwhites. If the sample proportion is too high, the estimate, based on the sample as a whole, of the proportion of the population having a syphilitic infection will be too high, because, in general, syphilis is more widespread among the nonwhite population (see page 1316). In general, the sample must have essentially the same composition as the population from which it is drawn if reliable inferences are to be made about that population. Tabulation of the data from the sample should examine this point.

The technical problems of developing the specific forms used in a study, of insuring uniformity in filling them out, of deciding the exact method of obtaining a sample, of training enumerators to gather data if a field survey is involved are beyond the scope of this chapter. It is suggested that the reader examine a number of the references at the end of this chapter and the next with respect to these points. Puffer (1950) and Pearl (1940) discuss some of these points.

The discussion to this point has been concerned with the *planning* of studies—with the reasoning process involved in deciding what data shall be collected, and from whom it shall be collected. Unless the study is carefully planned in relation to the initial question or hypothesis to be tested, no amount of statistical manipulation of the data after they have been collected will provide clear-cut answers. It follows from this that the planning of studies is primarily a matter of teamwork between the investigator (and his staff) and the statistician. This teamwork must begin at the beginning—at the formulation of the problem and in the planning of all subsequent stages. Otherwise, the benefit to be derived from such teamwork is likely to be no greater than that derived by the patient if the clinician seeks consultation after the patient is dead.

**Tabulation of Data.** Tabulation is merely a systematic arrangement of the data which have been collected. Such an arrangement is absolutely essential if one is to obtain a picture of the interrelationships among items. Suppose, for example, in connection with the operations of a tumor clinic, a question is raised as to how the interval of time between onset of symptoms varies with the sex of the patient and the status of the tumor at the time of the patient's first visit to the clinic. The answer to such a question could be of considerable value in planning an educational program concerning the desirability of early medical consultation if there are suspected symptoms.

The basic data for answering the question would be in the records of patients

\* Within the limitations of the serological test itself.

tending the clinic. A simple listing of the pertinent facts with regard to each patient would provide data such as the following:

Patient	Sex	Status of Tumor	Interval between Onset of Symptoms and Consultation
A.W.	F	Primary	4 months
T.G.	F	Primary with regional metastases	8 weeks
P.F.	M	Remote metastases	1 year
		etc.	

Clearly some sort of organization of such a listing would be required if the association between sex, status of tumor, and the time between onset of symptoms and seeking consultation is to be studied.

Whatever organization is attempted, it must be able to answer this type of detailed question: How many females with a primary tumor without metastases were seen within one month, two months, etc., of the time of recognition of symptoms? How does this compare with the females in whom the tumor was found to be primary with metastases? To answer questions of interrelationships such as these, the data must be cross classified, with the items placed in relation to each other as follows:

Time Between Recognizing Symptoms and Consultation	Status of Neoplasm on Admission						Total by Sex		Grand Total
	Primary		Primary with Metastases		Secondary				
	M	F	M	F	M	F	M	F	
ss than 6 months									
months to 1 year									
year to 1 year and									
6 months									
etc.									
TOTAL									

This kind of table will answer all questions regarding the three factors: time interval, status of tumor, and sex, and their relationships to each other.

From this discussion, certain general principles of tabulation emerge, the most important of which is that the form of tabulation which is used is dependent upon the specific questions to which it is desired to obtain answers. It is a very useful procedure in the planning of studies to attempt to sketch out table formats. This will help to insure that all the information needed to give the desired answers is obtained, and will often sharpen up the questions which are under investigation. Setting up dummy table forms also makes it possible to get a rough idea of how many observations are needed to make the table worth while. For example, it is readily seen that if, in addition to the three items in the above table, we wish to add the kind of tumor, a great many more observations would be necessary than without that added breakdown.

The attempt to classify or systematically arrange the data in a table in itself means that decisions must be made as to what classifications to use. For instance, in the previous example, some decision would have to be reached as to what time

intervals are to be used. Should it be individual months, years, or six-month periods as in the above table? How should the status of the tumor be classified? Should metastases be further broken down into those which are regional to the primary tumor and those which are remote? What is meant by "secondary"? These are questions which must be decided before the data are tabulated. The actual decision must be made by those familiar with the material, and must be suited to the purpose at hand.

The process of classification reveals that there are in general two kinds of data. These can be distinguished by the characteristics of the scale along which they are classified. Whenever the division points on the scale can be identified numerically, the data are referred to as *measurement data*, and the table showing the frequency with which observations occur along the scale is known as a *frequency distribution*. Data on age, weight, blood pressure, temperature, etc., are measurement data. Table 44-5, page 1330, shows a frequency distribution of weight at birth of first-born infants.

The classification of data when the scale of classification cannot be marked numerically is much more difficult. Consider, for example, the classification of cases of tuberculosis as to stage of the disease at time of discovery—minimal, moderate, far advanced. Where is the dividing line between minimal and moderate? The classification, here, is based on some attribute of the material rather than a measurable characteristic, hence these are known as *attribute data*. Examples are data classified by stage of disease (as in tuberculosis), diagnosis, sex, race, etc.

The importance of making the distinction between these two types of data lies in the fact that because of the relative objectivity of measurement data, most investigators will agree on a definition of where the division points on the scale fall so that observations classified in this manner have the same meaning for almost everyone. This is not the case, however, with attribute data. Even a superficial examination of the tuberculosis literature, for example, indicates quite a bit of disagreement as to what is a minimal, moderate, or far advanced case, or even as to what is a case (Birkelo, 1947). The point, however, is that some definition must be agreed upon before it is possible to make meaningful tabulations (Densen, 1949).

Since the objective of tabulation is an orderly presentation of the observations, it is important that a table be so organized as not to require reference to the text to be understood. Table titles should be explicit as to the kind of data presented in the table, what time period they cover and for what area they have been collected. Heads of columns and rows should be clearly marked and the units in which the data are expressed clearly shown. Whenever percentage or rates are presented, the base on which they are computed should be indicated. The reader is referred to Walker and Durost (1936) for more detailed discussion, and to Puffer (1950) and Pearl (1940) for procedures in the mechanical handling of various types of records.

**Graphical Presentation of Data.** The presentation of statistical material in graphic form is a device for emphasizing salient points which may be lost in the mass of figures in a table. There are many varieties of graphs, a few of which are illustrated in this and the next chapter. Ordinarily, the graph of attribute data takes the form of a *bar graph* such as is shown in Figure 45-10 (page 1369). When one wishes to show the trend of data with time, a *line diagram* (Fig. 45-6, page 1356) is used. At times, however, one may be interested in the relative or percentage

ange with time as well as the amount of change, in which case a ratio or *arithmic line diagram* may be used (Fig. 45-12, page 1373). When dealing with measurement data, a *histogram* (Fig. 44-4, page 1331) is often used to show the general characteristics of the frequency distribution.

The points to be considered in construction of graphs such as those just mentioned may be found in Pearl (1940) as well as in many other standard statistical texts. The reader is also referred to Weld (1947) for an extensive treatment of the subject. One general point may be made here, however. The test of a good graph whether it is readily understandable without recourse to the table containing the data from which the graph is drawn. Rules for achieving this desideratum are presented in the references just cited.

**Analysis.** The process of analysis is essentially one of comparison—comparison, for example, of the mortality (or some other measure) of those treated with a drug and those not treated, or of the subsequent experience with the disease of those inoculated against whooping cough and those not inoculated, or of the mortality of household contacts of cases of tuberculosis compared with that of the rest of the population, etc. When such comparisons are made, it is the exception rather than the rule to find that the absolute numbers in the two groups being compared are exactly the same. It may happen then that there are more deaths, for example, in the treated group than in the untreated group, simply because there are more people in the former exposed to the risk of dying during the period of observation. It therefore becomes necessary to take account of the numbers in each group. The simplest way to do this is to relate the deaths during a period of time, if that is the event in which interest lies, to the population exposed to risk during this time. The resulting figure is a death rate.

In the study of the interplay of the various factors concerned in the production and control of disease, a great many different kinds of rates are used. Each serves a different purpose and is subject to a different interpretation, but all are based on certain fundamental principles. These are most easily arrived at by considering the construction of certain rates as examples. The crude death rate serves as a good starting point. This rate is found according to the following formula:

$$\text{Crude death rate} = \frac{\text{total deaths during a given period of time}}{\text{average population present during period}} \times 1,000$$

This is a very simple rate to compute. The numerator is obtained by adding up all the deaths that occurred during the period of time for which the rate is being computed (usually, but not necessarily, a year). The denominator is the average population present during the time period.\* If a count of the average population is not available, some estimate of it must be made.\* The following example gives the computation of the crude death rate for Pittsburgh in 1949:

$$\frac{\text{total deaths in 1949}}{\text{estimated average population, 1949}} \times 1,000 = \frac{8,507}{714,874} \times 1,000 = 11.9$$

\* The usual procedure for collecting the information on deaths and for estimating the population is considered further in the chapter on Health of the Population.

This figure may be interpreted as meaning that, on the average, for every thousand individuals in the population of Pittsburgh in 1949 there were nearly 12 deaths.

**Factors Influencing Crude Rates** (see page 1358). The crude death rate is a composite of the death rates of the various classes of the population. If, for example, the proportion of colored people in the population is high, the crude rate will be pulled toward the death rate of the colored people and it, too, will be high (see page 1312). This important point may be illustrated by the following hypothetical example:

Age Group	City A			City B		
	Population	Deaths	Death Rate per 1,000 Population	Population	Deaths	Death Rate per 1,000 Population
Young	1,000	10	10.0	2,000	20	10.0
Old	2,000	40	20.0	1,000	20	20.0
Total	3,000	50	16.6	3,000	40	13.3

It would appear from an examination of the crude or total death rates that mortality conditions in City A, with a crude rate of 16.6 per 1,000, are somewhat worse than in City B, where the rate is only 13.3 per 1,000. But on closer examination it is seen that the death rate in each of the two classes of the population—*young and old*—is exactly the same. The sole reason for the difference in the crude rates lies in the *differing proportions of young and old population* in the two cities. City A has a higher proportion of its population in the group with the high death rate—i.e., in the old group. This group exerts a stronger pull on the total death rate in City A than in City B; hence, the crude rate is higher in the former than in the latter.

Table 44-1. Age distribution of cases and deaths among males and case fatality ratio of Rocky Mountain Spotted Fever occurring in certain western\* and eastern\* states

Age in Years	West			East		
	Cases	Deaths	Deaths per 100 Cases	Cases	Deaths	Deaths per 100 Cases
0-14	55	5	9.0	170	23	13.5
15-39	239	32	13.3	124	17	13.7
40 and over	330	145	43.9	107	43	40.1
All ages	624	182	29.1	401	83	20.6

From Topping, N., Pub. Health Rep., 56 1699, 1941.

\* The western states are Montana and Idaho, while the eastern states are Maryland and Virginia. All cases and deaths are reported to the State Health Officer; Montana, Idaho, and Maryland, 1930-39, inclusive; Virginia, 1933-39, inclusive.

The data in Table 44-1 (Topping, 1944) illustrate the importance of this point in relation to the study of factors influencing the occurrence of disease in a population group.

"In spite of several published statements to the contrary, it has long been the popular conception that Rocky Mountain spotted fever is a more highly virulent, and, therefore, a more fatal disease in the West than in the East" (Topping, 1941). The large difference between the two areas in the crude case fatality ratio for males of all ages would seem to bear this out. However, examination of the rates for individual age groups shows that in the two younger groups the ratio is actually slightly greater in the East than in the West, and in the oldest group the difference is considerably less than that for all ages. It will be noticed, however, that there is an entirely different age distribution of cases in the West than in the East, the former having a much higher proportion of cases in the older ages. The result is to pull the total ratio for all ages in the West up toward that of the 40 and over group. The disparity in the ratio for all ages \* is, therefore, largely due to the differences in age distribution in the two areas. Similar data are presented in the paper for females. The author concludes that there is no support in the data presented for the "popular conception" quoted above.

These examples illustrate two major considerations with respect to rates. These are: (1) rates are only comparable if the populations upon which they are based are comparable, and (2) that comparisons are best made in terms of rates for specific groups of the population. Such rates are known as *specific rates*. Rates are frequently made specific for race, sex, and age, or for any combination of these. The principle of constructing specific rates, however, need not be confined to these three factors. Rates may be constructed for any factor being studied, *as long as the numerator can be related to the population from which it arises*.

The principle of relating the numerator to the proper denominator is well illustrated by tracing the formation of the *maternal mortality rate*. The maternal mortality rate is a measure of the risk to the mother of dying from causes associated with childbirth. The numerator of the rate is the total number of deaths due to puerperal causes † occurring during the time period in which we are interested—say, one year. The denominator should be all those individuals exposed during the year to risk of appearing in the numerator. This is certainly not the total population, since males do not experience this risk. Neither is it the total female population, for only those females in the reproductive ages—say 15 to 50—are subject to this risk. However, in any given time period such as one year, the only females in the reproductive ages who are actually exposed to this risk are those who become pregnant. The denominator, then, should be the total number of females who become pregnant during the year.‡ This, of course, is not a figure which is readily obtainable. However, a good approximation to it can be obtained by substituting

\* It is possible to adjust the total ratio for the difference in age distribution. The procedure for doing this, known as the adjusted or standardized rate procedure, may be found in most statistical texts dealing with medical or public health statistics.

† The decision as to what constitutes a "puerperal" cause is usually made according to the International List of Diseases, Injuries, and Causes of Death.

‡ Since some of the deaths may occur in the following year, a small error is introduced which, however, is ordinarily compensated for by death of mothers becoming pregnant in the previous year.

the number of live births for the number of females pregnant during the year, since for every live birth there must be a mother exposed to the risk of dying from the hazards associated with childbirth. (A small correction is ordinarily made for plural births.)

Thus, the maternal mortality rate as ordinarily computed is given by:

$$\frac{\text{deaths due to maternal causes}}{\text{live births}} \times 1,000$$

The objection might be raised that mothers whose pregnancies terminate in a stillbirth are just as much, if not more, at risk of dying from maternal causes as those whose babies are born alive, and, therefore, the denominator should be total births (live births plus stillbirths) rather than just live births. Logically, this argument is correct, but because of the unreliability of stillbirth data these are not included in the denominator of the rate.

**Rates and Ratios in Common Use and Their Formulae.** The following rates and ratios are frequently encountered:

1. Crude birth rate

$$\frac{\text{number of births during a calendar period}}{\text{average population present during same period}} \times 1,000$$

2. Crude death rate

$$\frac{\text{number of deaths during a calendar period}}{\text{average population present during same period}} \times 1,000$$

3. Age-specific death rate

$$\frac{\text{number of deaths in a particular age group (e.g., 25-34) in a calendar period}}{\text{average population in same age group during same calendar period}} \times 1,000$$

4. Infant mortality rate

$$\frac{\text{number of deaths under 1 year of age in a calendar period}}{\text{number of live births during same calendar period}^*} \times 1,000$$

5. Neonatal mortality rate

$$\frac{\text{number of deaths under 1 month of age in a calendar period}}{\text{number of live births during same calendar period}^*} \times 1,000$$

6. Maternal mortality rate

$$\frac{\text{number of deaths from puerperal causes during a calendar period}}{\text{number of live births during the same calendar period}} \times 1,000$$

7. Cause-specific death rate

$$\frac{\text{number of deaths from a particular cause during a calendar period}}{\text{average population present during the same calendar period}} \times 100,000$$

8. Case rate or morbidity rate

$$\frac{\text{number of cases of a particular disease developing during a calendar period}}{\text{average population present during the same calendar period}} \times 1,000$$

\* The number of live births is used because of difficulty in counting the population under one year or one month of age.

## 9. Case fatality ratio

$$\frac{\text{number of deaths from a particular cause}}{\text{number of cases of the same cause}} \times 100$$

## 10. Prevalence ratio

$$\frac{\text{number of cases of a particular disease at a particular time}}{\text{population present at that time}} \times 100$$

The multiplying factors shown in the above formulae are those which are most frequently in use; other multiplying factors may be used if desired as long as they are always stated in the presentation of the material. The calendar period ordinarily used in calculating rates 1 through 8 is one year, although at times it may be computed for longer or shorter periods. It will be noted that formulae 9 and 10 are designated as ratios and that they do not refer to a *period* of time. This brings us to consideration of two fundamental types of rates used in the study of biological phenomena—incidence rates and prevalence rates.

**Incidence and Prevalence.** The increasing importance of the chronic diseases has led to the recognition that there are two fundamentally different measures of the frequency of disease in a population, regardless of the type of population. One of these measures the rate of occurrence of the phenomenon *during* a given period of time. This is an *incidence rate*. The other measures the proportion of the population which exhibits the phenomenon *at* a particular time. This is a *prevalence ratio*.

The general formula for the prevalence ratio is given above. For the incidence rate, the general formula may be written as follows:

$$\text{Incidence rate} = \frac{\text{number of events in the population at risk during the specified time}}{\text{mean population at risk of event during specified time}}$$

Comparison of the general formula for the incidence rate with rates 1 to 8 above will show that they are all incidence rates. The event used in the formula may be death, the occurrence of a case, the occurrence of certain symptoms or any defined phenomenon.

The general relationship of prevalence and incidence may be expressed as  $P = I \times D$ , where  $D$  is the average duration of the disease in an individual case expressed in the same time units as  $I$ . From this formula, it may be seen that when  $D$  is short, as in the case of the acute infectious diseases, the prevalence is usually not very different from the incidence of disease. However, in the case of diseases such as tuberculosis, syphilis, cancer, etc., the prevalence may be very much greater than the incidence. Puffer (1950) shows how these relationships may be used to explain why, although the Negro death rate from tuberculosis is much higher than the corresponding white death rate in Tennessee, the prevalence figures are less in the former group than in the latter. The studies of Turner (1943) on the principles concerned in measuring the frequency of syphilis also revolve around this basic distinction between incidence and prevalence.

**The Life Table Approach to the Determination of Incidence Rates.** The determination of an incidence rate requires keeping a group under observation over a period of time, recording the event of interest when it occurs. If everybody entered a study at the same time and nobody was added or dropped out during the study

except by reason of experiencing the event, it would be fairly easy to determine the numerator and denominator of the incidence rate. However, the usual situation is that a certain number of individuals are available for observation at the beginning of the study, others are added later, some drop out because they experience the event under study, others drop out for other reasons. Thus, a listing of the experience of individuals in a study might be as follows:

Individual No.	Date of Entry to Experience	Date Leaving Experience	Reason for Leaving Experience	Length of time in Experience
1	January 1	December 31	end of study	365 days
2	July 1	December 31	end of study	184 days
3	Sept. 15	December 31	end of study	107 days
4	May 10	October 1	death	194 days
5	January 1	July 1	withdrew	181 days
6	January 1	August 15	lost to observation	227 days
7	August 15	December 31	end of study	138 days
8	February 20	Sept. 1	death	192 days
9	October 10	December 31	end of study	82 days
10	January 1	May 1	withdrew	120 days

Total experience 1,790 days = 4.9 yrs.

The problem of computing the incidence rate from such material lies in the determination of the denominator of the rate; i.e., the mean population at risk of event during the specified time. This is accomplished by making use of the concept of a *person-time unit of observation*. The time unit is usually a year, but it may be any other unit. A person in the experience for a full year (if that is the unit used) is said to contribute a person-year of experience to the observations. Two people in the experience for half a year will each contribute half a person-year experience. Together they contribute one person-year of experience. Thus, the 10 people in the above listing have contributed a total experience of 4.9 person-years or the arithmetically equivalent experience of 4.9 persons present in the study for a full year. Since there were two deaths in this experience, the average annual death rate is, substituting in the general formula for the incidence rate:

$$\frac{2}{4.9} \times 1,000 = 408.2 \text{ per thousand}$$

It will be noted that this device permits individuals who experience the event (individuals 4 and 8 in the above example) or who leave the experience for other reasons before completion of the study (individuals 5, 6, and 10) to make their contribution to the total up to the time they leave the experience. It is, perhaps, easier to see that the time factor must be taken into account by rewriting the general formula as follows:

$$\text{Incidence rate} = \frac{\text{number of events in population at risk during observation}}{\text{person-time units of risk during observation}}$$

Table 44-2. Experience of children in test and control groups in study of active immunization against pertussis

Time Period in Months	Number of Children						Person-Months at Risk $L_x = l_x + \frac{(n_x - d_x - w_x)}{2}$	
	Present at Beginning of Month $l_x$		Number Entering Study During Month $n_x$		Number Withdrawing During Month for Specified Reason			
					All Other Reasons $w_x$			
	Pertussis Attack $d_x$		Test		Control			
	Test	Control	Test	Control	Test	Control	Test	Control
1	1,403	1,605	79	66	4	19	30	38
2	1,448	1,614	45	26	2	21	11	41
3	1,480	1,578	60	19	3	24	8	21
4	1,529	1,552	5	18	2	33	19	37
5	1,513	1,500	10	14	7	35	25	40

$$\text{Annual incidence or attack rate} = \frac{\text{Number of attacks}}{\text{Person-years of risk}} \times 100$$

$$\text{Test group} = \frac{37}{1,111.4} \times 100 = 3.3\%$$

$$m_x = \frac{d_x}{L_x}$$

$$\text{Control group} = \frac{243}{1,095.7} \times 100 = 22.2\%$$

Adapted from Tables 2 and 4, "A Study in Active Immunization Against Pertussis," by Pearl Kendrick, Am. J. Hyg., Vol. 29, No. 3, Sec. B., May, 1939.

In a practical problem involving larger numbers of observations than the above example, it is ordinarily easier to tabulate the entry and exit of an individual in a time period rather than to record the exact date of entry and exit, although this information should be available for each individual. The procedure for arriving at the person-time units of exposure is then carried out by a modified life table procedure as illustrated by the material in Table 44-2 adapted from a paper by Kendrick and Eldering (1939) concerned with the efficacy of immunization against pertussis.

Referring to the first line, the table shows that 1,403 individuals entered the test group in the first time period. If these 1,403 remained in the study throughout this time period of one month, they would contribute 1,403 person-months of experience. But during this first month, 79 individuals entered the test group. Since the exact date of entry is not being recorded, some may have entered in the early and some in the latter part of the month. On the average, it may be considered that each of the 79 individuals contributes one-half a month to the experience. Up to this point, therefore, we have accumulated  $1,403 + \frac{79}{2} = 1,442.5$  person-months of experience. However, some of these individuals were withdrawn from the test group during the month—four because they developed pertussis and 30 for other reasons. These individuals have already been counted in the experience, but since, on the average, they are in the experience only half a month, the other half should be subtracted from the experience. We then have as the accumulated person-months of experience

$$1,403 + \frac{79}{2} - \frac{4}{2} - \frac{30}{2} = 1,403 + \frac{79 - 4 - 30}{2}$$

$= 1,425.5$  person-months of experience as shown in the table.

Since during the first month we started with 1,403 individuals and added 79 more while 34 left the experience, we have  $1,403 + 79 - 34 = 1,448$  individuals present in the test group at the beginning of the second month. The procedure for calculating the person-months of exposure during this second time period is then repeated.

We may summarize the computational procedure as follows, the symbols under the wording being the conventional life table symbols:

$$\begin{array}{l} \text{Person-time} \\ \text{units of} \\ \text{exposure} \end{array} = \begin{array}{l} \text{number present} \\ \text{at beginning} \\ \text{of interval} \end{array} + \frac{1}{2} \left( \begin{array}{l} \text{number} \\ \text{entering} \\ \text{during} \\ \text{interval} \end{array} - \begin{array}{l} \text{number ex-} \\ \text{periencing} \\ \text{event during} \\ \text{interval} \end{array} - \begin{array}{l} \text{number withdrawn} \\ \text{during interval} \\ \text{for other reasons} \\ \text{than events} \end{array} \right)$$

$$L_x = l_x + \frac{1}{2} (n_x - d_x - w_x)$$

Having the person-time units of exposure (in this case, months) it is now possible to compute the incidence rate for the event—in this case, an attack of pertussis. The formula, with accompanying symbols, is:

$$\text{Incidence rate} = \frac{\text{number of events in population at risk during observation}}{\text{person-time units of risk of exposure}}$$

$$m_x = \frac{d_x}{L_x}$$

The table shows this same procedure carried through for each month of the study for both test and control groups. The total person-months at risk for each group are shown at the bottom of the table. These are converted to person-years by dividing by 12 and the annual attack rates are computed according to the formula.

Typical instances in which the foregoing process is employed are evaluation of the effectiveness of therapy following completion of treatment, the determination of the effectiveness of prophylactic procedures as in the example just given, the estimation of the chance of developing a particular disease or condition within a given period of time after observation, etc. Any dynamic process may be analyzed in this fashion. The basic information needed is the date of entry to the experience, the date of exit from the experience, and knowledge of the event when it occurs. Usually the material is tabulated in whatever time intervals are appropriate to the phenomenon under consideration—a year, a six-month period, a month, etc. One of the earliest examples of the use of this procedure may be found in Frost (1933). Berkson and Gage (1950) illustrate its use in the calculation of survival rates for cancer.

When the event to be recorded is death, there is usually no difficulty in determining in which time period it occurred. When, however, the event is some phenomenon such as change in immunological status, this is not always so easy. For instance, the event to be recorded may be change from a serological positive state to a negative one. Now suppose individual A is observed as being positive in the first three time periods (a time period might be six months) but he is not seen in the fourth time period, and when he is examined in the fifth time period he is found negative. The question arises as to how his serological state should be recorded in the fourth period. The reader is referred to Harris and others (1949) for a discussion of this problem. Where possible, of course, it is best that there be no gaps in the observations.

## THE GENERALIZATION OF OBSERVATIONS

It is rare that any given study is undertaken for the sake of the observations themselves. Rather, the objective is to obtain a set of facts which may serve as the basis for predictions about similar situations, that is, the observed material is expected to serve as the basis for generalization.

In the problem on immunization against pertussis, the value of the study lies in what these observations tell us about the effect of immunization on the attack rate of pertussis in general—that is, at any time immunization is given—not in the fact that, in this particular instance, there is a difference in the attack rate in test and control groups. In this sense then, the observed data are only a sample of all possible observations of this kind.

When the data are looked upon as a sample, the question arises concerning

the extent to which the observed difference between test and control groups may be generalized; i.e., may be considered as being indicative of a real effect of immunization. The reasoning process which leads to this question may be demonstrated by the following hypothetical situation.

**A Hypothetical Situation.** Suppose that immunization really has *no* effect on the attack rate from pertussis, that is, the hypothesis is set up that there is no real difference between test and control groups with respect to attack rates. Under these conditions, if we take a series of samples—that is, conduct a series of experiments like the one reported on above—then, in some cases, the test group will have a lower attack rate than the control group and in some the reverse will occur. The situation may be depicted as follows: Consider that we have a box with a very large number of red and white beads in it. The white beads represent individuals who remain free of the disease and the red beads are those who contract pertussis. Now, suppose we draw a sample from the box to represent the test group. We will get a certain proportion, *P*, of red beads (cases of pertussis). The proportion of red beads in the sample will not necessarily be the same as in the box, although it is an estimate of it. Now, let us draw a second sample,\* to represent the control group. The results may be recorded in line 1 of the following:

Experiment No.	Test Group % Attacked (red beads)	Control Group % Attacked (red beads)	Difference
1	8	13	-5
2	12	10	2
3	14	11	3
4	9	13	-4
.	.	.	.
.	.	.	.
.	.	.	.
k	10	11	-1
Average	P	P	0

It will be noted that line 1 represents the situation as it is usually met in an actual study in which a difference has been observed between test and control groups. In this case, however, *we know that the difference between the two groups can only be due to the operation of chance*, since both groups came from the same box. Reasoning by analogy, it might be perfectly possible in an actual problem to get a difference between test group and control group, purely through the operation of chance rather than because the agent being studied (immunization, in this case) had any effect at all. How, then, shall we discover whether an observed difference is likely to be due to chance or not?

If we were to take samples from the box over and over again, they would differ among themselves as to the proportion of red beads (per cent attacked) and we would begin to get some idea of the extent of this chance variation in the difference between the test and control groups. Lines 2, 3, 4 . . . k in the table show the development of this variation when the experiment is repeated over and over again. Figure 44-1 shows the situation diagrammatically. In the diagram, *p* repre-

\* The beads are replaced in the box after each drawing.

sents the true proportion of red beads (per cent attacked) in the box from which the samples are drawn. It will be noted that the curve for both the test and control groups centers around this value of  $p$  and, therefore, the curve of difference centers around zero.

Fig. 44-1. Diagram of variation which would occur on repeated sampling. Hypothetical situation.

Referring to the curve of differences, if we carried out an actual study and obtained a difference of such a magnitude that it fell at the point marked  $X$  in the diagram, which is well outside the extent of variation of most of the differences which would occur as a matter of chance, we would say that the observed difference is unlikely to occur by chance and is probably due to other factors. In other words, the observed difference  $X$  is not consistent with the hypothesis that there is no difference between test and control group. We would then seek an explanation for the observed difference. On the other hand, if the observed difference fell well within the curve of chance variation of the differences, the only conclusion to be drawn is that it could easily occur as a matter of chance, and is, therefore, the kind of difference that would be expected under the hypothesis.

Given any observed difference then, if we know how much it deviates from the center of the curve, we can say whether it falls inside or outside the "ordinary" limits of chance variation and so determine if it is likely to occur by chance. What is needed, therefore, is some index or measure which describes how the curve of chance variation spreads out around the center. This index or measure must possess certain characteristics. It must be able to distinguish between two curves such as are shown in Figure 44-2, panel A, in one of which the observations spread out

quite a bit and in the other of which they are more closely clustered about the center. However, this measure must also have approximately the same value for the two curves shown in panel B of Figure 44-2, which spread out essentially the same way around the center except for an outlying observation on one of the

Fig. 44-2. Curves of chance variation and the normal probability curve.

curves. A measure which described the curves in terms of the proportion of the total area within a stated distance of the center of the curve would have these characteristics. When the curve of chance variation approximates the bell-shaped normal probability curve \* such as is shown in the figures, the mathematical characteristics of the curve provide such a measure. It is known as the *standard deviation*.

The standard deviation is the distance out from the center of the curve which must be covered in order to encompass 34 per cent of the total area on either side of the center, or 68 per cent altogether, as shown in panel C of Figure 44-2. It is commonly denoted by the Greek letter  $\sigma$ . It may be seen by referring to panels A and B that this measure meets the requirements laid down above. It is not necessary to go out as far from the center to cover 34 per cent of the total area of one of the curves in panel A as for the other curve. In panel B, it is seen that the value of  $\sigma$  would be essentially the same for the two curves.

The proportion of the total area of the normal curve within a given distance of the center, expressed in standard deviation units, is shown in panel C. Reference to panel C will show how  $\sigma$  may be used to measure the extent of chance variation.

\* Not all curves of chance variation which would be obtained by repeating the observations over and over again are "normal." Usually, though not necessarily, if the number of observations is increased they approach the normal curve or they may be mathematically transformed into a normal curve. When the number of observations in the sample is less than 20, the "poisson binomial" is used to determine the desired probabilities. This procedure is described in any standard statistical textbook.

It may be seen from the diagram that if one goes out two standard deviations on either side of the center, a sizable proportion of the total area of the curve of chance variation is covered—95 per cent, in fact. It follows that, *as a matter of chance*, observations falling further away from the center of the curve than two standard deviations will occur only about five times in 100. If then the observed difference lies outside of two standard deviations, we may say that if there were really no difference in the two sets of observations which are being compared, a difference as great or greater than that observed would occur less than five times out of 100, purely as a matter of chance. These, then, are the betting odds that the observed difference is statistically significant. The dividing line between what is usually considered statistically significant and what is not is purely arbitrary. One may prefer to set the dividing line at three standard deviations, in which case the chances are only one in 100 that an observation will fall outside this distance from the center purely by chance. Ordinarily, the dividing line is placed at two standard deviations.

Table 44-3. Comparison of test and control group as to per cent attacked

Group	Attack	No Attack	Total	% Attacked per Year
Test	52	2,216	2,268	2.3
Control	348	1,959	2,307	15.1
Total	400	4,175	4,575	8.7

**Application to an Actual Problem.** Returning to the pertussis problem, we may summarize the findings of the study in Table 44-3. Such a table is known as a 2 by 2 table, or a *four-fold table*, because there are two categories each way in the table and four primary cells in the table. Is the difference in the attack rate in the test and control groups a real difference, or is it one which might arise by chance even though there was really no difference in the two groups? This question requires an answer before we can generalize these observations to conclude that pertussis immunization reduces the attack rate.

% DIFFERENCE BETWEEN TEST AND CONTROL GROUP

Fig. 44-3. Diagram of problem of determining whether observed difference is likely to be due to chance or not.

The approach to answering the question is as indicated above. We need to know if the observed difference of 12.8 per cent is more or less than two standard deviations away from the center of the curve of differences (see Fig. 44-3).

The curve centers at zero since the hypothesis to be tested is that there is no difference between the two groups, and we wish to determine the extent of chance variation under this hypothesis.

**The Computation of the Standard Deviation of the Curve of Differences.** Each of the three curves in Figure 1 has its own standard deviation. The standard deviation is computed from the formula  $\sigma = \sqrt{\frac{pq}{n}}$ , where  $p$  = probability of occurrence of the event,  $q = 1 - p$ , and  $n$  = size of the sample. If, in our hypothetical example, we knew the true proportion ( $p$ ) of red beads in the box (per cent attacked) we would use this in the formula for the standard deviation. This is unknown, however, and an estimate has to be made from the observed data. Since our hypothesis is that there is no difference in the two groups, the most likely value of  $p$  in the example is that for the total; hence,  $p = .087$ , and  $q = 1 - p = .913$ .

We then have the following formulae:

$$\sigma_t = \sqrt{\frac{pq}{n_t}} \text{ where } n_t = \text{the number of individuals in the test group,}$$

$$\sigma_c = \sqrt{\frac{pq}{n_c}} \text{ where } n_c = \text{the number of individuals in the control group,}$$

and

$$\sigma_{\text{difference}} = \sqrt{\sigma_t^2 + \sigma_c^2} = \sqrt{\frac{pq}{n_t} + \frac{pq}{n_c}} = \sqrt{\frac{.087 \times .913}{2,268} + \frac{.087 \times .913}{2,307}} = .0083$$

Then the observed difference divided by the standard deviation of the difference =  $\frac{.128}{.0083} = 15.4 \sigma$ 's

Thus, the observed difference is 15.4 standard deviations away from the center of the curve of differences (see Fig. 44-3). Since it is far beyond two standard deviations, a difference of this magnitude would occur by chance only once in millions of trials. Other things being equal, then, it appears as though the difference is a real difference which may be attributed to the effect of immunization.

**Interpretation of Results of Tests of Significance.** If a difference is found not to be statistically significant, all that can be said is that since it might easily arise by chance, it is not possible to determine whether the difference was the result of the experiment or not. If, however, the difference is found to be one which is unlikely to occur by chance, an explanation for the difference must be sought. *If the test and control groups are alike in every respect but that being tested*—that is, if all other things are equal—the difference may be attributed to the factor being tested. The reader is referred to the earlier discussion of this point (see page 1311).

In their study of the efficacy of immunization against pertussis, Kendrick and Eldering (1939) compare test and control groups on a number of factors such as age and sex, geographic distribution, family size, incidence of communicable diseases other than pertussis and number of nursing visits. The authors concluded that, for the purposes of their study, the two groups were similar with respect to factors which might influence the attack rate other than immunization. Under these

circumstances, therefore, the fact that the attack rate in the test group was significantly lower than in the control group may be interpreted as indication that immunization conferred some protection.

**The Comparison of Groups which are Classified into More than Two Categories.** The procedure just outlined is adequate for dealing with most situations involving the comparison of rates when the data can be arranged in the form of a four-fold table. Situations often arise, however, in which one or both of the factors to be compared are classified into more than two categories. Such an instance is shown in Table 44-4. The table was designed to examine the question of the rela-

Table 44-4. Distribution of infants born in Vanderbilt University Hospital in 1946, by type of feeding and by pay status of mother

Type of Feeding	Number of Infants				Per Cent of Total in Each Pay Status Group			
	Ward	Low Cost Private	Private	Total	Ward	Low Cost Private	Private	Total
Breast fed only	378 423	206 210	294 245	878	66.0	60.0	49.0	58.9

Chi square = the sum of  $\left[ \frac{(\text{the theoretical} - \text{observed frequencies})^2}{\text{the theoretical frequency}} \right]$

$$\chi^2 = \sum \frac{(T - O)^2}{T}$$

$$\chi^2 = \frac{(378 - 423)^2}{378} + \frac{(206 - 210)^2}{206} + \frac{(294 - 245)^2}{294}$$

$$+ \frac{(51 - 58)^2}{51} + \frac{(28 - 21)^2}{28} + \frac{(40 - 40)^2}{40}$$

$$+ \frac{(212 - 160)^2}{212} + \frac{(116 - 119)^2}{116} + \frac{(166 - 215)^2}{166}$$

$\chi^2 = 43.610$

d.f. = 4

n' = 5

P = < .000000

tionship between the economic status of the mother and the nursing of the baby. It may be seen that ward mothers seem to breast feed their babies more frequently than mothers on the private or low cost private service of the hospital. Is this really true, or could differences like those seen in the table readily occur as a

matter of chance? The general reasoning process which leads to this question and to its answer is the same as that which pertains to data which are classified into a four-fold table.

The hypothesis is set up that there is no real difference among the several pay status groups with respect to the method of feeding the baby. Under this hypothesis we might expect each group to show the same percentage breast fed, except for chance variation, as the total; namely, 58.9 per cent. Thus, in the ward group we would expect 58.9 per cent or 378 of the 641 ward babies to be breast fed, if the data are consistent with the hypothesis. Similarly, we would get an expected number for each cell of the table. These expected numbers are shown in italics in the table. The problem then is to determine whether the difference between the observed frequencies and those expected under the hypothesis are likely to occur as a matter of chance. Although this is the same type of question that arises with respect to data in the four-fold table, the technical procedure for answering it is slightly different and goes under the name of the Chi-square ( $\chi^2$ ) test. The computation of  $\chi^2$  is shown below Table 44-5. Its value is 43.610. Reference to a table \* of the probability of obtaining a particular  $\chi^2$  by chance alone shows that such a value would occur less than one time in a million purely through the operation of chance. It is very unlikely, therefore, that the hypothesis that there is no difference among the several groups is correct. We must now seek an explanation for the observed differences.

MEASUREMENT DATA

The discussion thus far has been largely in terms of attribute data (see page 1324) and it has been indicated that most of the reasoning about such data revolves around comparison of rates or ratios of one kind or another. In dealing with measurement

Table 44-5. Frequency distribution of weight at birth of 569 white first-born infants delivered at Vanderbilt University Hospital, 1941-1942

Birth Weight in Grams	Number of Infants
1,000-1,499	1
1,500-1,999	1
2,000-2,499	10
2,500-2,999	81
3,000-3,499	239
3,500-3,999	173
4,000-4,499	53
4,500-4,999	11
TOTAL	569

\* A table showing this probability may be found in Pearson (1948). It is entered with the calculated value of  $\chi^2$  and the value shown as  $n^1$  in the computation under Table 44-5.  $n^1$  is one more than the number of independent cells in the table. The number of independent cells is also known as the degrees of freedom (d.f.) and is the number of cells which can be filled in independent of the totals.

data, however, the reasoning is in terms of certain characteristics of the frequency distribution of these measurements. The general principles, however, are the same.

The approach to measurement data is best illustrated by a specific example. Table 44-5 shows the distribution of weight at birth of 569 first-born white infants delivered at Vanderbilt Hospital in 1941-1942. The data are presented graphically in Figure 44-4. It has been indicated earlier that it is unlikely that we will be inter-

Fig. 44-4. Frequency distribution of birth weights of 569 white first-born infants delivered at Vanderbilt University Hospital, 1941-1942.

ested in these data solely for their own sake, but rather for the knowledge they can provide about white first-born babies in general. For this reason, it is desirable to describe the data in terms of fairly general applicability. Figure 44-4 suggests that this might be done by describing where the distribution centers and how the observations spread out around the center.

**Describing the Symmetrical Frequency Distribution.** When the data are distributed in approximately the bell-shaped normal curve, the *arithmetic mean* \* is used as an indication of where the observations center on the scale. The arithmetic mean of the data in Table 44-5 is 2,439.0 grams. The measure of the variability of the observations around the mean which is used is the *standard deviation*. Its value for these data is 494.5 grams. (See page 1333 for the procedure used in computing these statistical measures.)

\* The arithmetic mean is ordinarily referred to as the average, but since there may be many kinds of averages, the term arithmetic mean is preferred.

How can these characteristics of the observed frequency distribution—the mean and the standard deviation—be used to yield information about the birth weights of first-born white infants in general? If these observations are thought of as a sample from the “population” (or box, as on page 1324) of all first-born white infants, and if we then take repeated samples from this population, the samples will vary among themselves purely as a matter of chance. The measures of central tendency will also vary from sample to sample so that we will have a distribution of the sample means which will vary around the true mean of the population from which the samples are drawn \* (see page 1324). The measure of the extent of the sampling or chance variation of the means will be given by the *standard deviation of the distribution of means*. This is obtained by dividing the standard deviation of the individual observations in the population from which the sample is drawn by the square root of the number of observations in the sample. Using  $\sigma$  to represent the standard deviation, we may write:  $\sigma_m = \frac{\sigma_{\text{population}}}{\sqrt{n}}$  where  $n$  is the number of observations in the sample. The formula shows that for a specific degree of variation of the individual observations in the population, the larger the size of the sample, the less the variability of the sample mean. Since  $\sigma_{\text{population}}$  is unknown, the standard deviation of the observed data is substituted for it.† For this example,

then,  $\sigma_m = \frac{\sigma_{\text{sample}}}{\sqrt{n}} = \sqrt{\frac{494.5}{569}} = 20.7$  grams. The value obtained by this formula is usually referred to as the *standard error* of the mean. Since the distribution of means may ordinarily be described by a normal curve, a standard error of 20.7 grams tells us that if we were to take repeated samples like the one in Table 44-5, 95 per cent of the means of these samples would vary within  $\pm 2 \times 20.7$  grams = 41.4 grams of the true mean of the population. Thus, we obtain some notion of the confidence which we may place in the observed mean as an estimate of the true mean.

Since the standard deviation of the observed data has been used as an estimate of the standard deviation of the individuals in the population from which the sample is drawn, the statement may also be made that if the observed sample were repeated over and over again, the chances are 95 out of 100 that the weights of individual infants would not differ from the true average weight in the population by more than  $2 \times 494.5 = 989.0$  grams.

In summary, then, if the mean and standard deviation of a frequency distribution which may reasonably be described by a normal curve are known, the standard error of the mean may be calculated and from these three measures, one can obtain a notion of how much one may rely on any generalization from the observed data to the population from which it is drawn. These statements only hold, however,

\* Bradford Hill (1950) gives the results of an experiment showing the actual variation of the means from sample to sample.

† The reader should note that just as the means will vary from sample to sample, so will the standard deviations. However, the use of the observed  $\sigma$  as an estimate of the population  $\sigma$  is not likely to introduce any serious errors, provided the size of the sample is sufficiently large—preferably larger than 30. The reader is referred to standard texts for procedure when the sample size is less than this.

when the sample is representative of the population to which it is expected to generalize. If, for example, white male first-born infants delivered at Vanderbilt Hospital should be selected in some way which would tend toward a disproportionate number of infants with low birth weights—for instance, if their mothers all had complications during pregnancy—generalization to all white male first-born infants would not be valid (see page 1312 and Densen, 1949).

**Procedure for Computing the Mean and Standard Deviation of a Frequency Distribution.** The basic definitions are as follows:

The *mean* is the sum of the observations divided by the number of observations.

$$\text{Formula: } \bar{X} = \frac{\Sigma(X)}{n}, \quad (1)$$

where  $X$  is an individual observation,  $n$  is the number of observations,  $\Sigma$  means “the sum of” and  $\bar{X}$  represents the mean.

The *standard deviation* is the square root of the sum of the squared deviations from the mean divided by the number of observations minus one.

$$\text{Formula: } \sigma = \sqrt{\frac{\Sigma (X - \bar{X})^2}{n - 1}}, \quad (2)$$

where the symbols have the same meaning as in the formula for the mean and  $\sigma$  represents the standard deviation.

**APPLICATION TO UNGROUPED DATA.** Suppose the following observations of hemoglobin on 10 individuals:

Hgb. in gm. Individual per 100 ml. of blood			
No.	X	$(X - \bar{X})$	$(X - \bar{X})^2$
1	14.3	—2.24	5.02
2	15.1	—1.44	2.07
3	15.7	—0.84	0.70
4	16.2	—0.34	0.11
5	16.5	—0.04	0.00
6	16.9	+0.36	0.13
7	17.3	+0.76	0.58
8	17.6	+1.06	1.12
9	17.8	+1.26	1.59
10	18.0	+1.46	2.13
Sum	165.4	0	13.45

$$\text{Mean } \bar{X} = \frac{\Sigma(X)}{n} = \frac{165.4}{10} = 16.54 \text{ gm. per 100 ml.}$$

$$\text{Standard deviation } \sigma = \sqrt{\frac{\Sigma (X - \bar{X})^2}{n - 1}} = \sqrt{\frac{13.45}{9}}$$

$$= \sqrt{1.49} = 1.22 \text{ gm.}$$

APPLICATION TO GROUPED DATA. When the number of observations is large the procedure used for ungrouped data is very time consuming. The entire process may be considerably simplified by grouping the observations and employing a device known as an "arbitrary origin." The computation may be illustrated with the data presented in Table 44-5, which is reproduced here.

Frequency distribution of weight at birth of 569 white first-born infants delivered at Vanderbilt University Hospital, 1941-1942

Birth Weight in Grams	Number of Infants	Arbitrary Scale		
X	f	x	xf	x <sup>2</sup> f
1,000-1,499	1	- 4	- 4	16
1,500-1,999	1	- 3	- 3	9
2,000-2,499	10	- 2	- 20	40
2,500-2,999	81	- 1	- 81	81
3,000-3,499	239	0	0	0
3,500-3,999	173	+ 1	173	173
4,000-4,499	53	+ 2	106	212
4,500-4,999	11	+ 3	33	99
TOTAL	569		+ 204	630

The effect of using an arbitrary origin may be shown diagrammatically.

It is seen that the origin is shifted so that zero on the arbitrary scale corresponds to 3,250 grams on the original scale and one unit on the arbitrary scale corresponds to 500 grams on the original scale. As its name indicates, the arbitrary origin may be placed anywhere in relation to the original scale. However, the computation is facilitated by placing it somewhere near the center of the distribution which is usually in the class with the greatest frequency.

The computation is now carried forward so that the mean and standard deviation are first determined in the units of the arbitrary scale and then converted back to the original scale.

Mean on the arbitrary scale  $\bar{x} = \frac{\sum xf}{n}$

Equivalent to Formula 1

$$= \frac{204}{569} = .358$$

Standard deviation on the arbitrary scale  $\sigma_x = \sqrt{\frac{\sum x^2 f}{n}}$

Equivalent to Formula 2 \*

$$= \sqrt{\frac{630}{569}} = \sqrt{1.11}$$
$$= 1.05$$

\* The formula here is equivalent to formula 2 except that we have divided by n rather than n-1. When the number of observations is greater than 30, the use of n rather than n-1 does not introduce any significant error.

Referring to the diagram, it is seen that a mean of .561 on the arbitrary scale corresponds to a little more than 3,500 gm. on the original scale. This may be expressed by formula as:

Mean  $\bar{X}$  = Arbitrary origin +  $i \left( \frac{\sum xf}{n} \right)$ , where  $i$  represents the size of the class interval.

$$\begin{aligned}\bar{X} &= 3,250 \text{ grams} + 500 (.358) \\ &= 3,250 + 179 = 3,429.0 \text{ gm.}\end{aligned}$$

The standard deviation is shifted back to the original scale by making a correction for the fact that the deviations were measured from the arbitrary origin rather than the mean and multiplying by the size of the class interval. By formula this is:

$$\sigma_x = i \sqrt{\frac{\sum x^2 f}{n} - \left( \frac{\sum xf}{n} \right)^2}$$

It will be noted that the second term under the square root sign is simply  $\bar{x}^2$ . Thus,

$$\begin{aligned}\sigma_x &= 500 \sqrt{\frac{630}{569} - (.358)^2} = 500 \sqrt{1.11 - .13} \\ &= 500 \sqrt{.98} = 500 (.989) = 494.5 \text{ gm.}\end{aligned}$$

The values of the mean and standard deviation obtained by this procedure are those presented on page 1331.

**Comparing Frequency Distributions.** As in the case of attributes, we frequently wish to compare one set of measurement data with another. For instance, we may wish to compare the average weight at birth of the white first-born infants at Vanderbilt Hospital with those of later birth order. In a sample of 320 infants of birth order later than the first, the mean weight was found to be 3,525 grams—96 grams heavier than the average weight for the sample of 569 first-born babies. Do the infants born to multipara mothers really weigh more on the average than the babies of primipara mothers, or could a difference of 96 grams easily occur as a matter of chance although no difference exists in the population from which the samples are drawn? This is exactly the kind of question which was asked about the difference in the percentage attacked in the test and control groups for the pertussis immunization problem and it is answered according to the same principles.

In the pertussis problem it was found necessary to determine how far away from the center of the distribution of differences the observed difference fell and to express this distance in terms of standard deviations (see Fig. 44-3). This information could then be converted into a statement as to whether the observed difference is likely to occur by chance or not. In order to do this the standard error of the distribution of differences had to be calculated. The standard error of the difference between two means \* is given by  $\sqrt{(S.E._{m_1})^2 + (S.E._{m_2})^2}$  where  $S.E._{m_1}$  stands for the standard error of the first mean and  $S.E._{m_2}$  for the standard error of the second mean. The standard error of the mean for first-born infants was found to be 20.7 grams. For the infants of later birth order the standard error of the mean is given by substituting in the formula  $S.E._m = \frac{\sigma_{\text{sample}}}{\sqrt{n}} = \frac{560}{\sqrt{320}} = 31.3 \text{ grams.}$

\* When the two sets of data are independent of each other.

The S.E. of the difference then is  $\sqrt{(20.7)^2 + (31.3)^2} = 37.5$  grams. The observed difference of 96 grams is therefore 2.6 times the standard error of the difference. Differences of this order will occur about one time in 100 as a matter of chance. If one considers differences which will occur less than five times out of 100 by chance as unlikely to be due to chance, then the observed difference of 96 grams is "statistically significant." It should be remembered, however, that "statistically significant" is just a phrase, and the dividing line of five times out of 100 is entirely arbitrary. The real question is one of the probabilities involved and it is up to the worker to interpret a probability such as one in 100 as "likely" or "unlikely" to occur by chance. If the particular case falls on what he considers to be the borderline between these choices, the only way out of the dilemma is to gather more data.

One may compare frequency distributions on other characteristics than where they center, such as the variability of the observations. For example, is the birth weight of first-born babies more or less variable than those of later birth order? The same principles hold in answering this question as that concerned with differences between proportions or differences between means. These principles apply when we are dealing with fairly large samples. The reader is referred to Yule and Kendall (1948) for details concerning comparison of distributions with respect to other characteristics than the mean and also for a discussion of the methods of dealing with small sample data.

**Describing Asymmetrical Distributions.** When the data do not form a symmetrical distribution the mean and standard deviation, respectively, are not good indices of the centering and scatter of the observations. The mean is too readily affected by an occasional extreme observation and the interpretation of the standard deviation depends upon having a normal curve. Under these circumstances, the median and the quartiles are used to describe the distribution. The data in Table 44-6 are illustrative of a distinctly asymmetrical distribution. The data are of particular interest in connection with the control of industrial dust hazards and they may be used to demonstrate the meaning of the median and the quartiles.

The median is that value on the scale of classification which divides the observations in half. Since there are 154 observations shown in the table, the median is the value of the 77th observation, if the observations were arranged in order from the smallest size particle to the largest. If the observations in the table are cumulated as shown in the last column it is seen that 60 particles have a size less than 3.30 microns and 80 have a size less than 4.40 microns. Since the observation in which we are interested is the 77th, the median value must, therefore, be between 3.30 and 4.40 microns. It is readily found if it is assumed that the 20 observations in this class are evenly distributed over the class.\* Since up to 3.30 microns we already have 60 observations, we need 17 more to come up to the 77th observation. This will take us nearly, but not quite, to 4.40 microns. In fact, if we take  $\frac{17}{20}$  of the class size of 1.10 microns and add this to the beginning of the class we will have a fairly good estimate of the median. Thus, the median is equal to  $3.30 + \frac{17}{20}(1.10) = 4.24$  microns. This means that half the dust particles have a

\* This is not an unreasonable assumption if the width of the class—in this case 1.10 microns—is not too great.

Table 44-6. Size of dust particles in the air

Particle Size (in microns)	Number of Particles	Cumulated Number of Particles
1.10-1.19	28	28
2.20-3.29	32	60
3.30-4.39	20	80
4.40-5.49	15	95
5.50-6.59	14	109
6.60-7.69	8	117
7.70-8.79	9	126
8.80-9.89	5	131
9.90-10.99	4	135
11.00-12.09	5	140
12.10-13.19	3	143
13.20-14.29	2	145
14.30-15.39	1	146
15.40-16.49	0	146
16.50-17.59	2	148
17.60-18.69	0	148
18.70-19.79	1	149
19.80-20.89	0	149
20.90-21.99	2	151
22.00-23.09	0	151
23.10-24.19	0	151
24.20-25.29	1	152
25.30-26.39	2	154
Total Particles	154	

Adapted from Drinker and Hatch, *Industrial Dust*, 1st ed., New York, McGraw-Hill Book Co., 1936, Table 24, p. 148.

size of less than 4.24 microns and half have a size greater than this. The mean of this same distribution is 5.85 microns, which is considerably above the value above and below which half the observations fall.

The quartiles are computed in the same manner as the median. The first quartile,  $Q_1$ , is the value below which 25 per cent and above which 75 per cent of the observations fall. It is, therefore, the value of the 38.5th observation \* (154 divided by 4). Referring to the table, it is seen that the value of  $Q_1$  is somewhere between 2.20 microns and 3.30 microns. Since up to 2.20 microns we have 28 observations, 10.5 more are needed. This brings us up to  $2.20 + \frac{10.5}{32}(1.10)$  microns = 2.56 microns. The value of the observation below which 75 per cent of the observations fall and above which 25 per cent fall is  $Q_3$ . This is the 115.5th observation, which means that  $Q_3$  lies somewhere between 6.60 and 7.70 microns. Up to 6.60 microns there are 109 observations and there are 8 observations in the class 6.60 = 7.70 microns. Hence,  $Q_3 = 6.60 + \frac{6.5}{8}(1.10)$  microns = 7.49 microns.

It will be noted that 50 per cent of the observations lie between  $Q_1$  and  $Q_3$  or, in this case, between 2.56 and 7.49 microns.

\* This illustrates the point that the calculation of the median really assumes continuous distribution.

The standard errors of the median and quartiles as well as a discussion of their use and limitations in generalizing the observations may be found in Yule and Kendall (1948).

**Association.** In the discussion of the effect of immunization on the occurrence of whooping cough, a four-fold table of the following form was set up (see Table 44-3):

Group	Attack	No Attack	Total	% Attacked
Test				
Control				
Total				

The per cent attacked in the control group was compared with that in the test group and it was determined that the difference was unlikely to occur by chance. Other things being equal, it was concluded that the attack rate varied with whether or not an individual was immunized. In other words, the attack rate was associated with immunization. This process can be more generally described by writing the four-fold table as follows:

Group	A	Not A	Total	% A
B	a	b	a + b	$\frac{a}{a + b}$
Not B	c	a	c + a	$\frac{c}{c + d}$
Total	a + c	b + a	a + b + c + d	$\frac{a + c}{a + b + c + d}$

Whenever  $\frac{a}{a + b}$  differs from  $\frac{c}{c + d}$  by more than would be expected as a matter of chance, we say that A is associated with B—that is, varies with the presence or absence of B.

The comparison of attributes usually takes the form indicated in the above table, although the number of categories may be extended as indicated in the discussion on page 1329. When we deal with measurement data the form of the table changes, depending on whether B alone is a measured variable or both A and B are measured variables. An example of the first case is given by the comparison of the birth weights of first-born infants and later-born infants (see page 1335). In this case the table takes the form:

B Grouped Values of Measured Variables	A	Not A
Group 1		
2		
3		
4		
5		
6		
.		
.		
.		
Total		
Arithmetic Mean		

Here A represents the first-born infants and Not A represents those of later birth order. The measured variable is the birth weight. Group 1 of the birth weights, for example, is the group of weights from 1,000 through 1,499 grams. We say that the measured variable is associated with whatever A represents if the difference between the mean value of the measured variable for A and that of Not A is unlikely to occur by chance and if A and Not A do not differ in other respects.

When both A and B are measured variables the table takes the following form:

Grouped Values of Measured Variable B	Grouped Values of Measured Variable A				Total	Arithmetic Mean
	Group a	Group b	Group c	....		
Group 1						$M_1$
Group 2						$M_2$
Group 3						$M_3$
Group 4						$M_4$
.						
.						
.						
Total						$M_A$
Arithmetic Mean	$M_a$	$M_b$	$M_c$		$M_B$	

An example of this form is shown in Table 44-7. The average cancer death rate without taking account of the diabetes rate ( $M_{11}$ ) is 113.3 per 100,000 population. If the cancer death rate were not associated with the diabetes death rate—that is, did not vary when the diabetes rate varied—it would have the same value \* in each specific diabetes death rate group. In terms of the symbols in the

\*Except for chance variation.

Table 44-7. Death rates from diabetes and from cancer and other malignant tumors in each state of the United States and the District of Columbia in 1940

Diabetes Death Rate											
	6-9	10-13	14-17	18-21	22-25	26-29	30-33	34-37	38-41	Total	Average Diabetes Rate
55-64	1	3	1							5	12.0
65-74		2								2	12.0
75-84		1	5	1						7	16.0
85-94			3	1		1				5	19.2
95-104				1	1					2	22.0
105-114				2						2	20.0
115-124			1			2				3	24.0
125-134					1	4	1	1		7	29.1
135-144					1	2	2	1		6	30.0
145-154					1		2	2		5	32.0
155-164							1		2	3	37.3
165-174						1		1		2	32.0
Total	1	6	10	5	4	10	6	5	2	49	23.8
Average Cancer Rate	60.0	66.7	85.0	98.0	130.0	130.0	145.0	148.0	160.0	113.3	
	$M_A$	$M_B$	$M_C$							$M_B$	$M_A$

Death Rate from Cancer and Other Malignant Tumors

table,  $M_a$  would equal  $M_b = M_c$ , etc.  $= M_B$ . By the same reasoning,  $M_1$  should equal  $M_2 = M_3$ , etc.  $= M_A$  if the diabetes rate were not associated with the cancer rate. Inspection of Table 44-7 shows that this is not so, but that as the diabetes death rate increases, the average cancer death rate also tends to increase. It appears then as though the value of the cancer death rate is associated with the diabetes death rate. It may also be seen that as the death rate from cancer increases, the average death rate from diabetes also increases, so that there is an association of the diabetes death rate with the cancer death rate. In general, then, it appears that the states with high cancer death rates also have high diabetes death rates, and vice versa. Having demonstrated that such an association exists, the investigator should seek the reasons for it.

A table such as Table 44-7 is known as a correlation table. The procedure just outlined may be used to investigate the existence of association. The question of the *degree* of association requires more advanced technics for its solution, and the reader is referred to Bradford Hill (1948) or Yule and Kendall (1948) for a consideration of this under the general heading of *correlation*. The reader's attention is called, however, to the similarity of the procedure as applied to Table 44-7 with that discussed under the heading of specific rates (see page 1316).

**Summary.** In order that the details presented in the previous paragraphs may be placed against a proper background, a brief summary is desirable. The study of man and his responses to his total environment, particularly as they are related to the phenomena of health and disease, is essentially the study of variation. The statistical method is a powerful tool for the investigation of this variation. The first and, in many respects, the most important step in undertaking such a study is a clear statement of the problem because the statement of the problem determines the kind of data to be collected and the manner in which this is done. When the data have been collected, they must be systematically organized or tabulated so as to bring out the interrelationships among items; i.e., to show the variation of the phenomenon being studied when classified in different ways. The process of classification results in a recognition of two types of data—attribute data and measurement data. Analysis, which is essentially comparison of one set of data with another, is made by means of rates or ratios for attribute data and by means of certain characteristics of the frequency distribution, such as averages and measures of variation, for measurement data. Since the observed material is almost always expected to serve as the basis for generalization, one must consider how much the observed data may be expected to vary if additional samples were taken—that is, one must consider the reliability of the data as a basis for generalization. This requires knowledge of the extent of sampling variation, and ways of measuring this are presented.

The most involved analysis has little value unless it helps to throw light on the initial question. It cannot do this unless the initial question is carefully stated since, if it is not, the analysis is aimless. For this reason the investigator and the statistician should work as a team in the formulation of the question and in the planning of the analysis. One should regard the statistical consultant in the same way as the general practitioner may regard the specialist. He must have sufficient knowledge of the work of the specialist to know when to call upon him for help. This chapter has attempted to provide information on the principles of statistical

reasoning so as to permit the investigator to recognize the elements of a statistical problem and to enable him to consult the trained statistician when he needs to do so.

## THE HEALTH OF THE POPULATION

PAUL M. DENSEN, Sc.D.

**Introduction.** The maintenance of health and the control of disease in the population require that we know how much disease there is, where it is and, if possible, why. Insofar as we can answer these questions we will be able to define the problems with which we are confronted, to plan the attack upon them and to evaluate the effectiveness of the attack. The chapter on statistical reasoning has dealt with the general principles by which such questions are answered. The present chapter sets forth some of the knowledge of the health of the population which has been gained through the application of these principles.

## THE POPULATION

If we are to study man in relationship to his environment, particularly with reference to the influence of that environment upon health, it is essential that we have knowledge of how that relationship varies with the characteristics of the population. Does the relationship vary with age, sex, race, occupation, etc.? Such questions require that we be able to classify the population into the categories mentioned. We may then study how changes in these characteristics may modify the health problems with which we have to deal, and, conversely, examine the influence of changes in the health of the population on these characteristics. It is pertinent, therefore, that we inquire into the source of information about populations and their trends.

**Source of Data.** The principal source of information regarding the population is the census. In the United States, censuses of the entire population are provided for in the Constitution and one has been taken every 10 years since 1790.

An indication of the kind of information available from a census is afforded by the following condensed list of items included in the 1950 census of population and housing.

1. **PERSONAL DATA:** Age, race, sex, marital status, highest grade of school completed, place of birth, citizenship, place of residence (city, town, village, or rural), employment status (for persons 14 years old and over), occupation by industry and class of worker, income in the previous year, certain data concerning migration, service in the armed forces and certain information concerning the number of children borne by each married woman.

2. **HOUSING DATA:** Home owned or rented and value of home or rental, the number of rooms, information concerning sanitary facilities and water supply, the

cost of utilities; if the home is rented, whether it is furnished or unfurnished and the cost of utilities; if owned, whether the property carries a mortgage and the market price, etc. Not all these data are obtained for all persons. Some of the information is obtained on a sample basis, a procedure instituted for the first time in the 1940 census.

Most of the types of data collected in a census are of interest to the health worker in one way or another. For example, the data on rental value of home, etc., are of interest in relation to the problem of housing and health, a subject coming in for increasing study.

**Population Estimation in Inter-Censal Years.** In order to study trends in birth rates, death rates, morbidity rates, etc., in years between censuses, it is essential that there be available some estimate of the size of the population in the area for which the rate is being computed. Such estimates may be made in a variety of ways. Most of them represent an extrapolation of past experience, either graphically or by the use of some mathematical expression to represent the growth pattern of the population. Among this latter group are the "arithmetic" method, which assumes that the population increases by a constant amount in each time period, and the "geometric" method in which the assumption is that the percentage increase is constant. These methods have the inherent difficulty that they permit the population to increase indefinitely, although for short periods this problem is usually not troublesome. Another method which is often used employs the "logistic" curve, which takes account not only of past growth of the population, but also of the possible presence of an upper limit to this growth. A description of the application of these methods may be found in Smith (1948) and Pearl (1940).

The Census Bureau at the present time does not use any of these methods directly to estimate state and local populations. It employs a procedure which attempts to estimate the net migration to or from an area from a knowledge of changes in elementary school enrollment plus consideration of the births and deaths occurring in the area and data on individuals in the armed forces. The method is fully described and compared with other methods by Shryock and Lawrence (1949).

In addition to estimating the population in state and local areas as just described, the Census Bureau also takes special censuses of local areas from time to time either as a complete count or on a sampling basis.

The reader will find in the tabular arrangement in Table 45-1 specific sources in which population data are presented.

**Population Growth and Characteristics.** Study of these various sources of information concerning the population reveals several trends in the characteristics of the population which are of great significance in relation to the nature of the medical and public health problems of the present and of the future. The major trends are the following:

1. **DECLINE IN THE RATE OF GROWTH OF THE POPULATION.** The first census in 1790 recorded a population of almost 4,000,000 for the continental United States. Preliminary estimates based upon the 1950 census indicate that the population has grown to nearly 150,500,000. The growth of the population between these two dates has been by no means uniform. Up to 1860, the rate of increase per decade was well over 30 per cent. Thereafter the rate declined somewhat until in

the period 1930-1940 it was only 7.2 per cent. There is some evidence of a rise in the decade 1940-1950 to about 1.4 per cent per year as compared with 0.7 per cent per year in the previous decade.

2. AGING OF THE POPULATION. Partly as a result of the decreased rate of growth of the population and partly as a consequence of the disproportionately large drop in the death rate of infants and children, there has been a steady increase in the proportion of the population in the older ages. In 1900, half the population was less than 22.9 years of age, whereas in 1940 the corresponding median age was 29.0 years. This aging of the population may be seen in Figure 45-1, which shows the proportion of the population age 60 and over from 1890 to 1940.

Fig. 45-1. Per cent of the population of the United States 60 years of age and over, 1890-1940.

The increase in the proportion of older persons in the population results in increasing emphasis on the health problems of such persons, such as the cardiovascular-renal diseases and cancer. However, it has been suggested (Reed, 1948) that research in the problems of this age group of the population would profit from a consideration of the well individual rather than being directed almost solely toward the sick individual (see pages 1310 to 1312 in Chapter 44); that is, that preventive programs must approach the problem from "a population base rather than on a base of illness."

3. INDUSTRIALIZATION OF THE POPULATION. Increasing industrialization is a characteristic of modern civilization. This industrialization has brought with it its own peculiar occupational hazards which have given rise to the development of medical services within industry which, within recent years, have been concerned not only with the treatment of occupational illness but also with the whole problem

of the worker and his relationship to his working environment (Division of Industrial Hygiene, 1943).

Apart from the problems associated with specific health hazards in industry, the concentration of large groups of the population in particular industries has led to attempts to "approach community health or comprehensive medical care of the families of industrial workers by way of the industry itself" (Reed, 1948). An outstanding example of such an attempt is the Welfare Fund of the United Mine Workers Union. The effect of these developments is to increase the number and variety of agencies dealing with medical care problems in the community. Finding the most beneficial method of integrating the activities of these several agencies should be a problem of major interest to medical practitioners, health administrators and the public alike.

4. **URBANIZATION OF THE POPULATION.** Increasing urbanization of the population has also changed the character of the health problems which must be dealt with today. Not only has there been urbanization of the population itself, but there has also been increasing urbanization of medical resources and medical knowledge. These trends have led to various plans designed to improve the medical and public health facilities of the rural areas, most of which seek to develop a regional pattern with the urban medical center at the hub and small hospitals affiliated with health departments on the periphery.

In urban areas, increasing concentration of the population has brought new environmental control problems in relation to waste disposal, food, and water supply, and has served to emphasize the increasing importance of housing in the health picture. These are problems which are dealt with on a community basis. On the other hand, the urbanization of medical facilities and the rise of the chronic diseases has led to an approach to the problems of specific illnesses, such as cancer and heart disease, through the individual as well as through the population in general.

### NATALITY AND MORTALITY

One cannot progress very far in an examination of the characteristics of the population and their relationship to health and disease without consideration of the course of the birth and death rates. The relationship of these vital statistics to each other is a major determining factor in the future course of the population. In addition, they provide a particular kind of measure of the health of the population. The fact that the mortality from all forms of tuberculosis has dropped from 71.1 per 100,000 population in 1930 to 33.5 in 1947 is a source of gratification to all concerned with the health of the public. On the other hand, the steadily climbing death rates from cancer and heart disease are indicative of the problems still before us.

**Source of Data.** Historically, in the United States, information concerning the occurrence of births and deaths in a population was obtained by attempting to take a census of these events just as we take a census of population. This procedure, however, proved very unsatisfactory, and today the occurrence of births and deaths in the population is obtained through a registration system. For a description of early methods of collecting the data on births and deaths, see Billings (1880).

The essence of the registration procedure is the requirement that whenever a birth or death occurs, a certificate indicating this fact must be filed with a local registrar of vital statistics within a short period of time after the occurrence of the event. In the case of a birth, a physician is responsible for seeing that the birth certificate is filed with a local registrar. In the case of a death, however, the physician is responsible only for certifying to the medical facts concerning the death, while the funeral director is responsible for the actual filing of the certificate with the local registrar. Essentially the same procedure holds for stillbirths. Figure 45-2, taken from the *Physician's Handbook on Death and Birth Registration*, Tenth Edition, shows the detailed flow of these certificates from their initiation by the physician to their final filing in the State Health Department of Vital Statistics.\*

\* Certain cities and local health departments may be permitted to file these certificates in their own offices.

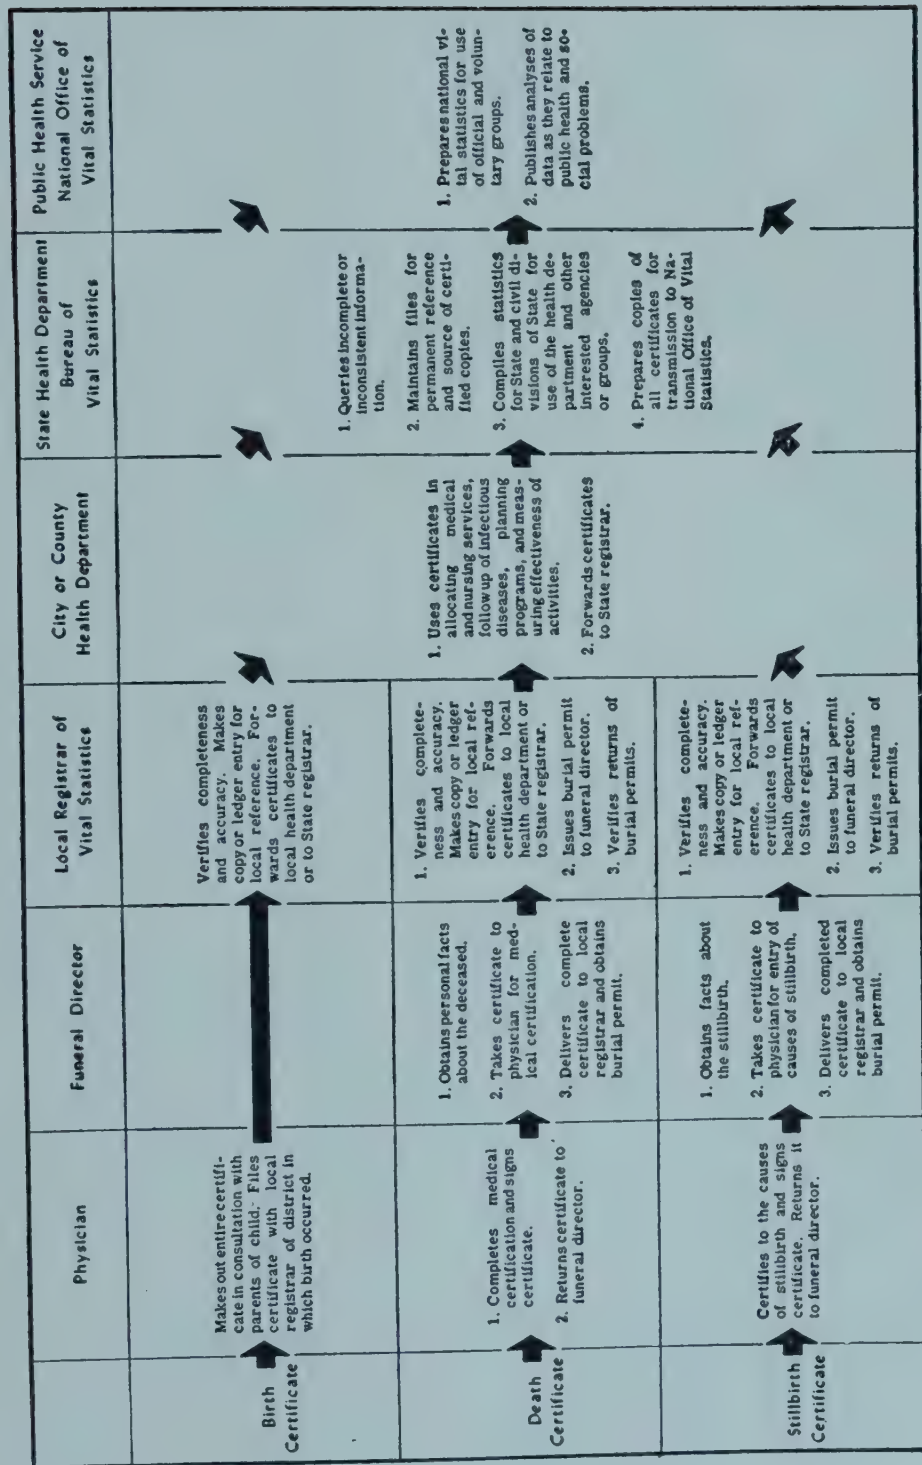

Fig. 45-2. The registration system in the United States. Flow chart of birth, death and stillbirth certificates.

**Uses of the Death and Birth Certificates.** There are two general functions served by death and birth certificates. One of these has to do with the protection of the rights of the individual. The death certificate establishes the fact and date of death for such purposes as: (a) claiming life insurance carried by the decedent; (b) claiming pensions; (c) settling estates; (d) providing information concerning age, sex or race, etc. The birth certificate is ordinarily used for such purposes as: (a) establishing the date of birth for entrance to school; (b) obtaining licenses; (c) entering military services; (d) voting; (e) proving citizenship; (f) establishing family relationships; etc.

The second major function of the certificates is statistical. The tabulation and analysis of the data present on the death certificate aid in determining the incidence of specific causes of death, in planning the control of communicable disease, in investigating the nature and occurrence of fatal accidents, in establishing the need for health programs and in measuring the effectiveness of health services. The birth certificate provides information on which health departments base plans for immunization of children, care of crippled children, evaluation of the need for health facilities and the evaluation of the effectiveness of infant care. In addition, statistics derived from birth and death records provide data for basic research and for program planning and evaluation.

**The Standard Certificates of Birth and Death.** In order to serve the purposes indicated in the above paragraph, the information on the birth and death certificates should be reasonably uniform among the several states. Without such uniformity, good national statistics and comparisons among states would be virtually impossible. Although each state has the right to use any certificate it pleases, the Federal Government has led the way toward uniformity with the development of model certificates to serve the states as a guide. Most states follow this model certificate in major respects.

The standard certificates of death, birth and stillbirth are shown in Figures 45-3, 45-4 and 45-5. The particular items which sometimes cause difficulty and the general instructions for filling them in are shown in the figures. However, certain items are of such great importance that they deserve special comment.

**THE BIRTH CERTIFICATE.** Because of the importance of the certificate in later life to prove the date and place of birth, it is very important that the name of the child and the parents be clearly written, as well as the date of birth of the child.

**THE DEATH CERTIFICATE.** The physician is responsible for filling out the medical part of the death certificate, whereas the funeral director is responsible for the personal particulars on the certificate. The medical information requested on the Standard Certificate of Death is based upon the recommendations of the World Health Assembly made in Geneva in July, 1948. It has been accepted by all states in this country and is being put into general use.

The most important feature of the medical certification is its emphasis on *the underlying cause as determined by the physician*. Tabulations made from the information supplied by the physician will reflect the frequency with which these underlying causes occur. Clearly the data in these tabulations can be only as accurate as the original certification by the physician. In the final analysis, it is the physician who determines the reliability of the information available on the causes

This is a permanent document. Type or use permanent black ink. Do not use ball-type pen.

THE FUNERAL DIRECTOR IS TO COMPLETE ITEMS 1-3, 5-17, 24, 25.

To be filled in by Vital Statistics Office.

Differentiate between urban and rural areas (i.e., within or outside city or town limits).

Use such terms as White, Negro, Indian, etc.

Complete both 10(a) and 10(b) for all persons 14 years and over, even though disabled, retired, unemployed or institutionalized.

In 10(a) give occupation followed during most of working life. Use specific terms, such as welder, farm laborer, carpenter, etc.

In 10(b) give business or industry in which occupation named in 10(a) was followed. Use specific terms, such as coal mine, cotton mill, automobile factory, farm, etc. Do not use company or organization names.

THE PHYSICIAN, MEDICAL EXAMINER, OR CORONER IS TO COMPLETE ITEMS 4, 18-23.

In part I, give the sequence of events that led to death, specifying last the underlying cause which initiated the train of events. Do not report symptoms or mode of dying.

In part II, report other important diseases or conditions, if any, that contributed to the death but were not related to the causes given in part I above.

Complete items 21(a) - 21(f) if death was due to violence or external causes.

Form 45-3 (1949 Revision of Standard Certificate) CERTIFICATE OF DEATH

Form 45-3 (Revised, Budget Bureau No. 45-375)

STATE OF Michigan STATE FILE NO.

1. PLACE OF DEATH a. COUNTY Crawford b. CITY OF RURAL-GRAYLING TWP. c. CITY (if outside corporate limits, give RURAL, and give township) d. TOWN Rural e. BEAVER CREEK TWP. f. FULL ADDRESS (if not in hospital or institution, give street, city, county, and state) g. STREET ADDRESS RR 1 Roscommon

2. USUAL RESIDENCE a. STATE Michigan b. COUNTY Crawford c. CITY (if outside corporate limits, give RURAL, and give township) d. TOWN Rural e. BEAVER CREEK TWP. f. FULL ADDRESS (if not in hospital or institution, give street, city, county, and state) g. STREET ADDRESS RR 1 Roscommon

3. NAME OF DECEASED (Last, first, middle) James Smith

4. DATE OF DEATH (Month, Day, Year) June 21, 1949

5. SEX Male

6. COLOR OR RACE Negro

7. MARRIED NEVER MARRIED

8. DATE OF BIRTH (Month, Day, Year) April 10, 1912

9. AGE (in years, if under 1 year, give weeks and days) 37

10. USUAL OCCUPATION (Give kind of work done during most of working life, and if disabled, the mode of living, such as retired, invalid, etc.) Retail coal

11. BIRTHPLACE (State or foreign country) South Carolina

12. CITIZEN OF WHAT COUNTRY? U.S.A.

13. FATHER'S NAME James Smith

14. MOTHER'S MAIDEN NAME Maude Richardson

15. WAS DECEASED EVER IN U.S. ARMED FORCES? YES

16. SOCIAL SECURITY NO. 232-02-5678

17. INFORMANT Mary Alice Smith

FOR MEDICAL AND HEALTH USE ONLY  
(This section MUST be filled out)

(SPACE FOR ADDITION OF MEDICAL AND HEALTH ITEMS BY INDIVIDUAL STATES)

To be filled in by Vital Statistics Office.

Differentiate between urban and rural areas (i.e., within or outside city or town limits).

If rural, give name of neighborhood, locality, or section (e.g., Salem, Five Corners, Three Oaks, etc.).

Use such terms as White, Negro, Indian, etc.

Give business or industry in which occupation named in item 11(a) was followed. Use specific terms, such as coal mine, cotton mill, automobile factory, farm, etc. Do not use company or organization names.

Indicate occupation followed during most of working life. Use specific terms, such as welder, farm laborer, carpenter, etc.

Fig. 45-4. The standard certificate of live birth.

This is a permanent document. Type or use permanent black ink. Do not use ball-type pen.

THE FUNERAL DIRECTOR IS TO COMPLETE ITEMS 1-5, 7-17, 25, 26.

Differentiate between urban and rural areas (i.e., within or outside city or town limits).

In cases of plural births, separate certificates must be prepared for each liveborn or stillborn child.

Use such terms as White, Negro, Indian, etc.

For 11(a) give occupation followed during most of working life. Use specific terms, such as welder, farm laborer, carpenter, etc.

For 11(b) give business or industry in which occupation named in item 11(a) was followed. Use specific terms, such as coal mine, cotton mill, automobile factory, farm, etc. Do not use company or organization names.

An entry should be made for each item, (a), (b), and (c). Enter "0" when this is the proper answer.

THE PHYSICIAN IS TO COMPLETE ITEMS 6, 18-23.

Report fetal causes of stillbirth and also maternal causes, if any. Give specific type of congenital malformation or disease of fetus, and of disease or condition of the mother.

of death and the success of efforts to control mortality as measured by the vital statistics.

**THE STILLBIRTH CERTIFICATE.** In order to reduce fetal and maternal losses, it is essential that medical and health agencies have data on the extent of the stillbirth problem and of the fetal and maternal conditions associated with it. As in the case of a death, the physician is responsible for the medical part of the certificate. *A stillbirth is defined as a fetus showing no evidence of life after complete birth (no action of heart, breathing, or movement of voluntary muscle) if the twentieth week of gestation has been reached.* There is still some variation among the states in the employment of this definition. The physician and nurse should inquire of the state health department what definition is followed in their state. If there is any evidence of life after complete birth, even though momentary, the birth should be registered as a live birth, and a death certificate also filed.

Detailed instructions for filling out the birth, death and stillbirth certificates may be found in the *Physician's Handbook on Death and Birth Registration*, Tenth Edition. The Handbook is available from the National Office of Vital Statistics, Washington 25, D. C.

**Factors Influencing the Reliability of Registration Data.** There are a number of factors to be considered in the interpretation of data derived from the vital statistics registration system. Among these are the accuracy of certification, the completeness of reporting, and the statistical classification of the material in the vital statistics offices.\*

1. **CERTIFICATION.** The accuracy of the statements concerning causes of death has increased with advances in medical knowledge and with the development of understanding on the part of the physician of the importance of the death certificate. Indirect evidence of this is the rising proportion through the years of certificates reporting more than one cause and the nature of the causes themselves. A smaller proportion of vague and ill-defined terms is found on death certificates today than used to be the case. However, there are still many certificates bearing such terms as "heart disease" which do not aid very much in attempting to define the present day problem of the cardiovascular diseases, since there may be so many different things giving rise to so-called "heart disease." The more accurately the cause of death is stated on the certificate, the greater will be our understanding of the factors contributing to mortality from specific causes.

2. **COMPLETENESS OF REPORTING.** Clearly if all births or deaths are not reported the resulting birth or death rate will be too small. Various tests of completeness of reporting of births have been made from time to time, the most recent large scale one reported on being that conducted by the National Office of Vital Statistics in conjunction with the 1940 Census (Grove, 1941). This study indicated that for the United States as a whole, about 92.5 per cent of the births were reported. However, there was considerable variation in various parts of the country, the lowest percentage recorded being 79.6 per cent and the highest 99.4 per cent.

In examining the trend of various vital statistics rates, one should seek an explanation for any sudden changes in the direction of the trend, since a sudden change in reporting may raise or lower the rate. In the case of the infant mortality

\* Where only one of the three types of data—mortality, natality, stillbirth—is mentioned, it is to be understood that the discussion which follows is equally pertinent to the other two types.

rate, the neonatal mortality rate and the maternal mortality rate (see page 1318, Chapter 44) changes in completeness of reporting may affect either numerator or denominator, a rise in the former increasing the rate, and in the latter decreasing it. A method of studying the effect of incompleteness of reporting on the birth rate, the stillbirth rate, and the infant mortality rate through the use of current records on file in local health departments was reported by Peterson (1940).

3. **CLASSIFICATION.** The classification procedure employed in tabulating the large masses of vital statistics data may have a very marked effect upon the various vital statistics rates (see page 1313, Chapter 44). This is well illustrated by the classification of causes of death. The importance and general applicability of this classification warrant a discussion of its development before presenting an example of how its use may affect the death rates.

The thousands of different medical terms—good, bad and indifferent—used to describe diseases and their manifestations must be grouped in some way if “generalizations are to be made about the health conditions in various localities, the efficacy of public health work, and the progress of therapeutic medicine” (Linder and Grove, 1943). The recognition that such a grouping is needed is not new. The foundations for the present grouping, known as the International Statistical Classification of Diseases, Injuries and Causes of Death, were begun in 1853 by William Farr and Marc D’Espine. The present classification is the sixth revision of the original International List adopted in 1893. Former lists dealt only with mortality, but the present classification includes morbidity as well.

“There are many approaches to the classification of disease. The anatomist, for example, may desire a classification based on the part of the body affected. The pathologist, on the other hand, is primarily interested in the nature of the disease process. The clinician must consider disease from these two angles, but needs further knowledge of etiology. In other words, there are many axes of classification and the particular axis selected will be determined by the interests of the investigator. A statistical classification of disease and injury will depend, therefore, upon the use to be made of the statistics to be compiled” (World Health Organization, 1948). In keeping with this principle, the 1948 revision of the International Classification groups the various diseases and morbid conditions into 612 categories plus certain additional categories for the classification of injuries by external cause and by nature of the lesion. These categories are in turn grouped into 17 main sections, such as Infective and Parasitic Diseases, Neoplasms, etc.

This classification process may affect the death rate for a specific cause in two general ways:

1. By the assignment of the certificate to a particular category of the International Classification when more than one cause of death is listed. The method \* by which this is done seeks to give priority to the primary cause of death indicated by the physician, but at times there may be exceptions. For instance, a certificate with bronchitis and typhoid fever as the causes of death, stated in that order, would be assigned to typhoid fever and would not appear in the death rate for diseases of the respiratory system.

2. By what is included under a given title. For instance, tuberculosis of the

\* The rules by which this is done are set forth in Volume I of the Classification (World Health Organization, 1948)

respiratory system is classified with the infective and parasitic diseases rather than with diseases of the respiratory system. The decision to classify tuberculosis this way is only taken after consultation with tuberculosis experts, the medical profession in general, pathologists and others concerned with the problem. The question of changes in what is included in each category is particularly troublesome when the decennial revisions of the Classification are made to bring it in line with the advances in knowledge during the previous decade. Any changes which are made will affect the comparability of data over a period of time which includes the revision date. Studies of the effect of the changes made in the Sixth Revision as compared with the Fifth Revision of the International Classification have been published by Erhardt and Weiner (1950) and by Marks (1949).

There are other classification problems which may affect the comparability of vital statistics data, such as the classification by age, race and sex, the classification into urban and rural, the classification by residence, and others. These are discussed in detail by Linder and Grove (1943).

Fig. 45-6. Trend of the crude birth rate and death rate in the United States, 1915-1947.

**Natality.** The trend of the crude birth rate as revealed by analysis of the data obtained through the operation of the registration system just described is shown in Figure 45-6. Until relatively recently, the birth rate has been steadily declining until the low point in the depression year of 1933. Thereafter, there was a slow rise with improved economic conditions until the effects of the war in Europe began to be felt. The effects of the entry of the United States into the war, of the withdrawal of large numbers of young men and of the return of veterans may be traced in the curve. The 1947 figure of 25.8 per 1,000 population, the highest ever recorded, reflects the postponement of births due to the war and the earlier starting of families that might ordinarily have been begun in 1948 or later. The greatest

part of the increase has been in one- and two-child families. It seems unlikely that these high birth rates will continue indefinitely. For a detailed discussion of the effects of war on various characteristics of the population see Thompson (1948) and Whelpton (1948).

A better measure of the inherent reproductive capacity of the population than the birth rate is the net reproduction rate. This is because the current age distribution of a population may be a result of high birth rates in the past, so that differences between the birth rate and death rate at any given time may give a false impression of the capacity of a population to reproduce itself. A net reproduction rate of exactly one means that under a given schedule of mortality and fertility, a generation of newborn girls would, by the end of the reproductive period of those that survived, have given rise to sufficient births to exactly equal the numbers of the original generation. A rate of more than one indicates an increasing population and, correspondingly, a population with a rate of less than one is not reproducing at a rate sufficient to maintain itself.\* The net reproduction rate for the United States for 1905 to 1910 was 1.34. It reached a low of 0.98 in the depression period of 1931 to 1935, but rose again thereafter, and in 1945 its value was 1.11.

**FACTORS INFLUENCING BIRTH RATES.** The significance of the decline in the birth rate and its subsequent rise cannot be appraised without more detailed knowledge of the fertility rates † of different classes of the population. There are considerable differentials among the several classes. The effect of age has been mentioned several times. Fertility rates classified by color show much higher rates for the colored population (Bureau of the Census, 1943) and in general the more rural and agricultural the region, the higher the rate. Generally speaking, the higher the socio-economic status, the lower the fertility rates (Whelpton and Kiser, 1943). However, there have been some indications that the proportional contributions to natality of the higher economic groups may be increasing (Jacobson, 1944; Ciocco, 1940c). There are large variations by educational status (Whelpton and Kiser, 1943).

A number of studies (Pearl, 1939; Stix and Notestein, 1940; Beebe, 1942) have sought an explanation of these differentials in group fertility in terms of the relative prevalence of efforts to control fertility artificially. The evidence of these studies leaves little doubt that the prevalence and effectiveness of contraceptive efforts vary directly with socio-economic status. When analysis is restricted to groups practicing contraception similarly or to groups omitting it altogether, class differences in fertility rates disappear. In other words, differences in group fertility are not inherent biological differences.

The exploration of the motivational factors which lead couples to limit the size of their families has barely begun (Whelpton and Kiser, 1943). Yet, only out of such exploration will the social and psychological factors affecting fertility emerge. If, as has been suggested at times, attempts should be made to formulate a national population policy, the pros and cons can be assessed dispassionately only against a background of facts. These are largely lacking.

\* A more complete discussion of the meaning of this rate and of the method of computation may be found in Chapter 12, Dublin and others (1949).

† The fertility rate is defined as:  $\frac{\text{children under 5}}{\text{women 20-34}} \times 1,000$ .

**Mortality.** The crude death rate in 1948 was 9.9 per 1,000 estimated population. This is the lowest rate ever to be recorded for the country as a whole and represents a decline of 42 per cent from the rate for 1900, which was 17.2 per 1,000 population. The decline has been fairly uniform over this period with the exception of the peak produced by the influenza epidemic of 1918 (see Fig. 45-6). Examination of the trend of the crude rate alone does not do full justice to the dramatic advances which have been made against disease since 1900. These are more clearly revealed by an analysis of the mortality statistics by cause.

**MORTALITY BY CAUSE.** The change in the character of the leading causes of death since 1900 is apparent in Table 19-1, page 720. Particularly striking is the reduction in the death rates for tuberculosis and pneumonia, which reflects the application of advances in medicine and public health. The fact that the diseases of middle and old age are far more prominent as causes of death in 1948 than at the turn of the century is clearly seen in the table.

Table 45-2. Number of deaths in the population of the United States in 1947 from selected causes, compared with the numbers expected in that year on the basis of the mortality rates, by sex and age prevailing in 1940

Cause of Death	Deaths in 1947		Lives Saved in 1947 by Improvement in Mortality Since 1940	Lives Lost in 1947 by Increase in Recorded Mortality Since 1940
	Actual	Expected on Basis of Mortality in 1940		
All Causes	1,445,370	1,712,396	267,026	—
Pneumonia and influenza	61,836	118,670	56,834	—
Cardiovascular-renal diseases *	671,907	723,166	51,259	—

\* Includes intracranial lesions of vascular origin, diseases of the heart, and nephritis (all forms).

That considerable progress is still being achieved all along the disease front is brought out by the data in Table 45-2. Cancer was the only cause of death in which more lives were lost in 1947 than would have been expected in relation to the 1940 mortality. As is pointed out in the article from which the data are taken (Metropolitan Life Insurance Co., 1949), this increase is relatively small. "The extraordinary progress in reducing the death toll in the past few years, all the more remarkable because it was achieved during a period of war and postwar adjustment, is a tribute to American medical practice and public health administration."

One effect of the continued decline in the mortality from the infectious and filth-borne diseases is to increase the proportion of deaths attributed to relatively few causes. In 1948, for example, nearly 50 per cent of the deaths were accounted for by the three categories of heart disease, arteriosclerosis, and cancer. The increase in the rates from cardiovascular diseases has been considered in detail in a series of Statistical Studies of Heart Diseases (1948). In the second paper in the series, Woolsey and Moriyama summarize the factors contributing to the apparently increasing death rate from this cause. They state that "Since 1930, when the registration area was virtually complete, the mortality assigned to heart disease has definitely increased for every age group over 45 years of age and has remained the same or declined in all the younger age groups. At ages over 45 years, however, there has also been a compensating decrease in the mortality from a certain group of causes of death known to be closely associated with heart disease, such as intracranial lesions of vascular origin, chronic nephritis, arteriosclerosis, and high blood pressure."

With respect to the increase in the crude death rate from cancer between 1900 and 1945 an analysis of the vital statistics data made by the National Office of Vital Statistics (1949) has the following to say: "The rapid increase in the crude death rate since 1900 is due in large part to the increase of elderly persons in the population. Although the crude death rate for cancer nearly doubled for 1945, this increase is reduced to 52 per cent after allowance is made for the aging of the population. Moreover, the increase occurred almost entirely during the first 35 years after the organization of the death registration area in 1900. Since 1935, the age-adjusted death rate has shown no appreciable change either upward or downward." This situation is shown graphically in Figure 45-7 along with the trends by race and sex. The graph also demonstrates that although the death rate from cancer among females has declined slightly in recent years, that for males has increased, although it is slackening in pace. It would also appear that there is a great deal of difference in the death rates from cancer by race, but the excess mortality of white males "is fictitious and arises from inaccuracies in recording" (National Office of Vital Statistics).

We shall not attempt a discussion of the other leading causes of death here. A detailed analysis of the trend in the mortality from accidents may be found in a report of the National Office of Vital Statistics (1949). The point may be made here, however, that the prevention of accidents is largely a matter of education and in recent years evidence has accumulated that there is an accident-prone individual toward whom efforts to reduce the toll might be directed (Farmer and Chambers, 1939; Greenwood and Woods, 1919).

For a discussion of the mortality from diabetes the reader is referred to I. M. Moriyama (1948) and to Dublin and others (1949). The latter reference also contains an extended discussion of the contribution of medical science to the reduction of mortality from specific causes.

Fig. 45-7. Age-adjusted cancer death rates by race and sex: death-registration states, 1900-1945.

**INFANT AND MATERNAL MORTALITY.** These two classes of mortality have been discussed in detail in Section 3, Chapter 14. It is pertinent here, however, to mention the studies of Gardiner and Yerushalmy (1939) and of Yerushalmy and others (1940a, 1940b, 1941) because of the manner in which they demonstrate the knowledge which may be gained through a study of the material on birth and death certificates. These authors point out that "maternal deaths have rarely been studied in conjunction with all the births from which they arise" and that "the distribution of maternal deaths according to the factors under investigation, when a similar distribution for the surviving mothers is not known, does not afford a measure of the risk of death associated with these factors." Only a few of their conclusions will be mentioned here as an indication of the kind of information which is available:

1. There is a strong association between death of mother and loss of offspring.
2. Rates of loss of both mother and infant were about twice as high in the group with a history of previous loss as in the group with no previous loss, and the previous losses were found to be more strongly related to loss of offspring than to loss of mother in the current pregnancy. The suggestion was made that the father may also play an important part in these cases of repeated losses in the family.

The significance of such observations for the reduction of maternal and infant mortality lies in the fact that they suggest that the increased mortality of infants born to mothers who have a history of previous loss "is due, at least in part, to constitutional and biological factors in the parents." In this connection the reader

should note that the observations were made prior to the discovery of the Rh factor. From the administrative standpoint they indicate that those in charge of maternal and child health programs may, at times, find it useful to make the program selective for those with the greatest probability of loss.

**INFLUENCE OF AGE, SEX AND RACE ON MORTALITY.** The variation in mortality by age, sex, and race may be seen in Figure 45-8. The high rate in infancy is not

Fig. 45-8. Death rates by age, race, and sex: United States, 1946.

equalled again until about 70 years of age and the lowest point of the curve is at about 11 years of age. Table 45-3 also shows that since 1900 the mortality at every age has declined, particularly in the early years of life. The rate for the nonwhite group is higher at every age than that for the white population both for males and females. The female mortality is less than that for the male at every age, but the excess mortality of the male over the female is greater in the white population than in the nonwhite group.

Many investigators have sought explanations for the differentials in mortality by sex and race. The weight of the evidence is in favor of a biological explanation of the sex differences (Ciocco, 1940b) rather than that they are the result of different kinds of environmental exposures. The explanation for the differential mor-

Table 45-3. Death rates per 1,000 population by age groups and percentage reduction, for the death registration states: 1900 and 1947

Age Group	Deaths per 1,000 Population		Per Cent Reduction
	1900	1947	
Under 1 year	162.4	33.7	79.3
1-4 years	19.8	1.6	87.6
5-14 years	3.9	0.7	82.1
15-24 years	5.9	1.5	74.6
25-34 years	8.2	2.1	74.4
35-44 years	10.2	4.1	60.2
45-54 years	15.0	9.3	38.0
55-64 years	27.2	19.8	27.3
65-74 years	56.4	44.6	21.0
75-84 years	123.3}	117.1	
85 years and over	260.9{		
All Ages	17.2	11.5	33.2

From Statistical Abstract of the United States, 1949, Table 77, page 70. (Reproduced with permission.)

tality by race is not so clear because of the difficulty of keeping the influence of economic circumstances constant. The Negro mortality, however, appears to be declining somewhat more rapidly than the white mortality (Gover, 1946a and b, 1948).

**INFLUENCE OF OTHER FACTORS.** There are many other factors besides those already discussed which influence the risk of dying. Only a very brief summary will be attempted here primarily to indicate the direction which studies of mortality have taken. The reader is referred to Dublin and others (1949) and to Sydenstricker (1933) for more detailed discussion.

Students of the problem have long been interested in the relative importance of heredity and environment in relation to mortality. Studies which have been undertaken in the area of inheritance of longevity have been based on genealogical records, family history records and life insurance data. Although there are a number of difficulties in each of these approaches, the accumulated evidence seems to indicate that longevity is influenced by the hereditary make-up of an individual (Pearl and Pearl, 1934).

Several studies have been undertaken on the relationship of the mortality from certain causes among offspring to the mortality from these causes in ancestors. Tuberculosis, cancer, cardiovascular diseases and diabetes are examples of areas in which such studies have been undertaken. These studies seem to indicate that there is a greater concentration of mortality from these diseases in families than one would expect from a knowledge of the mortality in the general population.

The mortality by marital status is of interest because it suggests further lines of research. Generally speaking, the mortality of the unmarried is greater than that for the married of the same age. Widowed individuals seem to have the highest rates, divorced individuals come next followed by single individuals, and married individuals have the lowest rate. This relationship seems to be true irrespective of sex or race when all causes of death are considered. However, there are differences between the sexes when specific causes are taken into account.

In this connection the studies of Ciocco (1940a, 1941) are of interest. He

shows that "there is a high positive correlation in the length of life of husbands and wives" and that "there is . . . a tendency for husbands and wives to die from the same cause when one of the spouses died from either tuberculosis, influenza and pneumonia, heart disease or cancer." Analysis of the experience of siblings of the spouses and a comparison of observed mortality with that expected from random pairings of the population led Ciocco to infer that the association in length of life of spouses is "probably the result of factors that enter into marital selection" but that "the common immediate environment, or conditions depending upon the intimate personal contact, or both, seem to be especially important in the occurrence of mortality from tuberculosis, influenza, pneumonia, cancer and heart diseases."

Studies such as those mentioned on the influence of heredity and of marital status on mortality point up the importance of familial studies in attempts to understand the distribution of the chronic diseases among the population. The epidemiological relationships indicated by such studies suggest possible bases for the further development of the practice of preventive medicine by clinicians and for control programs in health departments. The studies of Yerushalmy previously mentioned are a case in point. Further studies on the relationship between physiological state and subsequent mortality also seem desirable as, perhaps, furnishing leads for the development of sound preventive programs.

Little has been said about the relation of occupation to mortality although the increasing industrialization of the population makes this subject of increasing importance. The influence of socio-economic status on mortality is also of importance. The reader is referred to Dublin and others (1949) and to Sydenstricker (1933) for more detailed discussion.

## MORBIDITY

Any attempt to paint a picture of the state of health of a population will have completed only a very small portion of the canvas if only mortality is considered. Some of the most important causes of illness have a relatively low mortality—common cold, for instance—and the importance of others is minimized because they are reflected only indirectly in mortality data, e.g., mental diseases.

Knowledge of the extent and incidence of morbidity in the population, however, is far less complete than is that for mortality and, except for the notifiable diseases, there is no registration procedure comparable to that which exists for death.

**THE DEFINITION OF ILLNESS.** The primary problem in any attempt to gather information concerning illness in the population is that of defining what is to be counted as an illness. This problem does not exist in mortality statistics, since the fact of death is irrefutable. Moreover, it is to the interest of the family of the deceased to see that the fact of death comes to the attention of legally constituted authorities; therefore a machinery exists for gathering mortality information (see page 1350) quite apart from purely statistical considerations.

These conditions do not apply to the collection of morbidity statistics. When is a person ill? If, for example, one has a slight rhinitis which does not incapacitate him or cause him to lose time from work, is this to be counted as an illness? The suggestion may be made that one count only illness seen by a doctor. However, such an illness as the common cold, which is responsible for a considerable amount

of illness in the population, may never be seen by a doctor. A number of other definitions suggest themselves. What is actually counted will depend upon the purposes to be served by the data and upon the procedure by which they are collected. Various definitions have been adopted in different studies. Some include only illness lasting seven days or longer, others count all conditions resulting in time lost from work of one day or more, and still others use other definitions. Clearly, any estimate of the amount of illness in the population at a given time or of the rate at which illness develops in it will vary with the particular definition used.

Although the task of acquiring knowledge concerning morbidity in the population is by no means easy, there is a growing body of information on the subject which has been collected in a variety of ways.

**SOURCES OF DATA.** The nature of the various sources of information concerning sickness in the population and their historical development are reviewed in detail by Collins (1941). We shall attempt here to give only a summary of the procedures by which such information becomes available in the present day and to indicate the general nature of the findings. The reader is referred to Collins for an extensive bibliography on the subject.

The various procedures for gathering morbidity data can be grouped into two broad classes: (a) those in which the basic record is collected routinely, even though the morbidity data are only a by-product rather than the primary purpose of collecting the record, and (b) those procedures which are carried out on a one-time basis or, at least, if they involve successive repetitions, are essentially discontinuous or nonpermanent in character. The latter group has come into considerable prominence in recent years.

**THE REPORTABLE DISEASES.** The procedure by which physicians are required to report certain diseases to the health authorities when these diseases occur in their practice falls in the first category. At the present time, all states require the reporting of certain diseases although the list is not the same for each state (Fowler, 1944). The data are summarized periodically by the United States Public Health Service in *Public Health Reports*.

From the standpoint of obtaining a picture of the extent of illness in the population, there are serious deficiencies in these data in addition to the variation that exists in the diseases to be reported in the various states. There is evidence that the data collected in this manner understate the extent of the problem and, generally speaking, only the "epidemic" diseases are required to be reported, although in recent years there has been a tendency in some states to require the reporting of such diseases as cancer and rheumatic fever. The data collected are useful for establishing the general trend of specific diseases but cover only a very small portion of the problem of illness in the population.

**SICK BENEFIT ASSOCIATIONS.** Much of our knowledge of illness in the population in the past derives as a by-product from the records of sick benefit associations. In connection with the verification of an application for payment of a sick benefit, certain information is obtained, which includes physician's statement on the diagnosis and other facts about the illness. The records are usually fairly complete because of the financial considerations which hinge on the information. However, the data are not representative of the total population, since they refer only to a particular working group. In addition, payment is usually restricted to those cases lasting

more than a certain length of time—usually seven days. Such data have the advantage, however, that they can be related to a known population base and various types of illness rates can be computed.

**HOSPITAL RECORDS.** Hospital records are a third source of information on illness for which the basic records are collected routinely. These, of course, will refer only to those cases ill enough to be hospitalized. (Very little has as yet been done with out-patient statistics.) It is ordinarily difficult to relate the statistics of any one hospital to the population which it serves because this information is usually unknown, although in one or two isolated instances such a correlation has been made (Crosby, 1939). However, when data are collected from all the hospitals in an area, the population of the area may be used as the base for rates, provided nonresident cases are eliminated. Such a procedure was advocated as early as 1913 by Bolduan and even earlier by Florence Nightingale. The Hospital Discharge Study of the Welfare Council of New York City (Deardorff and Frankel, 1942) represents one of the first attempts of this kind in this country. Stocks (1950) describes a program in England to collect information in this manner which is made possible by the operation of the National Health Service. The widespread development of Blue Cross programs also provides a source of data on the hospital experience of a group of the population, although admission data from this experience are higher than in the general population because the financial obstacles to hospitalization have been to some degree removed. The experience of the Veterans Administration medical program also provides data on illness among a group of the population, but such data are difficult to relate to a known population base.

Other sources of routinely collected information are school absenteeism records and records of the illness experience of the Armed Forces.

Practically all of the sources of information in this first group are for a selected portion of the population—restricted with respect to age or economic status or severity of illness or type of illness or other factors. Although the data that are yielded by them are not representative of the population at large, nevertheless, they are useful in many ways. Knowing, for example, something of the nature of the selection sometimes permits the estimation of maximum or minimum values of the rate for the population in general. The data are useful to the administrator in charge of the specific program from which they arise in planning and evaluating the program, and, as in the case of the school population, they may give a fairly accurate picture of the illness experience of specific groups.

In the last two decades there has been an increasing realization of the need for more comprehensive morbidity data on the population as a whole. As a result of this need, several surveys and studies have been undertaken which have yielded valuable information. These surveys fall in the second class of procedures for gathering data—that is, in the class in which the data are derived from records which are essentially of a noncontinuous nature.

The earliest attempt in the United States to obtain information about sickness in the population in general was that made in conjunction with the 1880 census at the instigation of John Shaw Billings. A question was asked about the number of persons sick and unable to work on the day of the census. The reader will recognize that the resulting data furnished information on the *prevalence* of illness in the population (see page 1319). Since the census was taken as of June 1st, the seasonal

variation in illness was not taken into account. The next fairly comprehensive survey was that of the Metropolitan Life Insurance Company in 1915-1917, which was also a prevalence study but did include data on duration of the illness and, since it covered a two-year period, did allow for seasonal variation. The studies initiated in 1916 by the United States Public Health Service on pellagra in South Carolina mill villages began a series conducted under the auspices of this agency, among which is the classic one under the direction of Edgar Sydenstricker in Hagerstown, Maryland, in 1921. The study of South Carolina mill villages and the Hagerstown study mark the first attempts to obtain data on the *incidence* of illness in a population group by means of periodic visits at fairly frequent intervals and inquiry as to the occurrence of illnesses during the period between visits. In the Hagerstown study the canvassed population was visited at intervals of two months for a period of over two years.

In the early thirties the studies of the Committee on the Costs of Medical Care and the Health and Depression studies of the Public Health Service (1935) followed the general pattern of the Hagerstown study. However, the most extensive study to date from the standpoint of over-all coverage has been the National Health Survey of 1935-1936 (Perrott and others, 1939) which covered 2.5 million people in 83 cities. Data were also obtained on a little over 140,000 persons in 23 primarily rural counties to obtain some information on rural health. The data collected were confined to: (1) illnesses which result in inability to carry on usual activity for seven consecutive days or longer during the year prior to the enumerator's visit, and (2) serious physical handicaps and chronic diseases that were present but not necessarily disabling on the day of the visit.

Whereas the National Health Survey was extensive in coverage, the results of an intensive survey carried on over a five-year period from 1938 to 1943 in Baltimore with regular monthly interviews are of interest because the method of the study made for completeness of information and also tended to give proper weight to chronic illness in the total picture (Downes and Collins, 1940).

The introduction of sampling procedures by the Census Bureau in the 1940 Census and the subsequent use of such procedures to gain more current information about the population and the labor force has turned attention to the possibility of using these "current sampling" procedures to obtain information about the health of the population. Such information, however, is limited to prevalence data. Two such studies are reported by Sanders and Federman (1943) and by Woolsey (1950). The latter is of interest in that it harks back to the use of census procedures to gain the data, as did the initial attempt of Billings.

**Morbidity in the Population.** The picture of the health of the population afforded by these various sources is as follows:

**GENERAL.** A good general picture of the health of the population in urban areas is afforded by the data in Table 45-4. It is to be noted that the extent of illness may be measured in a variety of ways and that the numerical values obtained will be dependent upon the definitions of such terms as illness, disability, chronic disease, etc.

**THE PREVALENCE OF ILLNESS.** The percentage of persons disabled on the day of visit (4.4 per cent) in the National Health Survey was higher than that found in the study of the Metropolitan Life Insurance Company (1.9 per cent) and in

Table 45-4.\* Rates of illness according to several measures

Item	Type of Information	Rate
1	Percentage of persons disabled on day of visit <sup>a</sup>	4.4
2	Percentage of persons disabled for the whole 12 months immediately preceding visit <sup>a</sup>	1.2
3	Percentage of persons reported as having a chronic <sup>b</sup> disease or impairment <sup>c,d</sup> Illnesses disabling for a week or longer during the 12 months immediately preceding the visit: <sup>e,f</sup>	17.7
	Frequency per 1,000 persons:	
4	All illnesses	171
5	Acute	123
6	Chronic <sup>b</sup>	48

\* For explanation of table and chart references, see original source.

the Health and Depression study (2.3 per cent). This is partly due to the inclusive nature of the definition of illness, and partly, perhaps, to the fact that the National Health Survey figures refer to an average winter day. The prevalence figure obtained in Woolsey's study in February, 1949, for the civilian noninstitutional population 14 to 64 years of age was 4.7 per cent. A more detailed comparison of the rate in Woolsey's study with that of the National Health Survey by age groups shows a good agreement of the two sets of figures. The prevalence rates for disabling cases in the intensive study of Downes and Collins in Baltimore varied from about 3 per cent for the summer months to a high of about 5 per cent in February and March.

THE INCIDENCE OF ILLNESS. As has been emphasized, the illness rate of a population will vary with the type of survey and the definition of illness. Surveys conducted like the Hagerstown study and the Eastern Health District Study yield figures on the order of one case per person per year. "On the other hand, illnesses causing inability to work for seven consecutive days or longer will amount annually to only 125 to 200 cases per 1,000 persons; as the rates are higher for the very young, the old, and for those not gainfully employed, the working population will

average 75 to 125 cases per year but the total population of all ages will have a rate nearer 200 cases per year” (Collins, 1941).

The figures just cited measure the *frequency* of illness. They are average values. Some persons may have no sickness at all; others may have much more than one illness per year. One may also measure the *severity* of illness. This is usually expressed as days of disability per 1,000 persons observed (see Table 45-5, and Collins, 1941).

Table 45-5.\* Annual frequency of acute and chronic illnesses disabling for a week or longer,<sup>a</sup> according to age<sup>f</sup>

Age in Years	All illnesses	Acute	Chronic

THE CAUSES OF ILLNESS.\* The findings of the Hagerstown Survey and of the study of 9,000 families with respect to the causes of illness are contrasted in Figure

\* The reader is referred to Collins for a consideration of the causes of illness at different ages.

45-10. The data for the National Health Survey, which, it will be remembered, pertained only to illnesses of seven days' duration or longer, are presented in Table 45-6. The picture which emerges from these studies indicates that the most frequent causes of illness in the population are the respiratory diseases, followed by the infectious diseases and epidemics including the common communicable diseases of childhood, and then the diseases of the digestive system. Accidents, too, are an important cause of illness. When attention is focused, however, on the amount of disability for which a particular class of disease is responsible, the cardiovascular-renal diseases head the list, followed by the nervous and mental diseases. Orthopedic impairments were found to have the third highest disability rate in the National Health Survey and, measured in these terms rather than frequency of illness, diseases of the respiratory system had dropped to fourth place. Accidents still remain a major contributor to total days of disability.

Adapted from data in Physical Examinations of Selective Service Registrants in the Final Months of the War, Medical Statistics Bulletin No. 4, Washington Headquarters, Selective Service System, June 1, 1946.

Fig. 45-11. Rejection rates per 1,000 registrants physically examined for the armed forces according to the principal causes of rejection and according to race, World War II.

Because of their special interest, and because they pertain to a particular age group in which the over-all illness rate is low, the findings of Selective Service examinations in World War II are presented in Figure 45-11. The importance of

mental and cardiovascular disease even in this relatively young age group is to be noted.

The idea that these findings or, at least, their forerunners in young men might have been discoverable earlier and possibly prevented has been explored by Ciocco and others (1941), using the records of physical examination of Hagerstown school children during the period 1922 to 1928 and classifying them as to whether the children examined were in later years accepted or rejected on physical examination by draft board physicians. The general findings of this study were that "a relatively large number of the selectees who have been rejected because of defective dentition and vision already gave evidence of the same defects 15 years ago when they were in elementary school" and "growth as measured by weight, posture, and the physician's estimate of the state of nutrition . . . are useful as crude predictive indexes of adult physical development." Further studies of this type are needed as a background for the development of sound programs of preventive medicine.

Table 45-7.\* Annual frequency of acute and chronic illnesses disabling for one week or longer<sup>c</sup> (per 1,000 persons) as related to economic status<sup>f</sup>

Annual family income and relief status	All illnesses	Acute	Chronic <sup>b</sup>

**ILLNESS AND ECONOMIC STATUS.** The relationship of illness to economic status is shown in Table 45-7. In general, diagnoses of an acute nature seem to be less responsible for the high rates of the low income group than those of a chronic nature. These findings agree in general with those of other studies. The relationship of illness to other socio-economic factors such as urbanization, housing, occupation, etc., are discussed by Sydenstricker (1933), Downes (1948), Britten and Altman (1941), and Vernon (1939).

**THE EXTENT OF HOSPITALIZATION.** Data on the extent of hospitalization are relatively meager, due in part to the difficulty of relating admission data to the proper population base. Figure 45-12 shows the trend of admission rates as found in various studies. All of the curves show a rising admission rate. In a study of

the hospital experience of two counties in rural Michigan (Sinai and Paton, 1949) which extended over the period 1940 to 1945, this rising trend was also evident, the rates for one county increasing from 50 per 1,000 population to 82, and in the other from 49 to 75. During this time period, the proportion of hospitalizations

Reproduced by permission from the Am. J. Pub. Health, 31:10, 1941.

Fig. 45-12. Annual hospital admissions per 1,000 population (excluding newborn and admissions to mental and tuberculosis hospitals), United States, 1931-1938; Province of Ontario, Canada, 1927-1938; 2,444 families living in the Eastern Health District, Baltimore, in 9 hospitals, 1926-1935; resident discharges from Mary Imogene Bassett Hospital, Otsego County, New York, 1928-1937.

paid for by Blue Cross increased markedly. The hospital discharge rate for the Saskatchewan Hospital Services Plan (Health Services Planning Commission, 1947) for the first six months of 1947 was 140 per 1,000 population. This figure, however, must be interpreted in the light of the fact that the system is a tax-supported hospital care insurance plan. The rate in the 9,000 Families Study was 61.6 per 1,000 population per year over the period 1928 to 1931.

There is considerable variation in hospitalization rates by sex, females having a much higher rate than males. However, when hospitalizations of females for genital and puerperal conditions are eliminated, the over-all rate for females is not very different from that for males. The curve for the incidence of hospitalization by age shows two peaks—one in the early school ages and another in the child-bearing ages. The rates then fall off somewhat, to increase again at the age of about sixty. In the Baltimore study (Councell, 1941) over 60 per cent of all admissions were due to tonsillectomy, delivery, accidental injury, appendicitis, and female genital diseases.

From these data it is clear that the most frequent causes of hospitalization are not the most frequent causes of illness or even of mortality. Nevertheless, such data

are of value in planning for hospital facilities and in focusing attention on problems of preventive medicine.

**PREVALENCE OF IMPAIRMENTS.** The National Health Survey found approximately 2 per cent of the population with a permanent orthopedic impairment of such a serious nature that the individuals were considered to be partially or completely crippled, deformed, or paralyzed. A little less than 1 in 1,000 persons was found to be blind in both eyes. It is believed that this figure represents total or practically total blindness.

Dublin and others (1949) in their chapter on longevity and physical condition discuss the findings of life insurance companies as to the presence of medical impairments such as overweight, heart disease, glycosuria, etc., among presumably healthy individuals. They compare the observed mortality among individuals found to have such impairments on examination with that expected based on an appropriate life table. The reader is referred to their book for an interpretation of the results. Here we shall only say that many of the impairments investigated were associated with a high *excess* mortality.

The kind of question asked concerning impairments has been studied in relation to the presence of chronic sickness by Ciocco (1946). The data in this study were not subject to the selective factors of the life insurance material, the observations on sickness having been made in the original Hagerstown surveys of Sydenstricker. The general question was as follows: What is the subsequent mortality of individuals found to have chronic disease in the initial survey as compared with those who were free of chronic disease at that time? It was found that persons with cancer, tuberculosis, and the cardiovascular-renal diseases died, in the 20-year interval of the study, at a greater rate than persons of comparable age and sex with no chronic ailment in the initial survey. There was no excess mortality, however, for those persons found to have neuritis, rheumatism, and certain respiratory conditions at the beginning of the 20-year interval.

**FUTURE NEEDS.** It has been indicated that "premises for action" directed towards improving the health of the population would, perhaps, become clearer as man's relationship to his total environment is more fully understood. The results of various statistical approaches to the exploration of this relationship have been outlined in this chapter. In addition to providing factual information, these approaches indicate some of the tools available to probe the vast areas which still remain unexplored.

In the study of problems associated with an aging population, the technic of making observations on a group of individuals and then observing the same individuals at a later date appears promising. Mention has already been made of the subsequent mortality of individuals having chronic disease as contrasted with those not having such chronic disease, and of the studies by life insurance companies of the relationship between impairments and mortality. The relationship of such impairments or of physiological defects to subsequent morbidity is as yet largely unknown. The study of the findings of school health examinations among those accepted and rejected many years later by Selective Service examinations bears on this last point. More studies of this kind are needed. They would seem to be of particular importance in relation to programs aimed at prevention.

A second area in which further work would appear likely to be fruitful is that

concerned with the association of various familial factors with the occurrence of disease. There is mounting evidence of familial concentration of such chronic diseases as cancer, diabetes, rheumatic fever, etc. The further study of factors influencing such concentration and the exploration of the possibility of familial concentration of other diseases may, at the very least, be expected to permit health authorities to define more closely the groups and individuals requiring special attention.

The relationship of economic factors to health can be studied adequately only through the family unit, since it is the only unit with both biological and social significance. Referring again to the study of the findings on school health examinations and their relationship to the Selective Service examinations, we may ask whether the individuals found to have defects on the school health examinations acquired these as the result of such influences as nutrition and housing, or whether they were largely the result of their hereditary make-up. These are factors the effects of which are obviously influenced by the family environment and, therefore any attempt to study their influence must begin with a consideration of the family unit.

The several investigations just cited have a common element of considerable significance for the further study of the factors influencing the health of the population. They all proceed from a population group of some kind. The school health and Selective Service study was not limited to those individuals having defects but started with all school children and subsequently divided them into the two groups, with and without defects. Exploration of the familial concentration of diseases has also been most profitable when it has proceeded from a general population group. If we are to learn anything about what has been termed the "epidemiology of health," it is essential that the importance of beginning with the population group be fully appreciated.

The last few decades have witnessed considerable advances in our knowledge of the health of the population. Not only have we added to our factual information, but our knowledge of how to get at the facts has also increased. There is hope, therefore, that the future will shed light on many areas which, if not altogether dark at the present time, are, nevertheless, a murky gray.

## PUBLIC HEALTH ORGANIZATION AND ACTIVITIES

ERNEST L. STEBBINS, M.D., M.P.H.

### 46

#### NATIONAL HEALTH SERVICES

The term "public health" has had many and varied interpretations at different times in different countries and under different philosophies. The most generally accepted definition in the United States at the present time is that of Winslow who defines public health as "the art and science of preventing disease, prolonging life, and promoting physical and mental efficiency through organized community effort." Public health administration might therefore be defined as the application of available knowledge to that end. The development of public health as a science or as an art has been an evolutionary process drawing knowledge from many fields of science, coordinating and integrating the various parts to accomplish the end of improving man's health. It is a sector of social science.

The administration of a public health program requires some competence in a number of seemingly unrelated branches of science. President Dodds of Princeton University, in a discussion of the expert in government, quoted Brooks Adams as defining administrative ability as "the capacity of coordinating many and often conflicting energies in a single organism so adroitly that they shall appear as a unity. This presupposes a power of recognizing a series of relations between numerous social interests with all of which no man can be intimately acquainted. It is possibly the highest faculty of the human mind."

The health of the people has long been recognized as a proper concern of government. Throughout recorded history governments have, within the limitations of available knowledge, assumed responsibility in a varying degree for the protection of the health of the people. The motives of government assuming this responsibility have not always been the same. In a feudal system the primary purpose may have been to maintain an adequate number of fighting men for defense against an aggressor or to more effectively dominate a neighboring people. In an enlightened society the motive is presumably a more altruistic one.

The nature of governmental activity in the interests of public health has changed markedly over the years. The earliest movement was primarily an effort to prevent the introduction of epidemic disease into the group by restriction of movements of peoples through isolation or quarantine. Efforts were also made to prevent the spread of infectious disease within the group through the utilization of the police power of the state. As knowledge of sources and modes of infection increased, the public health activities of government related more and more to the control of the

environment, the extent and the nature of activity in this field depending upon the character of the community to be protected. In urban communities it was found necessary for government to control the public water supply to be assured of an adequate quantity and of a safe sanitary quality of the water consumed by the citizens. Controls over the production and distribution of milk and many other foods have been found necessary. The control of the disposal of human wastes is essential to the health of the people; this has led to the development of extensive sewerage and drainage systems and, in many instances, to the treatment of such wastes in a manner that will prevent the occurrence of nuisances or the transmission of disease through this means. In parts of the world the control of insect breeding for the protection of the health of the people is a major governmental activity.

During the past 50 to 75 years great advances have been made in the protection of the public health through the control of the environment. During this period there has been a changing emphasis. This has been an era of social legislation and social progress. Particularly in western Europe and the Western Hemisphere social reforms have been taking place in which public health has been an important issue. Governments have become greatly interested in child welfare, maternal welfare, improvement in housing, and aid to the physically handicapped, as well as in the special disease problems such as tuberculosis, venereal disease, cancer, heart disease, and mental illness. The development of these interests has materially altered the character of the organization within government for the protection of the public health. The emphasis in governmental participation has changed from the impersonal approach through environmental controls to the personal approach through preventive medicine for the individual.

## THE NATIONAL HEALTH ORGANIZATION

The responsibility for a public health program is shared in most countries by the national government and the various political subdivisions of the nation. The degree of responsibility of the national government depends largely upon the political structure of the national and local governments. In a strongly centralized government there is a tendency for the major responsibility to be vested in the national government whereas in those countries where local autonomy has been retained health services, as well as other services of government, are implemented to a greater degree at the local level.

England might be cited as an example of a strong centralized authority in the national government. The Ministry of Health Act of 1919 created a Ministry of Health to which were assigned all health activities of the national government previously administered by other branches of government. The Ministry of Health is a major branch of the national government headed by a minister selected by the party in power, assisted by a permanent secretary who is a civil servant, and a chief medical officer, both selected on the basis of merit. The Ministry of Health has very broad powers of supervision over the local health authorities. Since the enactment of the national medical service act of 1947 the Ministry has had direct responsibility not only for the traditional public health services but for general medical service as well.

Historically, the national health services in Italy might be cited as an example of the opposite extreme in which the primary responsibility for health services has been at the local level. Until quite recently the local or communal health organization was primarily responsible for health services under a somewhat nominal supervision of provincial and national health authority, the national organization having a status of a "high commission" in the department of the interior. Another evidence of the lack of a strong central authority in Italy was the delegation of many of the major responsibilities for public health activities to voluntary agencies supported by large grants from the national government without a corresponding voice in the program. The almost world-wide tendency toward the concentration of taxing powers at the national level has a tendency to reduce local autonomy and this is apparent in Italy at the present time.

Another pattern of organization which may be observed in a number of different countries is a combination of public health with other more or less directly related activities of government into a department or ministry. An example of this type may be observed in the Norwegian Department of Public Assistance which administers a program of public health, welfare, and insurance.

## NATIONAL HEALTH SERVICES IN THE UNITED STATES

The administration of health services in the United States differs considerably from that of other nations primarily because of the different political structure of the nation. The national government has only those powers delegated to it by the sovereign states. The Constitution of the United States does not specifically delegate powers to the federal government in the health field with the exception of provisions for interstate and foreign quarantine. However, Article 1, Section 8, of the Constitution authorizes the federal government "to lay and collect taxes, duty, imposts, and excises. . . to provide for the defense and general welfare." The authority for the administration of national health services is derived from this provision for the federal government's interest in the general welfare. Under this authority, health services were developed over the years in various departments of the federal government, until recently with no central coordinating agency with the exception of the creation of a national board of health in 1879. This board, however, never actually functioned as a national health agency and went out of existence four years later.

### THE DEPARTMENT OF HEALTH, EDUCATION AND WELFARE

The Department of Health, Education and Welfare came into being as a result of legislation enacted by the 83rd Congress in 1953. This legislation gave departmental status to those activities of the federal government previously brought together and constituting the Federal Security Agency, which was established in 1939 as a result of the approval of a governmental reorganization plan of that year. The objective of that reorganization was "to group together those agencies of the government whose major purpose was to promote social and economic security, educational opportunity and the health of the citizens of the nation." The agencies which were brought together included the Social Security Board, including the United States Employment Service; the Office of Education; the United States Public Health Service and the federal functions of the American Printing House for the Blind. In 1940, further approval of reorganization plans resulted in the transfer of the Food and Drug Administration, St. Elizabeth's Hospital, Freedman's Hospital and the federal functions relating to Howard University and to the Columbia Institution for the Deaf to the Federal Security Agency. In 1946, further reorganization transferred the Children's Bureau with all of its functions except those relating to child labor to the Social Security Administration within the Federal Security Agency and transferred the Office of Vital Statistics from the Bureau of the Census to the United States Public Health Service. These various reorganization plans, culminating in the creation of the Department of Health, Education and Welfare,

brought under one general direction the major health activities of the federal government; it left many minor health activities distributed to various departments. In addition to the Veteran's Administration and the Armed Services, a number of departments of the federal government maintain rather extensive services directly or indirectly pertaining to health. In the Department of the Interior, the Office of Indian Affairs administers a program of medical care and public health among the Indian wards of the government. This function was transferred to the United States Public Health Service, within the Department of Health, Education and Welfare, in 1955. The Department of the Interior maintains a Bureau of Health and Safety directed primarily toward accident prevention. The Department of Agriculture, through the Bureau of Animal Industry and the Bureau of Entomology and Plant Quarantine, carries out programs for the control and prevention of disease and parasitic infections of domestic animals and for insect vector suppression. The Department of Agriculture also operates a program of inspection for all meat sold in interstate and foreign commerce, establishes standards of various food products and has control of insecticides. The Labor Branch of the Department of Agriculture provides medical and health services for seasonal workers and its Bureau of Human Nutrition provides rather extensive service in this field. The Farm Security Administration of the Department of Agriculture operates a medical care program among low-income farm groups. A number of other departments or agencies in the federal government carry on minor health activities.

### THE UNITED STATES PUBLIC HEALTH SERVICE

The United States Public Health Service is the principal agency of the federal government concerned with the development of public health programs. The Service is at present a division within the Department of Health, Education and Welfare. Prior to 1953, it was a division of the Federal Security Agency which was created in 1939 as a result of the approval of a governmental reorganization plan of that year. For approximately 140 years, the Public Health Service was a bureau in the Treasury Department, having been created as a marine hospital service in 1798. The work of the Public Health Service falls into three major categories, research, medical and hospital services and public health practice. The Service also administers financial grants to the states for general and special public health services and for the construction of hospitals, health centers, and other medical facilities. Grants are also made to public and private nonprofit research institutions for medical research and the training of scientists. The research programs of the Public Health Service include laboratory, clinical, epidemiological, engineering, statistical and administrative studies, all focused on contemporary health problems. Highly qualified scientists conduct the studies and facilities of the Service in the field and in laboratories of other institutions under cooperative arrangements. The Service also helps to increase the number of medical and public health scientists through fellowships and traineeships for qualified students. Public Health Service Research Grants augment the nation's medical research effort. These grants help support the investigations of research scientists in their own institutions. Grants are also made for the training of professional personnel in certain specialized fields such as mental health, cancer and heart disease.

The Public Health Service provides medical and hospital care for certain groups of people declared eligible by Congress to receive such care. Among these are the seamen of the American Merchant Marine, personnel of the United States Coast Guard, American and Alaskan Indians and civilian employees of certain branches of the government. The Service provides medical personnel for the ship and shore establishments of the United States Coast Guard and the Maritime Administration, for the prisons and reformatories of the Department of Justice, for the health programs of the International Cooperation Administration and for several other federal agencies. It administers the nation's foreign quarantine laws and regulations and conducts medical and psychiatric examinations of immigrants seeking admission to the United States. The Service provides leadership and technical assistance to states and local communities in the development of public health programs. It develops and promulgates standards for the protection of the public from milk- and food-borne diseases. In cooperation with state and local health departments it develops and tests new methods in the prevention and control of disease. One of the important functions of the Public Health Service is the licensing of the manufacturer of biological products. It collects and distributes national vital statistics and conducts special studies of health problems.

The Service is organized on semimilitary lines, is headed by a surgeon general, and consists of corps of commissioned officers and civil service employees. It was reorganized by an act of Congress in 1944, Public Law 410, known as the basic public health service law, which brought together into one statute all of the previous legislation concerning the Public Health Service and established the organization approximately as it is today. By this act there are four statutory bureaus: the Office of The Surgeon General, the National Institutes of Health, the Bureau of Medical Services and the Bureau of State Services.

In carrying out its assignments for the fiscal year ending June 30, 1954, the Public Health Service, for example, was responsible for administering about \$221,000,000. Two thirds of this amount, approximately \$132,000,000, was allocated to others in the form of grants to the states, private institutions, and individuals outside of the federal government. This sum was distributed as follows: \$65,000,000 for grants for the construction of hospitals and health centers, \$43,000,000 for grants to support research and training, and \$24,000,000 for grants to the states to maintain and improve health services. The remaining one third, \$89,000,000, went toward the direct operations of the Public Health Service, that is, administration of its hospitals and clinics, enforcement of foreign quarantine, laboratory and field research, collection and reporting of vital statistics and technical assistance to states and localities.

To carry out its mission, the Public Health Service employed in 1954 approximately 15,000 full-time personnel representing over 250 occupational specialties and including many health and related professions. Of these, about 2,500 were officers of the Public Health Service Commissioned Corps and 12,500 were career civil service employees. The Commissioned Corps, a long-established quasimilitary career organization, includes many of the professional personnel of the Service such as physicians, dentists, sanitary engineers, nurses and others. Commissioned officers undertake their careers in the Service early in their professional lives and like officers in the Armed Forces are commissioned in rank by the President with

the approval of the Senate. The chief officer of the Public Health Service is The Surgeon General, who is a member of the Commissioned Corps and is appointed by the President for a four-year term. The Deputy Surgeon General and Assistant Surgeons General, including the dental, engineer and nurse officers, of the Service are appointed by The Surgeon General from the Corps.

**Office of The Surgeon General.** The Office of The Surgeon General functions as a bureau of the Public Health Service under the immediate supervision of the Deputy Surgeon General. The bureau is responsible for the general administration of the Public Health Service and is concerned with policy development, program coordination and administrative staff services. This bureau consists of four divisions. Three of these, namely, finance, personnel and administrative services, provide administrative and managerial services for the organization. The fourth division is that of Public Health Methods.

The Division of Public Health Methods provides staff services for The Surgeon General and deals with a great variety of problems. The work of the Division falls into three major categories: (1) the identification and definition of current and future health problems; (2) the measurement of these problems against available facilities, health personnel and organization; and (3) the development of methods for judging the effectiveness of public health programs. One of its major responsibilities is the collection and analysis of data either through established sources or through original investigation or studies. This Division also gives assistance to various bureaus and divisions of the Public Health Service and to other governmental and nongovernmental health agencies. The Division of Public Health Methods also edits and publishes Public Health Reports, the official journal of the Service, which carries discussions and original articles in the general field of public practice and administration.

The Division of International Health cooperates closely with other agencies directly concerned with world health. The agencies with which the Public Health Service works closely on international health matters are the Department of State, through its International Cooperation Administration; the World Health Organization, a specialized agency of the United Nations; the Pan American Sanitary Bureau; and the Institute of Inter-American Affairs. This Division also assists in the recruitment of technical and health personnel for these activities and in some instances loans personnel for missions in international health work.

**The National Institutes of Health.** The National Institutes of Health had their origin in the Hygienic Laboratory, created in 1930. As the original name implies, this laboratory was developed to carry out research activities primarily in the field of infectious diseases. The original Hygienic Laboratory has been expanded and now is represented by the Microbiological Institute. The functions of the various institutes are to conduct and to support research into the cause, diagnosis, prevention and treatment of the diseases of man.

The Director of the National Institutes of Health has the responsibility for formulating service-wide research policies and coordinating research activities. An Inter-Bureau Research Planning Council was developed to insure balance and integration of the research program in all parts of the Service. The National Institutes of Health are located in Bethesda, Maryland, a suburb of Washington, D. C. In 1955, they were composed of seven research centers, all of which were physically

related clinical centers. Space in the clinical center has been allocated, and studies of cases in the major disease areas are under way.

The National Cancer Institute was established in 1937 and was the first of the specialty institutes created by Congress. The pattern for federal aid to medical research and training was established in the same law. The work of the Institute is divided into two major parts: (1) the increasing of basic knowledge of cancer, and (2) the application of present knowledge to the prevention of death from this disease. The creation of a mental health program of the Public Health Service dates back to 1946. At that time there was authorization also for the National Mental Health Institute, which came into being in 1949. The National Heart Institute and the National Institute for Dental Research were created in 1948. In 1950, the Congress passed legislation authorizing the development of the Institutes of Arthritis and Metabolic Diseases and the Institute of Neurological Diseases and Blindness. In setting up the Institute of Neurological Diseases and Blindness, it was specified that studies should include multiple sclerosis, epilepsy, cerebral palsy and blindness.

The laboratories of the National Institutes of Health are among the finest in the world. The recently completed isotope laboratory is one of the few radioscope laboratories in the United States designed solely for medical research. This new laboratory provides ideal working conditions, including the most elaborate devices and the most complete opportunities for investigation in this field. In order to provide opportunities for medical research, particularly in the study of chronic disease, the 500-bed clinical center has been developed. In this clinical center approximately twice as much space is devoted to laboratory investigation as to patient care.

The Division of Research Grants and Fellowships of the National Institutes of Health administers a vast program of aid to research in institutions other than the National Institutes. The major objectives of a research grants program are: (1) to expand research activities in medical schools, hospitals and other institutions; (2) stimulate research in smaller institutions where such programs have been limited or nonexistent; (3) to encourage investigators to undertake research in neglected fields; and (4) to provide training for scientific personnel. To insure scientific freedom and promote the highest quality in research, the recipient of a grant agrees to pursue his research project and to publish his findings independently. Grants are awarded only upon recommendation of the appropriate National Advisory Council authorized by Congress and composed of leaders in the medical sciences, education and public affairs. These councils also advise The Surgeon General on policy within the legislative framework of the program. The Advisory Council works through study sections consisting of panels of outstanding authorities in major medical research areas. The research fellowships program of the Public Health Service is administered by the National Institutes of Health and designed to help increase scientific manpower of the country. Fellowships provide financial assistance to the most able and promising young scientists during their training period, encouraging them to enter a career of research in medical and allied fields. The awards are made on a competitive basis upon the recommendation of committees composed of outstanding scientists. The traineeship program is designed to increase the number of qualified workers engaged in specialized clinical fields. The program of teaching grants in medical fields is designed to assist medical students in obtaining broader

knowledge in the field of medicine. These grants are largely the development of courses in heart disease, cancer and mental illness. All of the nation's medical schools are now contributing to the cancer teaching grants program.

**The Bureau of Medical Services.** The Bureau of Medical Services includes the Divisions of Hospitals, Hospital Facilities, Medical, Dental and Nursing Resources, Foreign Quarantine and Federal Employee Health; through these various divisions it carries out the major medical functions of the federal government. The Division of Hospitals operates the United States Marine Hospital System consisting of 22 hospitals varying in size from 30 to 1,400 beds. These include two tuberculosis sanatoria and the National Leprosarium. In addition to the Marine Hospitals, two hospitals are maintained primarily for the treatment of narcotic addicts but also admit neuropsychiatric patients under certain circumstances. With these facilities, staffed by some 6,000 employees, the Division provides more than two million days of care annually in its hospitals. Outpatient departments of hospitals record approximately 500,000 visits and a full-time clinic services another 45,000 each year. The larger institutions have been approved for interne and residency training of physicians and dentists. The hospitals also provide training programs in other fields related to medical care, for personnel such as medical record librarians, practical nurses and nurse anesthetists. One of the major activities of the Division of Hospital Facilities is the administration of a National Hospital Survey and Construction Program. Under terms of legislation enacted by Congress, the Division of Hospitals, with the advice and assistance of the Federal Hospital Council, is responsible for administering the Hospital Survey and Construction Act of 1946 as well as the 1954 extension of that Act. These activities include approval of official state construction plans, financial assistance and technical advice, and leadership to state and local governments and to nonprofit organizations. The objective is to help communities to measure and meet their needs for hospitals and health facilities. As of June 30, 1954, approximately 2,300 projects had been approved under this program. These projects have added 109,000 hospital beds and almost 500 health centers to the nation's facilities. Total construction under the program amounted to an expenditure of \$1,849,000,000, of which the federal share will be approximately \$618,000,000. The Hospital Construction Program has been directed primarily toward the improvement of general hospital facilities. In 1954, however, Congress broadened the program by authorizing surveys and earmarked appropriations for chronic disease facilities, nursing homes, diagnostic and treatment centers and rehabilitation facilities. In the future, therefore, increasing emphasis will be placed on the construction of facilities providing long-term care and medical services for the aged, rehabilitation services and medical care for ambulatory patients.

The Division of Foreign Quarantine administers the quarantine laws and regulations of the United States; it also acts as the medical branch of the Immigration and Naturalization Service, the Commission on Displaced Persons and the Department of State. All persons seeking entry into the United States as immigrants for travel, study or business have some type of examination. During the fiscal year 1949-1950, 1,500,000 persons passed through United States ports of entry and border stations, including American citizens, and were inspected for the presence of quarantinable disease. Displaced persons are examined at resettlement centers prior to admission to the United States. Inspection of ships and aircraft arriving at port of entry from other countries is a part of the foreign quarantine procedure.

**The Bureau of State Services.** The Bureau of State Services provides consultation, technical assistance and financial aid to state and local health services in many different fields. Many of the divisions of this Bureau investigate new public health technics and conduct demonstrations or pilot programs for the development of new and better methods of administering public health activities. The Bureau also lends specialists and technical personnel to state and local health depart-

### THE DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE

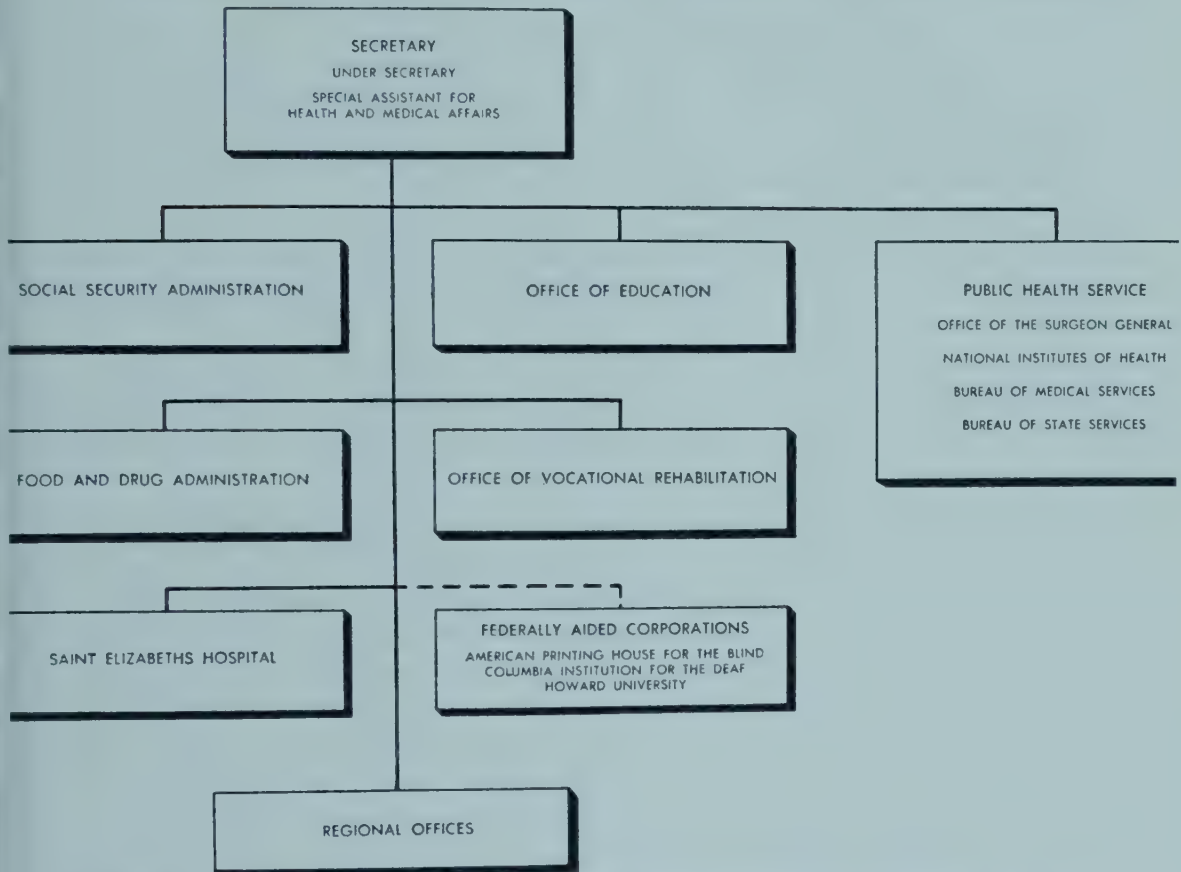

Fig. 47-1. Organizational chart—Department of Health, Education and Welfare.

ments to help solve specific problems and conducts training courses, seminars and educational programs for state and local personnel. It collects and publishes health statistics of value to state and local health departments. The Bureau is made up of 16 divisions, each of which offers service to the state and local health departments. These include the divisions of State Grants, Public Health Education, Public Health Nursing, Sanitation, Water Pollution Control, Engineering Resources, Environmental Health, Industrial Hygiene, Tuberculosis, Venereal Diseases, Chronic Diseases, Communicable Disease Center, Dental Public Health, and the National Office of Vital Statistics.

The Division of States Grants was established in 1949 to recommend and to put into practice uniform policies and procedures for all grants-in-aid operations of the Public Health Service. This Division centralizes the administration of grants to the states and assures the maximum of efficiency and integration. These grants-in-aid are administered by the Public Health Service and in 1954 amounted to \$24,000,000. This included \$10,100,000 for general health work, \$3,500,000 for venereal

disease control, \$4,300,000 for tuberculosis control, \$2,300,000 for mental health services, \$2,200,000 for cancer control and \$1,100,000 for heart disease. These grants permitted further expansion of state and local health services and also made possible the training of large numbers of public health personnel. Under the stimulus of these grants nearly all states are in the process of expanding their mental health, dental health and cancer control services.

The National Office of Vital Statistics is a source of official data on births, deaths, marriage and divorce in the United States. It also issues the official tables of life expectancy and maintains the birth registration and death registration areas. This Division also gives consultation to the states in matters pertaining to vital records and statistics and in working with other organizations carries on studies in special health statistics and demography. The Division also represents the United States in international planning to improve the world system of birth and death registration and vital statistics.

The Division of Public Health Education provides assistance to states, voluntary agencies, educational groups and community agencies in the development of health education programs.

The Industrial Hygiene Division carries on a program of research and provides a consultation service to states and local communities in the development of adequate industrial hygiene programs. Upon request, the Division carries on detailed studies of specific industrial hazards.

The Division of Environmental Health carries on extensive studies and provides consultation to state and local health departments in the broad aspects of environmental sanitation, including water supply, sewage disposal, milk sanitation, the hygiene of housing, and other environmental problems. The Division administers the provisions of the Water Pollution Control Act of 1948 and has established a program of study of the water pollution problems in the major river basin systems of the United States. Under the direction of this Division is the Environmental Health Center at Cincinnati, Ohio, which is designed to coordinate all laboratory and field research in the general field of environmental sanitation.

The Communicable Disease Center with its main operation in Atlanta, Georgia, is a relatively recent development in the Public Health Service. It is a field research and training center providing consultation to the states on all problems in communicable disease control and provides a unique training program for personnel from local and state health departments. The special fields of interest, both from the standpoint of research and training, include epidemiology, malaria control, murine typhus control, rabies control and the broad field of gastro-intestinal infections, particularly the role played by the fly in the transmission of various diseases. The laboratory services provided by the Communicable Disease Center are available to state and local health services. The Center has set up uniform procedures for the performance of diagnostic tests and has provided training for laboratory technicians and public health workers in general. During the fiscal year 1949 more than 1,500 trainees were enrolled in courses offered by the Center. The students who came to the Center for training were for the most part from state and local health departments but 124 came from 37 foreign countries.

It is generally recognized that chronic illness is becoming increasingly important in the United States. In addition to the programs of research and training in the specific fields of cancer, heart disease, and mental and nervous diseases, the

Public Health Service has established a Division of Chronic Diseases. The purpose of this Division is to detect chronic illness in the earliest stages in order that prompt treatment may be given to effect a reduction in fatality where possible. One of the important functions of this Division is to cooperate with state and local health departments to develop methods for the early detection of the chronic illnesses. The work of this Division is closely coordinated with the work of the Division of Tuberculosis.

## THE CHILDREN'S BUREAU

A second major health agency in the United States is the Children's Bureau. This agency was first organized in the Department of Labor in 1912. The functions prescribed for the Children's Bureau in the Act creating it specified that the Bureau was to investigate and report upon all matters pertaining to the welfare of children and child life. For approximately a decade the Children's Bureau confined its activities to research and propaganda in matters affecting mothers and children. In 1921, passage of the Shepard-Towner Act provided subsidies for distribution to the states for the promotion of maternal and child health work. The administration of the Act was assigned to the Children's Bureau; under its provisions, the Bureau succeeded in securing the establishment of units of child hygiene activities in many states which had previously been without them. This greatly increased public interest in the subject. With the expiration of this Act in 1929, the functions of the Bureau were sharply curtailed, but with the passage of the Social Security Act in 1935, administration of funds appropriated for distribution to the states as grants-in-aid for the promotion of the health of mothers and children was again given to the Children's Bureau.

This Bureau serves as a center for the development of standards of care and protection for children in the United States and for the study of all phases of child life, including both the physical and mental health of children and the social and economic factors that affect their well being.

In July, 1946, the Children's Bureau was transferred to the Federal Security Agency from the Department of Labor and became a part of the Social Security Administration. The defined functions of the Children's Bureau are: (1) to investigate and report upon all matters pertaining to the welfare of children and child life; (2) to administer the program of grants-in-aid to the states for maternal and child health and for crippled children, under the provisions of Title 5, Parts 1, 2 and 3, of the Social Security Act; and (3) to cooperate with other American republics under the program of the interdepartmental committee on scientific and cultural cooperation.

Organizationally, the work of all divisions of the Children's Bureau is coordinated by the office of the Chief. This office is supported by numerous advisory and planning commissions and boards. The Bureau receives valuable help from standing advisory committees in preparing its publications on child care and in setting policies for grants-in-aid programs and in gathering statistics. Other committees assist in the development of standards for services for children, planning research, and determining how well needs are met and how services can be extended and public understanding increased. From time to time, conferences are called to discuss special problems in the various fields of service for children.

The Children's Bureau makes available to national, states and local organizations and agencies, its publications and information service to help them in their programs for children and youth. These organizations and agencies include those that promote measures for the improvement of child health, professional associations, child-placing agencies and other agencies giving various kinds of care and service for children. The Bureau is divided into four major subdivisions: the Division of Research, the Division of Reports, the Division of Health Services, and the Division of Social Services.

**The Division of Research.** The Division of Research conducts research on the physical, social and emotional growth and development of children, and on the needs for methods of extending or improving programs for services to children. It develops standards growing out of research, provides service on research aspects of demonstrations and special projects under grants-in-aid programs, and conducts a clearing house for current research in child life for the use of research workers. It provides statistical service to the Bureau and prepares bulletins and leaflets on child care in cooperation with the Division of Reports. It also provides technical information and consultation within the areas of the work of the Division.

**The Division of Reports.** The Division of Reports furnishes informational service to the press and radio, prepares visual media and publishes popular materials on research and administrative programs of the Bureau. It also provides consultation service in writing, designing and distributing of materials for professional and lay audiences; it prepares editorial reviews and publication of technical materials. In addition, it provides advisory services to state agencies on information services interpreting child health and child welfare programs.

**The Division of Social Services.** This Division develops policies and recommendations for social services to children, including case work with children in their own homes, care in foster homes, institutions or day-care centers, and adoption and guardianship. It administers grants to state welfare agencies for child welfare services and provides, through central and regional offices, advisory services to public and voluntary agencies and to others on standards, methods, and organization of state and community services, and on laws and their administration for the care and treatment of children who are dependent, neglected or delinquent.

**The Division of Health Services.** The Division of Health Services develops policies and recommendations for health services for mothers and children. It administers grants-in-aid to state agencies for maternal and child health services, and services for crippled children, including the location, diagnosis and treatment of children who are crippled or suffering from conditions which may lead to crippling. It provides, through central and regional offices, advisory services to public and voluntary agencies and to others on technical and administrative aspects of medical care and health services for mothers and children. The Division also provides advisory services on administrative organization and methods, and consultation in specialized medical and related fields, such as pediatrics, obstetrics, orthopedics, cardiology, nursing, dentistry, hospital administration, physical therapy, medical social work and nutrition.

The Division of Health Services is divided into two major subdivisions. The Field Operations Branch is directly concerned with the administration of maternal and child health and crippled children's grants-in-aid to the states, supervision of

the Children's Bureau regional staff, and review of the state plans, budgets and methods of apportioning the funds allocated to states. Each of the eight regional offices has a medical director and, if fully staffed, includes consultants in administrative methods, social work, nursing and nutrition. Individually or as a team, regional consultants visit each state health agency and crippled children's agency, conferring with directors and staff members and advising on the operation of state programs, standards of services and ways of extending and improving health services for mothers and children.

Under the grants-in-aid program assistance is given to state public health agencies to enable them to extend and improve maternal and child health services, especially in rural areas and in areas suffering from severe economic distress. The Social Security Act, as amended in 1946, authorizes an annual appropriation of \$11,000,000.00 for this purpose. The program is in operation in all of the states, the District of Columbia, Alaska, Hawaii, Puerto Rico and the Virgin Islands. The state health department through its division or bureau of maternal and child health allots federal and state funds to county or local health departments for maternal and child health services, and provides consultation services for supervisors in the medical, dental, nursing, medical-social, nutrition and health education phases of the maternal and child health program, and to hospital administrators and hospital staffs on the improvement of services for mothers and children. Postgraduate courses in obstetrics and pediatrics are held for practicing physicians, and institutes and training courses are held for public health nurses and other health workers. The health needs of mothers and children are studied and, with the help of professional and citizens groups, efforts are made to mobilize the resources needed to meet these needs. Locally, the maternal and child health program is carried on by the county or city agency under the direction of the health officer.

Similar health services for school children are conducted in cooperation with schools and, in a limited number of areas, home delivery nursing service is provided at the request of the attending physician. Supervision is given to midwives in some counties, and nurse midwives are provided to train and supervise and give midwifery service. In a few states medical care for mothers at delivery and care for sick children is provided.

Programs for the care of the prematurely born infants are being developed in most of the states. These programs include one or more of the following services: educational courses on the care of premature infants for physicians and nurses; purchase of incubators for loan to hospitals or for home use; licensing and supervision in maternity hospitals and newborn or premature nurseries; ambulance service for transferring premature infants to suitable hospitals; medical and hospital care in a hospital center having specialty facilities; and furnishing trained personnel for care of premature infants. Adequate public health nursing programs for home follow-up of prematurely born infants are also included.

With grants-in-aid assistance many states are expanding sight and hearing conservation programs which vary from programs of testing sight and hearing to complete remedial service, including purchase of glasses or hearing aids. Programs to prevent dental decay by the application of sodium fluoride to the teeth of school and preschool children are also being developed extensively.

Funds from federal, state and local sources are not yet sufficient to make the many health services needed for women and children available in all counties and

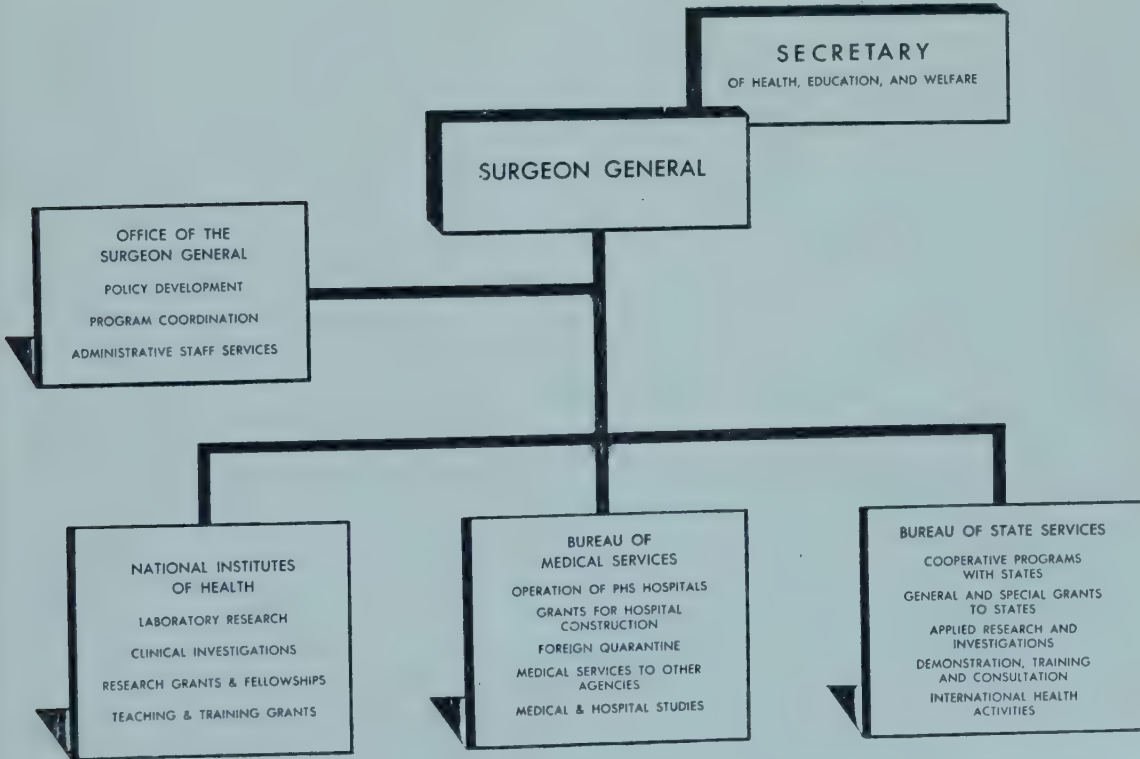

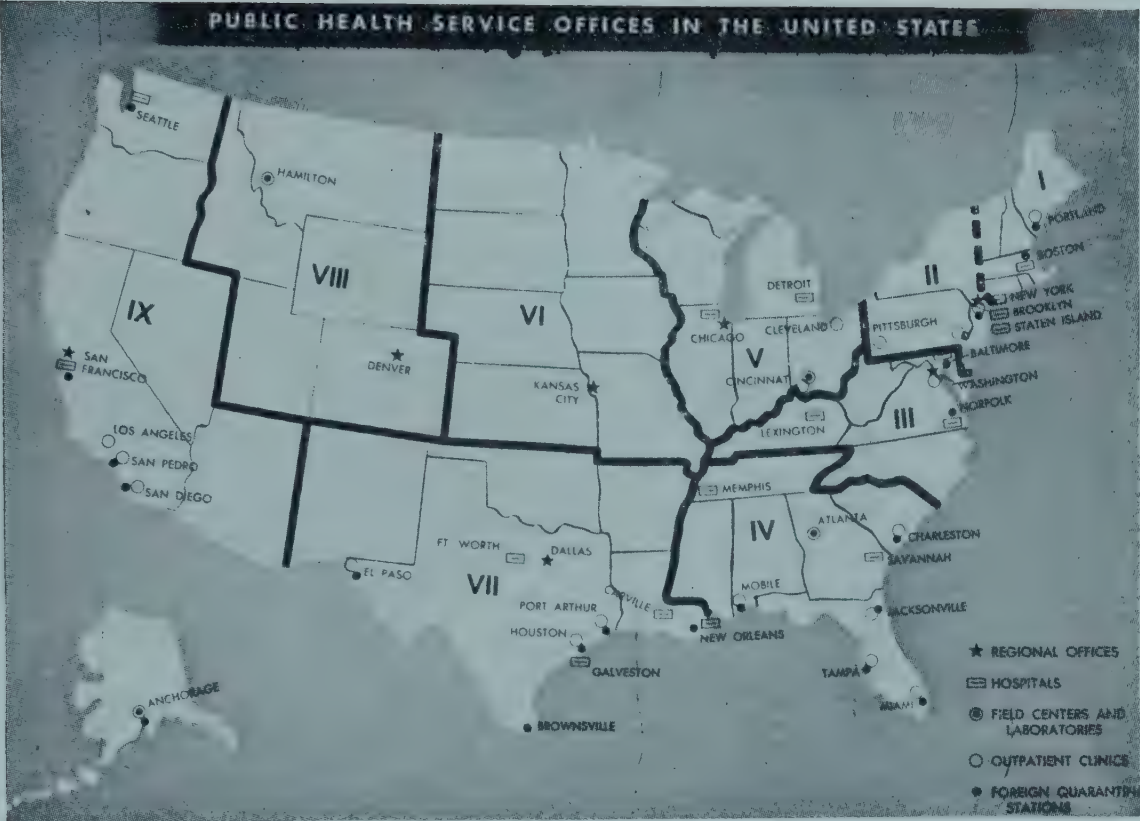

Fig. 47-3. Organizational chart—Department of Health, Education and Welfare, Public Health Service.

communities. Even where programs are started there are not always enough workers to meet the need. There is a marked shortage of the professional personnel required to carry out maternal and child health programs. With the increased birth rate, state and local health agencies are urged to create prenatal clinics and well-child conferences and public health nursing services for mothers and children so that those in need of such services will be able to secure them.

The Program Planning Branch of the Division of Health Services provides advisory services to regional offices, and public and voluntary agencies in specialized fields, including pediatrics, orthopedics, obstetrics, cardiology, psychiatry, nursing, nutrition, physical therapy, administrative methods, medical social work and hospital administration. It provides technical guidance and leadership to regional medical directors, and consults with educational institutions and national agencies on the promotion of training opportunities in the professional fields relating to maternal and child health. This branch also plans and formulates recommendations for the development of programs for maternal and child health services and services for crippled children, and prepares technical reports, articles and educational material in these fields.

**SERVICES FOR CRIPPLED CHILDREN.** Grants are made from the Children's Bureau to state crippled children's agencies to enable the states to extend and improve services for crippled children. The Social Security Act, as amended in 1946, authorized an annual appropriation of \$7,500,000.00 for this purpose. The program is in operation in all of the states except one (Arizona), in the District of Columbia, Alaska, Hawaii, Puerto Rico and the Virgin Islands. State plans are reviewed each year by the Division of Health Services for approval by the Chief of the Children's Bureau. Grants under Title 5, Part 2, are used to provide medical, surgical, corrective and other services, and care for children who are crippled or who are suffering from conditions that lead to crippling, and to provide facilities for diagnosis, hospitalization and after-care of such children. Twenty-six state agencies for crippled children include special programs for the care of children suffering from rheumatic fever or heart disease. Several states are developing programs for the diagnosis and treatment of children with hearing defects.

Approximately 175,000 crippled children received service in 1949 under state plans approved by the Children's Bureau. The state agencies responsible for administering services for crippled children in 1950 were as follows: 32 health departments, 10 public welfare departments, 4 crippled children's commissions, 3 departments of education, and 4 state university medical schools or hospitals. Each state agency for crippled children maintains a register. Approximately 510,000 crippled children were registered on December 31, 1948. Diagnosis and some treatment is provided in clinics held for crippled children in permanent clinic centers or at intervals in itinerant clinics. When hospitalization and medical and surgical care are needed, the state agency assumes responsibility for arranging care at a hospital as near as possible to the child's home and for obtaining the services of a physician or surgeon. Plans are made for the child's subsequent care in a convalescent home or in his own home and for medical and public health nursing supervision and physical therapy to complete his physical restoration. Medical social service is provided also to aid the child in adjusting at home, at school and in neighborhood activities. Children for whom such opportunities are appropriate are referred to vocational training when they reach 16 years of age.

## THE PROVINCIAL OR STATE HEALTH ORGANIZATION

Most national governments are divided into a number of political subdivisions having varying degrees of political autonomy. The major subdivisions of national government are usually called provinces, departments, or, as in the United States, state governments. These major subdivisions are in turn subdivided into local governmental authorities, municipalities, communes, counties, etc. In different countries the relationship of national government to the various subdivisions differs greatly in health supervision as in other governmental activities. In strongly centralized governments the primary responsibility for health activities is vested in the national government. In others, the primary responsibility is in the local subdivision. The general trend toward the centering of the taxing power in the central or national government has tended to transfer greater and greater control of health services to the central or national governments.

In the United States, as previously pointed out, the state government is the sovereign power and in health matters, as in other governmental activity, the national and local governments possess only those powers delegated to them by the state. The state constitution usually defines in broad general terms the responsibility of state government for the maintenance of the general health and welfare of the citizens. Acts of the state legislature define in more or less detail the organization and functioning of the state health department. Health laws in the 48 states differ greatly. In some, there has been extensive legislation specifying in great detail the health activities to be carried out and the organization of the health department. In others, only broad principles are laid down and special laws are enacted as urgent needs are recognized. A few states have detailed public health laws, codified and classified to form a well-planned legal basis for health activities; far more have scattered enactments to meet specific needs, which are imperfectly related one to another. In all of the 48 states there is some provision for a board of health or a comparable body whose functions are usually primarily advisory and legislative in nature. The size and composition of the board is usually specified in the law. The number of members varies from three or four to the total membership of the state medical society in one state. The qualifications for membership range from that of an intelligent public-spirited citizen to the very specific representation of professional groups interested in the promotion of health. The most frequent requirement is that a majority represent the medical profession. The members of the board of health are usually appointed by the governor for a fixed term of years; not infrequently the terms of the various members are staggered to provide for continuity in action. In addition to advisory functions, in most states the board is charged with certain legislative duties. The enactment of sanitary code regulations

declared to have the force and effect of law is a common responsibility. The validity of such legislative action depends upon the specific delegation of this power by action of the state legislature. In some states the board of health nominates or appoints the health officer. More frequently the health officer is appointed by the governor with the advice of the board. In some states the board establishes the qualifications not only of the health officer but of other professional personnel within the department. Actual appointment of the state health officer in these instances is by the governor and the appointment of other personnel in the department is the responsibility of its executive officer under civil service or merit system regulations.

In general, experience seems to indicate that the most effective state boards of health are those consisting of from 7 to 12 members appointed by the governor for periods of from four to six years with staggered terms so that there is continuity in action as a result of the maintenance of an experienced group. The combination of advisory and legislative function has proved to be very effective but the inclusion of any administrative responsibility has quite generally been found to be undesirable.

The state health officer is usually appointed by the governor as a member of his cabinet and is the head of a major department of the state government. His qualifications, duties and compensation are usually specified by state law. His term of office may be specified or he may serve at the pleasure of the governor. Efforts have been made to separate the health department from politics by the establishment of a term of office for the health officer that does not necessarily coincide with that of the term of the governor. For example, a six-year term for the health officer and a four-year term for the governor. In a few states the position of the health officer has by tradition become nonpolitical and where possible this seems to be a more adequate safeguard than the establishment of a fixed term.

### STATE HEALTH SERVICES

Historically, the states of the United States have been slow to recognize their responsibility for the health of the citizens. One of the first movements for the development of a state health department was in Massachusetts, where in 1850 abortive attempts were made to establish a state board of health and to develop a state health department. This was short lived and the first permanent state health organization was established in that state in 1869. This is generally accepted as the first permanent state health organization in the United States. Other states followed soon after this, and, stimulated by the great epidemics of cholera and yellow fever which prevailed during the 1870's, a considerable number of state health departments and state boards of health were established. The increasing recognition of the need for health services resulted in the establishment of some 18 state boards of health and state health departments within the decade. By the turn of the century, 38 states had developed some form of state health organization with state boards of health and at least rudimentary state health departments. By 1913, every state and territory in the Union had one.

The early boards of health consisted of groups of physicians who served without pay and who were authorized only to make investigations and to report their

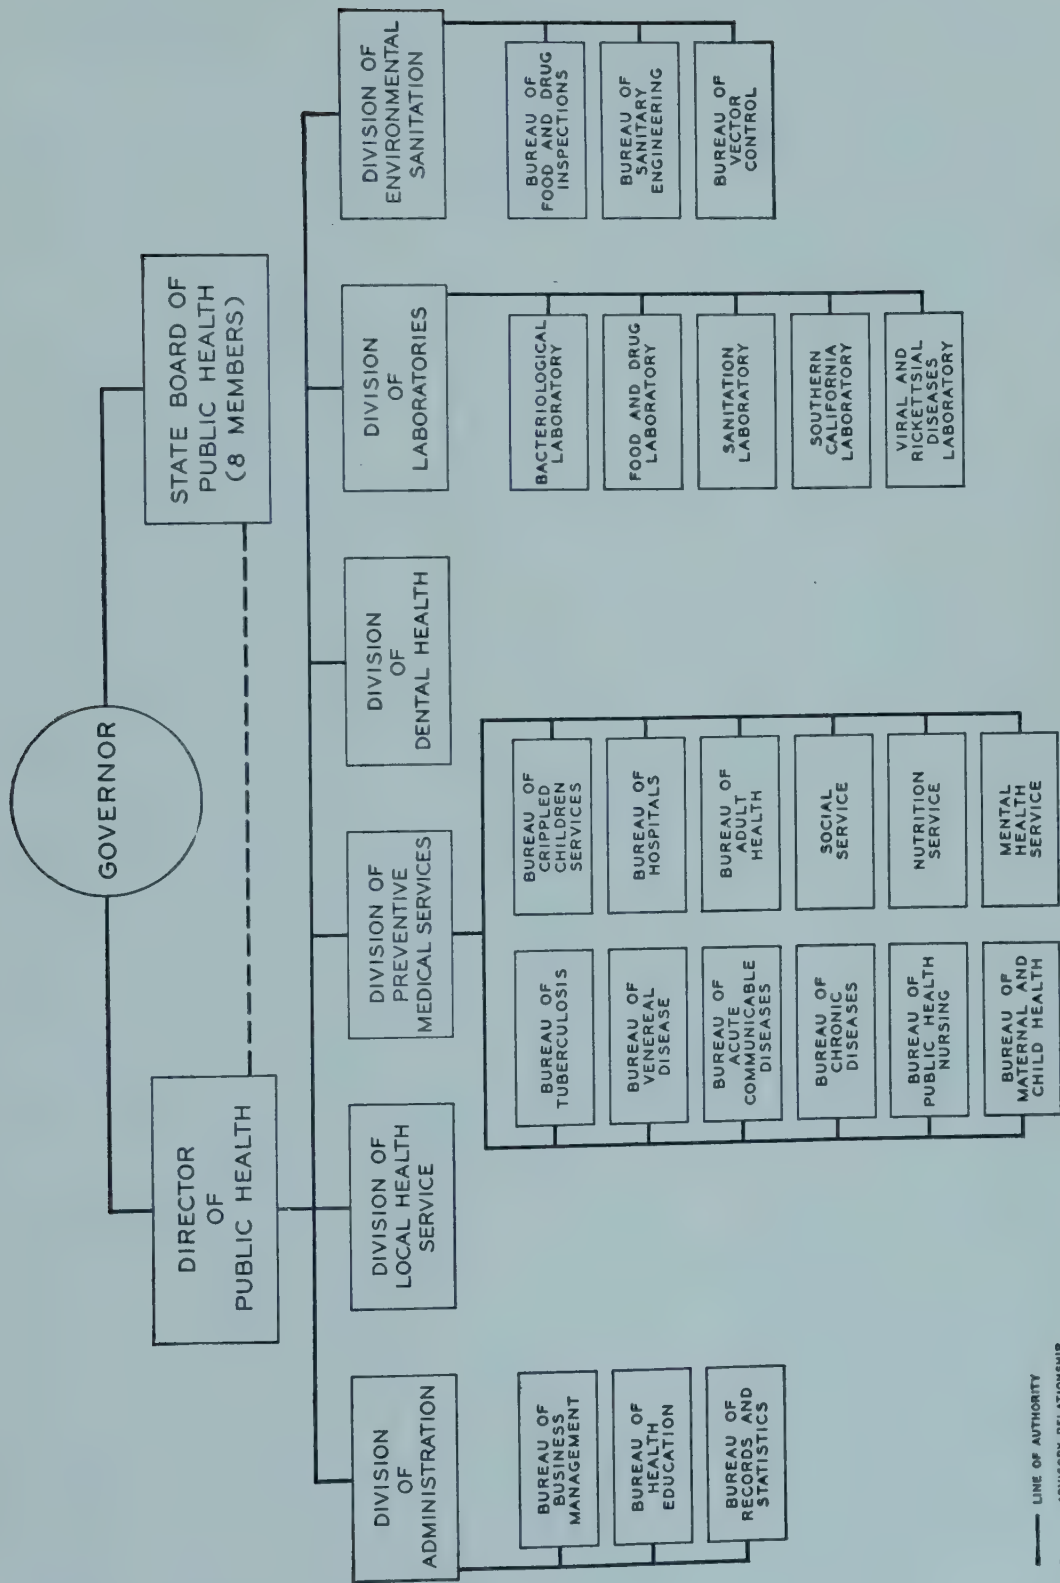

Fig. 48-1. State of California Department of Public Health.

findings and recommendations to the governor or the legislature of the state. At about the beginning of the twentieth century, the more progressive states began to develop more adequate staffs and to extend the programs for the prevention of disease and disability. In the early development of the public health movement in the states, control of communicable diseases was the principal objective. This required the provision of laboratory services for diagnosis. The next step in state health services was in the field of environmental sanitation, in the development of laws and regulations pertaining to water supplies, stream pollution, and sewage disposal. Sanitary engineering became one of the most important fields of state health department activity.

From the very beginning, state boards of health and state health departments were called upon by municipal and local officials for assistance in the control of epidemics. With the growth of interest in all health matters, these calls became more frequent and urgent. To meet these needs, the state boards of health began to provide field services for the diagnosis of doubtful cases of communicable disease and for the study and control of epidemics. This need of the small communities and rural areas for technical services has had a considerable influence on the development of the state health organization. It has been their task to work out plans and an organization whereby these essential services could be made available to smaller communities and to rural areas. One of the most important branches of the modern health department is the division of local health administration. In some states, an attempt has been made to provide local health service as a direct extension of the state health department's activities through the organization of health districts. In other states, assistance has been given to the development of local health services through a program of grants-in-aid or state-aid programs. In the latter system, financial support has been given to the development of local health services by matching local expenditures under various formulas with a proportion of the cost of maintaining local health services, provided they met basic standards of the state health organization.

The organization of most state health departments is on a divisional or bureau basis, providing certain standard services in the specialized fields. The usual subdivisions of a state health department are as follows:

1. Vital statistics.
2. Environmental sanitation.
3. Public health laboratory services.
4. Communicable disease control, including the acute communicable diseases, venereal diseases and tuberculosis.
5. Maternal and child health which may include services for the physically disabled.
6. Public health nursing.
7. Health education.
8. Industrial hygiene, although this is not infrequently included in environmental sanitation.
9. Mental hygiene.
10. Local health services.

There is considerable variation in the organizational pattern of various state health departments but these basic minimal services are now considered as essential to any state health activity. The minimum functions of a state health organization as defined by standards of the American Public Health Association are:

1. The study of state health problems and planning for their solution.
2. Coordination and technical supervision of local health activities.
3. Financial aid to local health departments.
4. The enactment of sanitary regulations applicable in local health programs.
5. The establishment of minimal standards for local health work.
6. The maintenance of central and branch laboratory services, including diagnostic, sanitary, chemical, biological, and research activities.
7. The collection, tabulation and analysis of vital statistics.
8. The collection and distribution of information concerning preventable disease.
9. The maintenance of a safe quality of water and the control of waste disposal.
10. Establishment and maintenance of minimal standards of milk sanitation.
11. Provision of services to aid industry in the control of occupational hazards.
12. The establishment of qualifications for health personnel.
13. Formulation of plans in cooperation with other organizations for meeting all health needs.

There is considerable variation in the pattern and the lines of authority within states. There is generally a reasonably straight line of authority from the governor to the executive officer or health commissioner of the state, with the state board of health serving for the most part as an advisory body and a quasi-legislative body. The state health officer is the administrative head of the organization in almost all states and he is assisted by various deputies or assistant commissioners. In order to simplify administration, there is a growing tendency to reduce the number of bureau or division heads reporting directly to the commissioner. There is an equal tendency to increase the number of professional or technical advisory boards and councils serving in a purely advisory capacity to the executive officer of the state health organization. The major subdivisions, while they vary in different states, show certain definite similarities in that general administrative services or the management services of the health department are grouped together and are more or less directly related to the executive officer's line of supervision. In addition to the major subdivision of administration there is usually a grouping of more or less related activities into the following major bureaus or divisions: environmental sanitation, medical services, and local health administration. This type of organization is in contrast to the rather diffuse pattern current one or two decades ago, when each specific activity of the health department had a separate divisional status with a specialist reporting directly to the executive officer in each special activity of the health department. With the expansion of the program of the official health agencies, no one person could conceivably be an expert in all phases of the activities, and the need for technical advice has been met by the establishment of a constantly increasing number of advisory committees and special consultants to the executive officer.

### THE BUREAU OF GENERAL ADMINISTRATION

The division of general administration is usually under the more or less direct supervision of the executive officer. This is true not only because the executive officer of the department is legally responsible for the administration of large sums of money but under certain state laws, the health officer, commissioner, or executive officer of the health department is personally designated as the responsible agent for many of the activities of the state health organization. There may be specific provision in the law for personal exemption from responsibility provided he oper-

ates within generally accepted standards of practice in the field of public health, and the health officer is not infrequently given by the law extensive emergency powers for the protection of the public health. The health officer is usually charged with the enforcement of the public health law of the state and the sanitary code as enacted by the public health council or state board of health. In some states, he is given specific police powers and in certain instances is deputized by the police authority to carry out certain police functions. In order to carry out the many and varied functions of the administrative office, certain subdivisions have been set up with specially qualified personnel to carry out these functions under the direction of the state health officer. While the division of responsibility varies in different health departments, the following are most frequently found: (1) a legal division; (2) a licensing or permit division; (3) a division of budget or audit and accounts; (4) a division of personnel management; (5) a division of public relations; and, depending upon the size or complexity of the organization, additional divisions.

**The Legal Division.** The legal division is responsible for drafting necessary legislation and for maintaining liaison with the legislative branch of the state government in order to advise and assist in the drafting, introduction, and support of sound public health measures. With rapidly developing programs of public health in many states, this is an important function of the state health department and may require the skill of individuals not only trained in the law but with a comprehensive understanding of public health problems.

Inasmuch as the state board of health has in most states a specific legislative function in the drafting of the sanitary code and the maintenance of sound regulations, the legal division has considerable responsibility in the development of sanitary code regulations, interpreting the legal implications, and the drafting of the regulations in a clear and concise form which will stand up under court scrutiny. In certain situations, the health department must take legal action to enforce sanitary code or other regulations of the department and not infrequently court action is taken in the name of the state health officer or in the name of the state board of health. In these instances, competent representation in court is essential either by a legally trained member of the staff or through the state attorney general's office.

With the development in many states of more and more complicated civil service regulations and procedures, legal advice is not infrequently needed in carrying out necessary disciplinary action, or in the determination of policy; with a competent, legally trained member of the staff, such advice can be most readily provided.

**Licensing or Permit Division.** Under the public health law in many states, the department of health is charged with the responsibility of inspection, approval, and licensing of a great many different types of business or commercial operations. Many state laws require the inspection and licensing of dairies, milk plants, restaurants, beauty parlors, barber shops, etc. In such instances, there are specific regulations as to the operation of such establishments and an inspection service must be provided. Not infrequently, rather considerable fees are charged in connection with the licensing of these establishments and, in some instances, a significant proportion of the financial support of the health department activities comes from this source. In order efficiently to operate such a program of licensing, a well-organized administrative unit is required to maintain close liaison with the inspection

services and the enforcement of sound sanitary regulations. In certain states, the approval and licensing of public health laboratories is also included within the responsibility of this division.

In recent years, there has been a growing tendency to place upon the state health department responsibility for maintaining certain standards for technical operators in fields which may have a direct or indirect bearing upon public health. In many states certain technicians are subject to regulations of and are licensed by the state department of health. These include laboratory technicians, x-ray technicians, midwives, oxygen-therapy technicians, exterminators, and, in some states, plumbers. In order adequately to carry out this function, boards may be created to examine applicants for licensure in these fields, to determine technical competence, and to maintain standards.

**The Division of Budget or Audit and Accounts.** As the responsibility of state health departments has increased, there has been more and more need for an efficient business management unit within the department. When it is realized that some state health departments at the present time operate on a budget of 20 to 30 million dollars per year, it is obviously necessary that an efficient system of business management be established. The mere matter of bookkeeping of departmental expenditures in larger state health departments becomes a major undertaking and requires competent personnel. This may include the purchase of considerable volumes of equipment and supplies with the possibility of great savings if efficiently conducted. In those states in which there is provision for state aid, either through state funds or through state and federal funds allocated to the state, there may be the problems of audit of accounts of local health services in order that expenditures of the local health department are in accordance with approved budgets. There are very few states that do not have financial relationships with local health services within the state at the present time and the maintenance of an adequate system of accounts in these joint programs is essential. The preparation of an annual budget for a large health department is a rather complicated undertaking and requires special skills. Moreover, the operation of a modern health department under a line item budget requires extensive dealings with the budget director to maintain an efficient operating department.

**The Division of Personnel Management.** In most state health departments, the personnel is sufficient to require the development of definite policies and the maintenance of an efficient service. This division should also be under the direct supervision of the executive officer of the state health department. It should serve the functions of recruitment and training of staff to maintain an efficient organization, and its responsibilities in this regard may be rather extensive. There has been increasing recognition of the great importance of the recruitment of professional staff and this has become an important activity in some health departments. In connection with recruitment, particularly of medical personnel, there is a need for the establishment of a training program, including academic and field training, to maintain an adequate staff. Impetus has been given to the development of these training programs as a result of the establishment of a specialty board in public health which requires a basic training that includes academic and approved field training. A number of state health departments have within recent years established

well-organized and supervised training programs to provide an adequate supply of trained personnel.

Another function of the personnel management division is the maintenance of personnel records and service rating programs. Under most merit systems, there is a necessity for evaluation of the quality of the work of employees of the department and efficiency rating forms have been developed in an attempt to measure accurately the efficiency of individuals employed by the department. These efficiency ratings present obvious difficulties in evaluating the services of an individual employee, but in competent hands may be of great value in maintaining a high quality of service. Another function of the division may be the development of inservice training programs for all types of employees. Many health departments rely rather largely upon part-time staff for the clinical operations of the department, recruiting clinic physicians from the general practitioner group within the state. In this group, inservice training is particularly important to maintain a high quality of preventive medical services in the clinics, and is also of vital importance in the development of new programs providing staff members with opportunity to obtain technical skills in the specialty fields that may be newly undertaken.

In most state health departments, merit system programs have been established and employment of personnel is through the civil service commission of the state. The personnel officer has an important responsibility in the maintenance of satisfactory relationships with the civil service commission, assisting in the development of satisfactory qualifications and duties for employees at various grades. This office may also assist the civil service commission in the development of job analyses, appropriate salary gradings and an adequate examination procedure.

Under civil service laws primarily designed for the protection of the employee, constant diligence must be maintained by the personnel office to avoid the perpetuation of mediocrity. This can best be done through careful use of the probationary period which permits of the early elimination of inadequate personnel under a civil service system. The personnel office also can, through proper use of disciplinary measures provided within civil service laws, eliminate incompetence from the service but only by the employment of sound personnel practices.

Within recent years, a new personnel problem has developed in some state health departments with the unionization of certain types of personnel. It would seem doubtful that sound personnel practice would permit of the direct opposition to unionization of health department employees but sound labor practices are necessary in order to avoid difficulties under these circumstances. One method that has been found to be effective in dealing with these problems is to set up grievance committees within the personnel division to provide for adequate hearings on all complaints that may be made by employees.

Another responsibility of the personnel division might well be the maintenance of staff morale. The efficient operation of any organization, whether it be a business firm or a health department, depends upon good staff morale. In maintaining staff morale, nothing will take the place of adequate salaries, reasonable hours of work, satisfactory holiday schedules, sick leave, and vacation time, but much can be done to improve staff morale under otherwise adequate conditions. One of the most important factors in maintaining good morale in a health department staff

is the provision of a satisfactory method of communication within the department. A clear understanding of responsibilities, methods of procedure, and lines of authority may be established through clearly worded rules and regulations of the department and manuals of operation available to the entire staff. Adequate lines of communication avoid misunderstanding and the feeling of having been left out of the councils of state. Another method of maintaining adequate understanding of the basic objectives of the health department may be the staff conference in which all members of the staff are brought together once a year or perhaps more frequently for a general discussion of problems common to all or the majority of the staff of the department. In certain circumstances, social events and sports may have their part to play in the maintaining of a high level of morale in the health department staff.

**The Public Relations Division.** The effectiveness of any health department's activities can be greatly increased by maintaining sound public relations. Moreover, with sound public relations, an effective job of health education is much more apt to be attainable. One of the most important channels for public relations is the press. Health is news, whether it is a report of a serious epidemic or a new record low in infant mortality. Many instances could be cited in which a newspaper campaign for improved health facilities has been the deciding factor in obtaining adequate appropriations. Relationships with the press must be maintained with a fine degree of diplomacy. The health officer who makes use of the press to bludgeon his appropriating bodies into providing adequate facilities may find himself in difficulty. On the other hand, a sound policy of giving out information impartially to all of the newspapers and reporters involved can, with few exceptions, develop a perfectly satisfactory relationship with the press. The radio and television offer opportunities for exploitation in the health field. Unfortunately, these have limitations in that the maintenance of a high quality of program on either radio or television requires highly skilled individuals and tremendous amounts of time and energy. Depending upon the technical skills that are available, these media of communication can be used to advantage.

Another extremely important field of activity is the relationship of the health department to the various civic organizations, such as the women's clubs, citizens' unions, health councils, and other community organizations. Many of these community organizations, particularly the voluntary health agencies, have a direct interest in health and they can be a tremendous force in the community for the improvement of health services and the support of a sound health program. The health officer and his division of health education should make use of the interests that are already developed in these organizations and, where they are not well organized, can well devote considerable energy to community organization in order to develop this interest and support.

No health department can afford to neglect the cultivation of satisfactory professional relationships, particularly with the state and county medical societies, to establish understanding of the health department's programs, to make use of these facilities in cooperative educational projects, and to obtain the advantage of competent technical advice.

## BUREAU OF ENVIRONMENTAL SANITATION

One of the major subdivisions of any health department is the division of environmental sanitation or the division of sanitary engineering. It has long been recognized that certain environmental controls are of tremendous importance in the protection of the public health. One of the earliest environmental factors to be recognized as capable of producing disease and disability was the public water supply. In the United States, elaborate measures, which have been outstanding in their accomplishments in the prevention of water-borne disease, have been provided for the safeguarding of public water supplies. In the final analysis, the health department is responsible for the procurement of safe water supplies and, in many instances, for the maintenance of an adequate supply. In the larger municipalities, rather elaborate provision has been made for the collection and distribution of water and this has been the responsibility of a division of government other than the health department. Nevertheless, the health department has a definite responsibility in almost every state to provide technical guidance in the selection of basic sources that will be free from contamination and to set up regulations to assure the continued sanitary quality of water that is to be used as a public supply. This involves the use of highly skilled sanitary engineers to determine the safety of the supply, the possibilities of contamination, and the adequacy of purification methods used. In the United States, most of the water supplies for urban communities are derived from surface sources and require complex purification processes, which may include filtration and chemical treatment. Certain safeguards are necessary to avoid the possibility of contamination within the distribution system. The state department of health must provide competent technical advisors in the development of treatment processes and of adequate and safe distribution systems. Having established an adequate source, method of treatment and distribution system, the health department still has the responsibility of supervising treatment in order to maintain a safe sanitary quality. To do this, supervision must be maintained throughout the processing of water and a system of sampling must be set up to determine the quality of the water at points of distribution. This also requires the maintenance of adequate laboratory facilities to determine the quality of the water.

The United States Public Health Service standards for water acceptable for interstate carriers provides a basic standard for water quality and also provides a very potent incentive to maintain the high quality of water in local communities. The threat of failure of approval of the water supply for interstate carrier use will sometimes bring about corrections otherwise difficult to obtain. Direct supervision of all public water supplies within a state is obviously beyond the possibilities of most state health departments. In order to be assured of a safe quality of water in all municipalities, the state health department may establish basic standards and a system of sampling in order to determine the compliance with these standards. Another method that has been used rather extensively is the specification of the qualifications of water-plant operators by the state health authority.

The safeguarding of private water supplies presents difficult problems both to the state and to the local health departments. Safe, private water supplies depend primarily upon education of the public, and many health departments have de-

veloped effective educational devices to assist the private property owner in procuring a safe supply for home use.

**Sewage Disposal.** Another major responsibility of the state health department is the development of safe methods of disposal of sewage, particularly from municipalities and from industries. Of primary concern in this field is the avoidance of stream pollution, either through utilization of the principle of dilution or through the treatment of sewage wastes prior to disposal in natural waterways. The first consideration must be the safeguarding of public water supplies from surface sources that might be polluted by municipal sewage disposal. Some state laws give the state health department broad powers and great authority to require the adequate treatment of sewage wastes. Another responsibility of the health authority is the requirement for disposal of human waste in such a way as not to produce a nuisance which might be of some health significance. In certain circumstances health hazards may be created by pollution of bathing beaches or areas from which seafood is harvested. In addition to these hazards from sewage disposal, the health department has increasingly concerned itself with the possibilities of local contamination through improper plumbing connections and construction. The important part played by cross connections in the contamination of municipal water supplies has been clearly recognized in the past two decades. Health departments have, therefore, established regulations for all new plumbing installations and as rapidly as possible are eliminating potential cross connections due to faulty plumbing. The problem of eliminating hazards from sewage disposal in private establishments is primarily one of the rural areas and suburban communities. Particularly in the southern part of the United States, there have been extensive programs of rural sanitation stimulating the construction of sanitary privies and septic tanks as a means of preventing the creation of nuisances, the spread of hookworm, and other helminthic diseases, and to reduce the prevalence of flies as a possibility in the transmission of disease. In rapidly developing areas around urban communities, extremely serious problems of sewage disposal have been created. These problems are met by the establishment of regulations as to the type of sewage disposal system that may be installed within these areas.

In some communities, the disposal of garbage and waste other than human waste is considered the responsibility of the health department. Although not specifically of health significance, the disposal of this type of waste may create a nuisance and the health department inevitably becomes involved. For this reason, sanitary code regulations require certain precautions in the disposal of garbage either through incineration, carefully controlled use of sanitary landfills, or, if garbage is to be fed to hogs, heat treatment which will assure the destruction of trichina.

See Chapter 41 for a technical discussion of sewage disposal.

**Milk Sanitation.** The protection of the milk supply of the community is a major function of a health department. The state health department establishes basic standards for the production, processing, and distribution of milk to assure a safe, sanitary quality. Local communities may establish regulations not inconsistent with the state regulations. Under modern methods of pasteurization and methods of testing for adequacy of pasteurization, there is no longer any excuse for the spread of infection through this medium. There is a growing tendency to

emphasize the requirement of pasteurization and the inspection of pasteurization equipment and procedures to assure safety in milk rather than extensive inspection on the producing farm. While dirty milk adequately pasteurized will not produce disease, it is generally agreed that citizens are entitled not only to a safe milk but to a clean milk and, on this basis, rather elaborate regulations have been established by most state health departments to assure a clean milk supply. Because of the confusion not infrequently created by conflicting regulations of municipalities having overlapping milk sheds, there has been a growing tendency to establish standard milk production codes not only within a state but between states. The United States Public Health Service Standard Milk Code has been accepted by an increasing number of states and will eventually, in all probability, provide for a relatively free interchange of milk throughout the United States. Regulations governing the processing of milk are of the greatest importance, particularly in large cities where tremendous quantities of milk are pooled and distributed. Great progress has been made in recent years in the development of efficient pasteurizing equipment which may be easily tested for efficiency, and, with the use of the phosphatase test, any defect in the pasteurizing process can be quickly detected. Constant vigilance is necessary to assure a safe milk supply for any community. Until quite recently, considerable attention has been paid to bacterial standards, butterfat content, and grading of market milk. There has been a growing tendency to discount the values of this type of grading and to require basic minimal standards in terms of cleanliness and bacterial counts and to consider only minimal butterfat content. From the public health standpoint, reasonably clean, adequately pasteurized milk with butterfat within normal limits is all that it seems reasonable to require. In rural communities where pasteurization is impracticable, elimination of tuberculosis and brucellosis from milking herds is imperative and precautions to avoid the use of milk from cows possibly suffering from mastitis is necessary. In private households and one-cow dairies, these are the only precautions that seem reasonable at the present time.

See Chapter 21 for a technical discussion of milk sanitation.

**Safeguarding of Food Supplies.** Regulations concerning the wholesale production and handling of food are usually prescribed in state sanitary codes. Responsibility for the inspection to enforce these regulations lies, for the most part, with the local health departments. In most states, the inspection of meat shipped in interstate commerce is primarily the responsibility of the Department of Agriculture of the Federal Government. Other local requirements may be set up for locally killed meat not destined for interstate shipment but here again, the inspection program is primarily a local health problem. The supervision of retail food establishments, particularly restaurants, is a joint responsibility of state and local health departments. Basic standards of cleanliness are established by state sanitary code regulations. In some states, rather detailed regulations concerning methods of dishwashing in public restaurants are prescribed. In a few states, a physical examination of food handlers is still required, although it has been rather effectively discredited. It is now pretty generally agreed that restaurant sanitation is most effectively handled through training courses for food handlers and the limited utilization of laboratory tests for the sterility of dishes.

See Section 4 for a technical discussion of food sanitation.

## THE BUREAU OF MEDICAL SERVICES

In the larger, and particularly in the more completely developed, state health departments there has been a tendency to group together those services which require medical activities as a basic part of the public health program. These bureaus or divisions usually include services for the control of the acute communicable diseases, tuberculosis, and venereal diseases; programs for maternal and child health; services for the physically handicapped, for dental hygiene and mental hygiene; programs for adult health, which usually include industrial health; and chronic disease services, including a program of control of cancer, heart disease and diabetes. They may or may not include subdivisions for social service and nutrition. Under such a bureau there is usually some administrative subdivision for the specific specialty programs of the department.

**Organization for the Control of the Communicable Diseases.** The measures employed by the health department in attempting to control the spread of communicable diseases are varied, differing according to the nature of the infectious agent causing a particular disease and the mechanism by which it is spread through the population. The oldest of all such measures is that of isolation. If it is believed that a particular disease spreads from the person suffering from it to those well persons who come in contact with him, the most obvious and natural procedure is to attempt to reduce the amount of this contact. This is usually done by isolating the sick person and restricting access to him to the smallest possible number of persons. The extension of this idea of isolation led to the restriction of travel and commerce between areas affected with communicable diseases and those in which the disease had not yet appeared. The enforcement of quarantine has in the past led to great hardship and suffering to helpless individuals and to costly and sometimes paralyzing interference with commerce and travel. Preventing the spread of disease by isolation or quarantine has not in practice proved to be as simple as it would appear. The recognizable case is seldom the sole source of infection and contact with him is not necessarily the means by which the disease is spread. Even under the most favorable circumstances the existence of a disease cannot usually be recognized until the patient has already had some, if not abundant, opportunity to spread infection. In some of the serious infectious diseases isolation is recommended primarily to protect the patient from possible secondary infections.

Another historic procedure for the prevention of the communicable diseases is that of disinfection. From earliest times, the effects, and frequently the dwelling, of the infected person have been washed, fumigated with aromatic or evil smelling substances, or even burned for the purpose of destroying any infectious substance that might cling to them. When it was demonstrated that many diseases are caused by living agents and that these agents can be destroyed by certain chemical substances, these ancient practices were strengthened in the minds of physicians and the population alike. This led to the use of such substances as formaldehyde, carbolic acid and bichloride of mercury for the disinfection or fumigation of persons and premises. It has been amply demonstrated that most infectious agents do not long survive outside the human body and that disinfection at the bedside of the actual secretions and excretions of the patient followed by the use of soap and water and otherwise normal cleanliness is of greater value than the elaborate pro-

cedures formerly employed. At the present time, therefore, disinfection is a simple procedure used only where study and experiment have indicated its value.

The demonstration by Jenner at the end of the eighteenth century that an individual might be completely protected against smallpox by inoculation with a mild and harmless cowpox vaccine made it possible for the first time in human history to control one of the great plagues. With advancing knowledge of the nature of the agents causing the infectious diseases, it has been possible to develop means of protection against a number of other diseases, and specific immunization has taken its place as one of the most important procedures in the control of the communicable diseases.

Many diseases are spread by arthropod vectors. These diseases may be controlled by measures that prevent the breeding of the specific insect vector concerned, destroy adult insects and protect human beings against their bites. Certain diseases are spread by contaminated food or drink, particularly water or milk. These diseases, principally those of the alimentary tract, may be prevented most effectively by the elimination of the possible sources of infection, although in certain of the intestinal diseases immunization procedures are available which under appropriate circumstances may be of great value.

The administrative organization of a health department must be developed to meet the specific needs of the community which it serves. There are certain general principles, however, that may be defined. In order to control a disease it is necessary to know of its occurrence; therefore, morbidity and mortality reporting is required. In order to be effective, the health department must have some mechanism for obtaining reports of those communicable diseases about which some action can be taken to reduce the spread of infection or to prevent serious consequences. Reporting of communicable diseases should be required, the report being sent to the local health officer for his information and such action as is prescribed by the sanitary code or by administrative regulations of the department of health. Certain diseases, such as typhoid fever, smallpox and diphtheria, have become so rare in many communities that the services of an experienced and skilled diagnostician are of great value to the practicing physician and are usually greatly appreciated. In addition to the reporting of those communicable diseases for which some specific action may be taken by the health department, it is usually desirable to have requirements either in the public health law or in the sanitary code requiring the reporting by physicians or others of recognized unusual prevalence of disease or localized epidemics in order that attention may be called to the occurrence. The health department should have available trained personnel for the carrying out of epidemiological investigations wherever these are indicated and provide specially trained epidemiological teams of physicians, nurses and sanitarians to investigate and control the unusual prevalence of disease in any part of the state; special units may be necessary to deal with diseases of particular importance.

There are certain diseases for which there is available a reliable immunizing agent and the departments of health maintain active programs to promote immunization against these diseases. Important among these are smallpox, diphtheria, pertussis, tetanus and typhoid. Immunization against smallpox has been so amply demonstrated to be effective in controlling this disease that many communities have required that all children be vaccinated, either in infancy or at the time of entering

school. This is particularly true in urban communities. One of the responsibilities of the health department is to enforce such regulations or laws where they exist and to stimulate universal vaccination against smallpox regardless of whether legal requirements prevail in the state. Diphtheria immunization has also been proven to be of unquestioned value in the prevention of the disease and it has been demonstrated that epidemic diphtheria can be prevented by the immunization of a significant proportion of the population. Compulsory diphtheria immunization has not been generally accepted in the United States but there has been over the years a growing tendency to accept immunization in infancy as a standard practice. Most health departments maintain clinics for the immunization of infants in families unable to obtain this service from pediatricians or practicing physicians. Many communities maintain an accurate register showing the immunization of infants and requiring the reporting by all clinics and physicians of immunizations carried out in order to have assurance of an adequately immunized population for the purpose of preventing the spread of the disease. In the past decade, the protective value of pertussis vaccine has been demonstrated. Whooping cough has been added to the group of diseases for which active immunization is urged. Tetanus toxoid was demonstrated to be of unquestioned value, particularly during World War II, and, while tetanus is a relatively uncommon infection in civilian populations, the threat is always there and with the development of combined diphtheria, pertussis and tetanus vaccine there is a constantly increasing proportion of the population that is also immunized against this disease. (See Chapter 16.)

**Tuberculosis Control.** The measures taken by the health department to prevent tuberculosis are, in general, based upon removal of the open case of tuberculosis from contact with his family and the general population. This usually can be effectively accomplished only when such a patient can be hospitalized. The major effort of the health department is, therefore, to set up a mechanism whereby the disease may be recognized in its early stages so that the infectious case may be prevented from continued exposure of other individuals and so that the individual case may be given as prompt treatment as possible in order to minimize the possibilities of extensive disease or death. The case-finding program of the department of health is, therefore, one of the important features of the tuberculosis control program. Cases of tuberculosis may come to the notice of the health department in a number of different ways. They may be reported by private physicians, hospitals or clinics; they may be diagnosed from specimens submitted to the health department laboratory; or, unfortunately, they may come to the attention of the health department only through report on the death certificate. In recent years, extensive efforts have been made by health authorities to detect cases of tuberculosis early through mass screening, using the small film x-ray technic, of populations, particularly those known to be prone to tuberculosis. Facilities are rarely available for the immediate isolation or hospitalization of the recognized case; therefore, supervision of recognized cases within the home is one of the important activities of the health department.

Wisely used, a tuberculosis register provides an effective means whereby the health department may maintain supervision over all known cases of tuberculosis and may detect additional cases through the examination of family contacts. The adequate follow-up of known cases of tuberculosis requires frequent nursing visits;

this applies particularly to sputum-positive cases, all of which should be hospitalized at the earliest possible date.

In the United States, the use of BCG vaccination as a means of protection of particularly exposed groups is being explored. The establishment of an organization or a plan for the vaccination of tuberculin-negative infants in population groups known to have a high tuberculosis mortality is under consideration in many areas.

See Chapter I for a technical discussion of tuberculosis control.

**Venereal Disease Control.** The venereal diseases, of which syphilis and gonorrhea are the most common and most important, are highly prevalent in the United States. They differ from the other communicable diseases with which the health department has to deal in that they are contracted usually as a result of promiscuous sexual contact. Any reduction in the amount of sexual promiscuity would, without question, result in a rapid decline in the number of new cases of venereal diseases. Efforts through education to reduce the amount of sexual promiscuity have, however, been almost uniformly unsuccessful and such progress as has been made in the prevention of venereal diseases has resulted from other means. Principal among these has been the reduction of the period of infectivity of the individual case through prompt and effective treatment, thus diminishing the probability of infection of others. Probably the most effective procedure to attain this end is to make good treatment quickly and easily available to every infected person. This may be done by the establishment of public clinics or by aid to practicing physicians to whom patients may go. These means will be effective only if accompanied by the carrying out of an educational program which will bring to the attention of the infected person or the potentially infected person the seriousness of the diseases and the importance of adequate treatment. A large proportion of cases of syphilis and gonorrhea occur in persons who are unable or unwilling to pay for treatment. For these people health departments have had to organize free public clinics. If treatment clinics are to be effective, consideration must be given to the ease and convenience of the patients. For this reason evening clinics are almost invariably a necessity in any venereal disease control program. Modern methods of treatment, particularly with penicillin, have greatly reduced the problems previously encountered in keeping patients under treatment for a sufficient length of time to render them noninfectious and to provide reasonable assurance of cure. These new methods of treatment have, however, created additional problems, particularly in gonorrhea where the promptness of cure materially increases the possibility and probability of reinfection.

There are differences of opinion as to the values of contact investigation but the experience of competent investigators would seem to indicate that under some circumstances careful interviewing and detailed contact follow-up is an effective means of finding new cases and reducing the sources of infection. Organized prostitution is, without question, an important factor in the maintenance of gonorrhea and syphilis. The experience of World War II, when vigorous efforts were made to suppress prostitution, demonstrated that the suppression of prostitution has the effect of reducing promiscuity and, thus, the incidence of venereal diseases. The almost inevitable linking of prostitution with other forms of vice and the frequency of corrupt practices among law enforcement agents make the suppression of prosti-

tution extremely difficult at any time and only the continued exercise of strong pressure of public opinion will bring about consistent control.

See Chapter 4 for a technical discussion of venereal disease control.

**Maternal and Child Hygiene.** When in the last years of the nineteenth century the excessive mortality of infants and young children began to attract the attention of physicians and others interested in human welfare, very little exact scientific information was available as to the causes of the deplorable conditions which were everywhere evident in the large cities. It had long been known that the mortality of infants was many times higher among the poor than among the more fortunate classes of the population. It was known also that breast-fed babies had a much lower mortality than did those artificially fed, and that the intestinal diseases, diarrhea, enteritis and what was called "cholera infantum," were major causes of infant mortality during the summer months.

The first efforts to reduce infant mortality were based on the assumption that the high infant mortality of the summer months was due primarily to impure milk, with the ignorance of the slum mothers and the general effects of poverty and low living standards as contributory causes.

The milk station, designed to make pure milk available to the poor, early outlived its usefulness. The great improvement in the cleanliness and keeping quality of market milk and the spread of pasteurization soon made the general milk supply as well suited for the feeding of infants as were the certified supplies formerly produced for that purpose. Along with the improvement in the milk supply, other sanitary improvements were made in the cities. Water supplies were made safe from contamination, sewer systems were extended and privies abolished, particularly in the smaller communities. Finally, and by no means least in importance, the automobile supplanted the horse as a means of transportation and with the disappearance of the horse and stable, the fly population, even in midsummer, decreased to a small fraction of what it had previously been. The result of all of these improvements, and it is impossible to decide to just what degree any particular one influenced the result, was a rapid decline in the prevalence of "summer diarrhea" and of infant mortality resulting from it. A high infant mortality became a phenomenon of the winter months rather than the summer months.

The infant welfare station has survived as the well-child conference and has everywhere come to be recognized as the most useful agency in the child hygiene program. It is primarily an educational institution. In a well-organized city, the health department conducts a sufficient number of these stations to serve all infants not able to secure similar service from a private physician. Approximately 30 per cent of the infants and young children resident in a large city fall into this class. Such clinics must be widely scattered in the community so that mothers may conveniently take their children to them.

The staff of a child hygiene clinic consists of a pediatrician, a nurse and, if possible, a voluntary worker or clerk to assist the nurse and the mother. The children seen at any regular session should be those from the district of the nurse on duty at that time and she should, so far as possible, be present during the interview between the mother and the pediatrician.

The clinic should, as far as possible, avoid the treatment of sick babies. It is not staffed or equipped for such a purpose and an attempt to treat sick babies

is usually not only inefficient in itself but entirely destroys the educational feature of its activity.

Although the infant under two years of age was of first interest to workers in this field, it was not long before the services of the child hygiene clinics were extended to cover the whole of the first six years of life.

In addition to the system of clinics and public health nurses, various minor phases of the problem of infant and child health have received attention. Maternity hospitals and infant boarding homes were, in the early years, large contributors to the numbers of deaths of infants and young children, and their licensing and supervision by the health department was early undertaken. Within recent years the mortality of premature infants has been greatly reduced by the inauguration of special procedures designed to give these cases such care as will insure their survival and normal development.

The extension to rural areas of a system of infant hygiene service, based on infant welfare clinics, has been slow and difficult. In thickly settled suburban areas the work may be carried on as in cities, but in a rural county without a city and with a population dispersed over a large area a number of difficulties arise. There is available for service in the clinics no such supply of young pediatricians as is normally to be found in a city. The distances that must be traversed by mothers who wish to bring their babies to a clinic are so much greater that the question of transportation is of the utmost importance. In rural areas, also, the private physician is not accustomed to having his patients served by any outside agency and, since almost every infant is at least potentially the patient of some physician, the profession may object to the conduct of such a system of infant welfare clinics.

In spite of these obstacles, some states have made substantial progress in extending the work. In such cases, pediatricians employed by the state for whole or part-time service, conduct infant welfare stations at natural gathering places and at regular intervals. The rural public health nurses maintain contact with the mothers, securing their attendance at the clinics and helping them carry out in the home the instructions of the physician. Where such sessions can be held as often as once a month the interest and cooperation of the mothers can be maintained. Such programs are still in the developmental stage, however, and in no large rural areas are the child welfare services developed to the degree usual in the cities.

See Chapter 14 for a technical discussion of maternal and child hygiene.

**Maternal Hygiene.** The United States was one of the last of the great nations to undertake governmental procedures to reduce the morbidity and mortality incident to pregnancy and childbirth. The training of midwives has been almost totally neglected here and as a result millions of women to whom the services of a physician were not available have been delivered by ignorant "grannies" whose only training was the word-of-mouth instruction by others as ignorant as themselves. Even the training of physicians in obstetrics was, until comparatively recent times, incomplete and unsatisfactory. These conditions gave this country the unenviable distinction of an inordinately high rate of maternal mortality. Obstetricians, in caring for their private patients, early found that much was gained when their cases came to them early and were seen at regular intervals during the whole of pregnancy. Attempting to apply these principles to the whole problem of maternity hygiene led first to the

establishment of "prenatal clinics" on somewhat the same basis as the child hygiene clinic. These clinics, operated first as an experiment by voluntary organizations and later adopted by many health departments as a routine procedure, were very successful from some standpoints. The pregnant woman coming to them as soon as her condition could be recognized could be carefully examined and necessary treatment could be given and adequate preparation made for the delivery. Even the best service of such clinics, however, could not prevent the unfortunate consequences of a hurried, clumsy or dirty delivery. It then became evident that in the cities, at least, the mothers unable to employ a private physician must be given not only supervision during pregnancy, but also a satisfactory delivery. This can sometimes be furnished in the home but, in general, it has been found cheaper and better to care for these cases in a maternity hospital.

The system of maternity hygiene in a well-organized health department thus includes a service for registering women in the very earliest months of pregnancy; a system of prenatal clinics, held at easily accessible points with sessions at convenient hours, to provide supervision during the whole of pregnancy; and, finally, a delivery preferably in a hospital at public expense. Such a system must be able to serve one fourth or even one third of all the births in an average city.

In rural populations where the economic level is low and the service of a physician difficult to secure, the conduct of successful procedures for the improvement of the hygiene of maternity is considerably more difficult than in the cities. In some counties, as yet largely on an experimental basis, the health department contracts with the private physician for the delivery of indigent cases for a fixed fee and requires the physician to render efficient prenatal service. In other rural areas, however, the shortage of physicians makes this procedure impracticable, and the only thing possible is to endeavor to improve the service of the midwives who must still deliver a large proportion of the babies. Under such circumstances as these the health department must, if possible, operate prenatal clinics to serve all the cases of these midwives. It may also require them to provide the midwives themselves with at least a minimum of equipment and, through nursing supervision, to improve the quality of their work.

In certain rural areas, health departments are experimenting with a plan in which nursing service is provided the patient at the time of delivery by the private physician. A still further demonstration is that of the Frontier Nursing Service in the mountains of Kentucky. The population of the area reached by this Service is so isolated by the character of the terrain and its economic status is so low that the practice of medicine as generally carried on in rural areas is impossible. The Frontier Nursing Service operates a number of stations staffed by nurse midwives, most of whom have been trained in England, who themselves deliver the mountain women in their own homes. It operates a small hospital in the center of the area where complicated cases can be treated and where other serious illnesses can be cared for. This service, operating under conditions of extreme physical difficulty, has had a most satisfactory record of maternal mortality but operates at a cost per patient far beyond the resources of most rural health departments.

An interesting feature of the work of the Frontier Nursing Service is the establishment of a course of training for midwives. A similar course has been established in Alabama for the training of Negro midwives. The total number of graduates from

these courses is still too small to influence the situation notably as a whole but their establishment and survival represents a breaking down of the idea so long maintained by the medical profession of the United States that the midwife is not a necessary part of the medical picture.

See Chapter 15 for a technical discussion of maternal hygiene.

**School Health.** A necessary part of any system of compulsory education is adequate provision for protecting the health of the child while in the school. A necessary part of any school curriculum is teaching in the fundamental principles of healthful living. For these reasons the health service is a vital part of the public school system. Such health services are sometimes operated by the health departments and sometimes by the departments of education. There are advantages and disadvantages to both arrangements, and either can be made to operate satisfactorily with good will on both sides.

While the department of education has primary responsibility for the construction and maintenance of the school plant, the department of health should have opportunity to review all plans for new school buildings before contracts are let, and should make regular systematic sanitary inspections of every school building several times during each school year. The general cleanliness and state of repair of the school plant will be much improved if reports on these inspections are made to the department of education by the health officer.

Medical supervision of the child in school is of great importance. Its first purpose is to discover and, if possible, correct any condition which may interfere with the education of the child. Its further purpose is to contribute to the normal and healthy development of the child as a future citizen. An incidental purpose is to provide attention for the numerous minor ills and injuries which always develop when children gather in large numbers for any purpose.

Health supervision of the children began with an effort to have each school child examined by the school physicians at least once each year. The force available for such inspections was always inadequate and the amount of time allotted to each child was thus so short that only the most hurried inspection was possible. Large numbers of children were found, it is true, to have defects which should have been corrected. The defects so discovered were principally those of the teeth, of the nose and throat, and of the special senses. The mere discovery of these defects was, of course, without value unless facilities for their correction were at hand. This was seldom the case and the annual inspection frequently resulted only in the rediscovery of conditions previously noticed, and for which no corrective action had been taken. A large part of the time of the nurses was employed in this work and in the resulting effort to persuade parents to have the defects corrected. Where the work was conducted by the health department it was not unusual for two thirds of the working time of the nursing staff to be devoted to the school work with results of but little value.

More effective procedures have slowly been evolved and in many cities at the present time a real effort is made to shift as large a proportion as possible of the work of examining the children entering school each year to the family physician. The details of these examinations are reported to the health department on forms furnished by it. While in the beginning of such a system much of the work done by private physicians is superficial and of but little value, persistent effort will

induce them to regard the procedure as one of importance and to devote to it the time and effort necessary to a satisfactory examination. Once the child has been carefully examined by his family physician, the physician usually interests himself in securing the correction of any defects that in his opinion need attention, and the school nurse is thus relieved of much labor. As for those children entering school whose parents will not or, for economic reasons, cannot have them examined by the family physician, they must be examined by the school physician. The number of these is not so great but that they may be given a careful and effective examination. Having entered the school under this system, a child is then not re-examined until ready to enter high school unless his teacher observes some indication of a need for special examination, in which case such an examination is promptly made.

It is necessary also to establish a routine for the handling of children who become sick during school hours or who receive minor injuries. These matters are usually taken care of by the school nurse. The decline in the prevalence and in the seriousness of the communicable diseases of childhood has much diminished the load of service formerly required of the school physicians and nurses for their control, and the restrictions put upon other children from homes in which such diseases occur have been much relaxed. Still further relaxation in the future is probable. At the present time the communicable diseases which give the school and health authorities most concern are pediculosis and scabies.

The education of the child in the principles and habits of health is, of course, fundamentally the responsibility of the educational authorities. For a variety of reasons only rarely is it well done at present. The principles of healthy living are not easily reducible to simple statements which can be given the child to memorize. On the other hand, the scientific training of teachers in the elementary schools is not usually sufficiently broad to enable them to make the fundamental principles of the subject at once plain and attractive to children. Progress is being made in this regard, however, and it is to be hoped that the children of future generations will govern their lives more on scientific principles and less on hereditary fables and folklore.

See Chapter 17 for a technical discussion of school health.

**Services for the Physically Handicapped.** Many state health departments, recognizing the very serious problem of crippling conditions, established crippled children's divisions or orthopedic divisions, the purpose of which was to obtain information concerning the prevalence of crippling conditions and to provide some services for the rehabilitation of the physically handicapped. These services developed to the level of a major division of the state health department in only a few states prior to the stimulus that came from the enactment of the Social Security Act and the provision of federal grants through the Children's Bureau. Under this stimulus, there has been a very rapid development of state and local services for crippled children in which reporting has been greatly increased and registers of crippled children have been set up in many states. Under the provisions established as conditional for the receipt of federal aid, well-organized and efficient programs of rehabilitation of the physically handicapped have developed. Not all of the crippled children's services are located in health departments. Some are in welfare departments, some are in departments of education and some are independent com-

missions. Under these programs, provision is made for the necessary medical and hospital care for the correction of physical defects in children and for vocational training.

The organizational pattern most frequently found in state health departments is a division or a subdivision within the Bureau of Medical Services, not infrequently headed by an orthopedic surgeon, although there is a growing tendency to place general medical administrators at the head of these units. The staff of these divisions consists of orthopedic nurses, medical social workers and physical therapists. Orthopedic or plastic surgery is usually contracted for in existing medical facilities in the community. By far the majority of physically handicaps cared for under these programs are due to orthopedic disabilities. In recent years, the program of the crippled children's divisions has broadened in scope and has included such crippling conditions as rheumatic heart disease and cleft palate.

See Chapter 18 for a technical discussion of services for the physically handicapped.

**Public Health Nursing.** The division of public health nursing may be in the general grouping of medical services or it may be assigned to local health administration. Public health nursing is a service division which touches upon every activity of the health department. This division not infrequently represents more than half of the personnel of the health department. There is almost complete agreement at the present time that public health nursing services should be generalized insofar as possible and that an individual nurse not be assigned to any specific type of activity except in a consultative capacity, but that the staff nurse be assigned to a geographical area and carry out when possible all of the nursing functions for the population of that area. In determining the size of the area it has been generally found that a nurse can provide the services required by a population of approximately 5,000 people. It is, therefore, desirable to have at least one nurse per 5,000 of the population to be served. The nursing service is under the general supervision of the health officer but adequate supervision should be provided. One supervising nurse to 6 to 10 staff nurses is necessary if adequate supervision is to be provided. The activities of the public health nurse include home visiting to cases of communicable diseases, including tuberculosis and usually venereal diseases, at which time she plays a very important role in education of the family and in training members of the family to adequately care for the sick individual. In the maternal hygiene service the nurse plays an extremely important role, keeping in close touch with the expectant mother, particularly in the latter weeks of pregnancy, and not infrequently carrying out under supervision such technical procedures as taking blood pressures and doing urinalyses. In the child hygiene program she not only assists at the well-child conferences but through home visiting maintains a continuous contact with the family, assists the mother in the care and feeding of infants, and maintains the continuity of contact between the health department and the child. It is largely through her efforts that a high level of immunity to smallpox and diphtheria is maintained in the community. In the generalized service, the nurse also has important responsibility in the school health program, assisting in examinations and, through her periodic conferences with teachers, screens out those children requiring further medical attention.

The public health nurse is also in a particularly advantageous position to assist

in the mental hygiene program. She is the member of the health department team most apt to be in a position to detect emotional disturbances or mental illness at an early stage and, if she is alert to this possibility, she may serve as a most effective screen for those individuals requiring further attention or clinic treatment. As health departments undertake more and more activity in the field of chronic diseases, there is particular need for bedside nursing care. In many communities voluntary nursing associations have traditionally provided this service and many have assisted in the routine public health nursing services. There is growing interest in a combination of the official public health nursing services and the voluntary bedside nursing programs. In a number of cities, apparently happy integrations have been effected in which these two services have been merged, making possible a more efficient utilization of the nurses in both organizations. If a complete bedside nursing program is to be undertaken, it is estimated that one nurse to 2,000 or to 2,500 of the population will be required. With the increasing importance of chronic diseases as a public health problem, there seems to be a growing need for this type of service which can probably be best provided in those communities where visiting nurse services are already established through such a merger.

**Mental Hygiene.** Mental hygiene is one of the more recent additions to the program of health departments. Until recently, mental illness was considered primarily a problem for hospital care and, unfortunately, usually only custodial care. With the growing recognition of the possibilities of prevention of emotional or mental disturbances, and with the increased recognition of minor disturbances and behavior problems, there has been a proportionately increasing demand that provision be made for the care of these cases. State hospital systems have been loathe to undertake this program and, because of the possibility of prevention in many types of emotional or mental disturbances, health departments have been urged to undertake this program. There are some very good reasons that can be put forward for the placing of this responsibility upon the health department. In the first place, members of the staff of the health department have broad contacts with the population, coming in contact through various clinical activities and through the nurses' home contacts with a significant proportion of the population. Furthermore, many of the behavior problems which require attention occur in preschool and school children, the physical well-being of many of whom is already the responsibility of the health department. Moreover, the health department represents the only medically oriented group in most governmental units. While it is true that most health officers are not qualified in psychiatry and few public health nurses have had training in mental hygiene, they have had basic training which would make the development of these additional skills feasible. Also, it has been traditional in health departments to seek specially qualified personnel for special activities. The establishment of mental hygiene clinics, under the direction of competent psychiatrists, psychologists and other necessary technical personnel, within the general administrative structure of the health department is not an unfamiliar pattern. It is also apparent that the mere establishment of a clinic is not all that is necessary. The social structure of the community must provide for the screening of those individuals who require this service from the general population. This can be done in the well-child clinics by properly oriented staff, by public health nurses who have had some training in mental hygiene, by school teachers, school psy-

chologists, and practicing physicians who are accustomed to working closely with the health department. The extent to which mental hygiene services may be needed in a community is not well known as yet. There is great need for further study of the extent of the problem and of the effectiveness of proposed methods of dealing with these problems. This cannot be done in a vacuum; carefully organized and operated programs in health departments may well help to answer these perplexing questions.

See Chapter 20 for a technical discussion of mental health.

**Adult Hygiene.** The reduction in morbidity and mortality which has been so encouraging in the past 50 years in the United States has been largely due to the reduction in infectious diseases and in the reduction in infant mortality. This has resulted in a change in the most important causes of death, a general aging of the population, and an actual increase in crude death rates from such diseases as diabetes, cancer and heart disease. There are differences of opinion as to whether these increases are actual or whether they are the result of better diagnosis. In either case, the fact still remains that these diseases are the most important causes of death and that if continued progress is to be made in the reduction of mortality these are the fields which must be given attention. Unfortunately, we have no simple preventive measure for any of these chronic diseases of middle and old age. In the light of present knowledge, the only approach possible is through early detection and adequate treatment. The idea of periodic physical examinations advocated so strenuously has not proved particularly effective, nor is it feasible for most of the population. Either the examination is so extensive and time consuming and requires so many laboratory tests as to be extremely expensive, or it is so inadequate as to be almost valueless. Education has been put forward as the only effective means of approaching the problem and there can be no doubt that well-planned and intensive educational campaigns which emphasize the importance of early diagnosis and point out both the danger signals and the necessity for medical attention when these are present, have a place in any program directed toward these diseases. Recently, hope has been raised that simple inexpensive screening methods for the early detection of at least some of these chronic disease problems will be developed; a promising example is the use of the small chest x-ray for the detection of lung cancer and certain types of heart disease. Simple laboratory tests for the detection of diabetes and, perhaps, other metabolic diseases seem to be within the realm of possibility. New and simple laboratory technics for the detection of uterine cancer and possibly small-film gastric x-rays for the detection of gastric cancer at an early stage also offer promise. None of these screening tests has as yet been adequately evaluated but carefully controlled studies by health departments seem to be indicated.

Industrial hygiene activities have developed along several different lines. In some states industrial hygiene has been a function of the labor department, where it was developed largely as a program directed toward the elimination of occupational hazards and the provision of general hygienic working conditions in industry. In recent years there has been a general tendency to broaden the scope of industrial hygiene to provide general health supervision for employed persons. In this broad sense it is a logical activity of the health department and one for which the health

department is probably the government agency best prepared to render this service. The program of industrial hygiene within a health department should include, in addition to the measures necessary for the prevention of specific occupational hazards, the promotion of a general health program for industrial workers. This general health program should cover general sanitation of industrial plants with proper attention to lighting, ventilation and other general conditions of housing; and, more important, it should promote pre-employment examination with work assignment in accordance with physical findings, a general medical and nursing service which would provide for correction of physical defects, and a program of public health education. Such a program would benefit not only the worker himself but also his family. In setting up such a program the staff should include a physician, an engineer, a chemist, and nursing service adequate for the population to be served.

See Chapter 19 for a technical discussion of adult hygiene.

**Hospital and Medical Care.** In recent years, health departments have assumed greater responsibilities in the field of hospital service and medical care. Particularly as a result of the Hill-Burton Act in 1946, state health departments were given the responsibility for surveying and planning for hospital facilities throughout the state. Also as a prerequisite for receiving federal funds for hospital construction the states were required to set up hospital licensure programs. This involved the review of existing hospital facilities, the establishment of standards for licensure and a continuing program of hospital inspection. State health departments were also given the responsibility of administering under advisory boards the funds made available to the state for hospital construction. As chronic disease programs have developed in state health departments, an important part of these programs in many states has been the development of chronic disease hospitals, again adding to the responsibilities in hospital administration already carried by the health department. In some states and cities the health department has been charged with administering programs of medical care for the indigent. Such programs usually involve the health department only in the administration of the program through contracts with existing medical facilities, such as hospitals and clinics, and with practicing physicians.

**Other Activities of State Health Departments.** The recognition of the importance of accidents, particularly home accidents, as a cause of death has stimulated the development of active programs of accident prevention in a number of state health departments. These activities may take the form of general education, as a part of the health education program, calling attention to the importance of accidents as a cause of death and disability and pointing out the factors involved in accident production. In other programs, inservice training for all health department personnel has been carried out with the idea that education in accident prevention shall become a routine part of the program of both public health nurse and sanitary inspector.

The importance of nutrition in the promotion of health has also been recognized as a field for possible health department influence. Here again, education is one of the best known approaches to the problem, although in some health departments provision has been made for clinical examination for the detection of malnutrition.

## THE BUREAU OF LOCAL HEALTH ADMINISTRATION

The function of a bureau of local health administration depends somewhat upon the organization of the state. In a few states the area of the state has been broken up into districts headed by a district health officer who is a full-time employee of the state health department and serves as a representative of the state health officer in dealing with local health departments. His function is to stimulate more adequate local health services and to serve as an advisor or consultant to local health officers or other local personnel. This method resulted in improvement wherever it was used but there is general agreement that the development of municipal and county health departments, with a reasonable degree of autonomy, is a more effective method of providing local health services. The bureau of local health administration is the unit of the state government which maintains general supervision over the activities of these more or less autonomous local health services, establishing minimal standards of operation in accordance with state law and providing advisory and consultation services to the local health units. In most states the bureau of local health administration is responsible for the administration of the program of state aid to local communities for health services. In a number of states the responsibility for recruitment and training of public health personnel for the state and local communities rests with the bureau of local health administration.

**Public Health Education.** No health program can be effective unless it can be brought to the people who need it and is acceptable to them. This depends upon an understanding of the basic principles of preventive medicine by the people who are to be served. The health department, therefore, must bend every effort to educate the population in the need for preventive services in order that they will seek them. Education of the public is not easy. It should begin in childhood; thus, an effective program of health education should be a part of every school system. In addition, adult education is necessary and is usually the field in which the health department plays the most important role. The health educator should be skilled in educational techniques and should be adept at community organization in order to make possible the most effective and most economical dissemination of health information. He may use all of the various media of communication, including the newspapers, the radio, motion pictures, and television, to the fullest extent. However, every member of the staff of the health department is in a position to assist in a program of health education. The public health nurse in her daily duties is doing one of the most effective educational jobs conceivable. The sanitarian in his regular visits has an opportunity to reach many people in a most effective way. The health officer himself has very definite responsibilities for general public education.

**Dental Health.** The frequency with which dental caries is found in young adults and adolescents clearly indicates the need for a preventive program which would, if possible, prevent these occurrences and the eventual loss of teeth. For many years the major emphasis was placed upon the cleaning of teeth and the slogan "a clean tooth never decays" was widely used. It is now generally agreed that this is not a sound basis for the development of a dental hygiene program. During the past 15 years there has been a tendency to discard this point of view and to attempt to provide actual preventive dental care, recognizing that early correction of defects in enamel will arrest caries. Education in nutrition has also been

Prepared by Dr. W. J. French, Health Officer, Anne Arundel County, Maryland.

Fig. 48-2. State department of health and county government.

emphasized as part of a dental hygiene program. The fairly recent evidence of the value of topical application of sodium fluoride in the prevention of dental caries has completely revolutionized the dental hygiene program of health departments. The fluoridation of water supplies deficient in this element also offers very real promise of a mass approach to improvement in dental health.

**Public Health Laboratory Service.** Public health laboratory services are among the oldest functions of a health department. Most state health departments maintain laboratories which provide various types of service, including bacteriological diagnosis, serological testing and chemical testing. Some health departments also maintain biological laboratories for the production of standard biologicals for the prevention and treatment of diseases of public health significance. The diagnostic laboratories of a state health department should be staffed by competent bacteriologists and serologists prepared to carry out all of the standard laboratory tests of value in the diagnosis of communicable diseases. The chemical laboratories carry out standard chemical tests on water supplies, and milk and food examinations. Depending upon the size of the state, the central state laboratory may serve the entire state with the provision of an adequate mailing system. More frequently, however, branch laboratories under the supervision of the director of the state laboratories are established in strategic positions throughout the state, providing service for specified areas in which they are located. In a few states, instead of, or in addition to, the state laboratory and the branch laboratories, there is a system of approval of local laboratories for certain procedures of public health importance. This approval may be based upon an elaborate system of testing the quality of the work done in the laboratories or it may be based primarily upon the qualifications required for the directors of these laboratories.

## LOCAL HEALTH SERVICES

## MUNICIPAL HEALTH ADMINISTRATION

Municipalities are secondary governmental units resulting from the incorporation of certain areas within the primary governmental unit, the state. The state is the sovereign power, but municipalities are granted certain powers and privileges, usually by special charter from the state. Municipalities are given varying degrees of autonomy by the state government, from almost complete autonomy, as in the case of New York City, Baltimore, San Francisco and a few other major cities, to a directly subordinate position of the smaller cities within a state. The health organization in a given city is determined very largely by two factors: (1) the degree of autonomy granted to the city by the state government, and (2) the per capita wealth or the per capita tax income of the municipality. It is impossible to describe a typical municipal health department because the health organization of any municipality depends upon so many different factors. There are however certain basic functions of a municipal health department.

The modern city must render effectively a wide variety of services if the health of its people is to be preserved. In the United States, city governments present many interesting differences but these differences are manifested mainly in the forms of organization of their legislative and executive branches or of administrative organization. However, in the operation of their service departments they are strikingly alike. The average city government has certain specific functions to perform. These include the maintenance of public works and the development of public services such as education, welfare, safety and health. There are usually a number of departments of government created to carry on the necessary activities of a city government, depending somewhat upon the size of the community. In the larger cities these functions may be minutely subdivided, whereas in the smaller cities they may be combined into not more than two or three major branches of the city government. Many of the branches of the city government have some bearing upon the health of the community. The department of public works is usually responsible for the construction and maintenance of the physical facilities maintained by the city government, such as streets, sewers, parks, public buildings, etc. The development of an adequate, basic source of water for a municipality is not infrequently the responsibility of a department of public works or a similar municipal authority. The basic planning for such a water supply and the development of the necessary physical facilities for the maintenance of an adequate water supply are not infrequently entrusted to a branch of the city government not primarily concerned with the public health aspects of this supply.

The department of education is usually a separate agency whose primary purpose is the maintenance of a sound educational structure in which the maintenance of the health of the school child may or may not be of major concern. In many cities the department of education maintains a separate and autonomous health service whose purpose is to maintain the facilities to promote the health of school children. In other municipalities the health services for the school child are a responsibility of the department of health working closely in cooperation with the department of education.

In many cities the development and operation of public hospitals and the maintenance of health and medical services for the indigent are a responsibility of a department of welfare. There is a growing tendency to separate the strictly medical aspects of the welfare program and assign these responsibilities to the official health agency.

The police department is charged with the responsibility of maintaining an adequate program of law enforcement which includes the enforcement of public health law and sanitary code regulations. As the program of accident prevention has progressed, the police department plays an extremely important role in the prevention of accidents, particularly traffic accidents. The fire department is a major department in most municipal governments and has certain responsibilities in the maintenance of health and the prevention of death and disability from fire and fire hazards. Within recent years there has been a general tendency to create within municipal health departments an active program of accident prevention in which the police department is primarily responsible for the development of a program for prevention of traffic accidents, the fire department for the program of prevention of certain types of accidents, and the health department for the prevention of home accidents, as a rule in close cooperation with these other departments.

The health department is usually responsible for those activities which are primarily designed to protect or promote the public health. It is the responsibility of the health department to coordinate and integrate the health activities of other municipal agencies in order to provide a well-rounded and well-integrated program. The health department is usually a major subdivision of the city government and is responsible directly to the mayor or city manager or other executive officer. Historically, the earliest form of municipal health agency was the "board of health." At first this municipal health organization consisted only of a group of physicians or other public-spirited citizens called together in time of epidemic to advise the city fathers how to prevent the introduction or spread of communicable diseases. Gradually this temporary, relatively unorganized function developed into a permanent municipal organization maintaining regular services and functions which include environmental sanitation, the prevention and control of communicable diseases, the prevention and elimination of nuisances and the supervision of establishments for the production, distribution, and serving of food. Early in the development of municipal health organizations one of the most important activities was the supervision of the methods of disposal of garbage and other refuse. In the early history of the municipal health departments these environmental safeguards were considered to be of primary importance and the staff of municipal health

departments consisted mainly of vaccinators, quarantine officers and sanitary inspectors.

As the relative importance of environmental sanitation and quarantine procedures was recognized to be secondary, toward the end of the nineteenth century municipal health departments embarked upon a program of personal and community health. They placed increasing emphasis upon the clinical aspects of disease prevention and upon the detection and treatment of tuberculosis, the venereal diseases and the acute communicable diseases. At the same time, with awareness of the extent of maternal and infant mortality, they developed more and more elaborate programs of maternal and child hygiene. The first quarter of the twentieth century was a period of rapid development of preventive medical services on a community basis, particularly for the younger age groups of the community. It was during this period that the programs of maternal and child health were most rapidly expanded. In many municipal health departments from 50 to 75 per cent of the resources of the department were devoted to prenatal and postnatal health services, the development of a program of well-baby clinics and the development of school health services.

There can be little doubt that this phase of health department activities contributed greatly to the reduction in morbidity and mortality from the diseases associated with childbearing and the diseases of infancy in early life. The marked reduction in morbidity and mortality in childhood, youth and middle age has increased the relative importance of the diseases and disabilities of old age and, at the same time, has caused a significant change in the age distribution of the population. This has quite naturally resulted in a markedly changed emphasis in municipal health activities.

The position of the city health officer is today a highly important one. It demands possession not only of detailed and accurate scientific knowledge but also a high degree of administrative skill. The health officer is almost always a graduate in medicine and is more and more commonly required to have special training in public health and preventive medicine before he is permitted to assume his duties as a city health officer. He is given wide authority and at his discretion may perform acts which are possible to no other agent of the government. The personnel of a city health department includes individuals with many types of skills and training. In addition to the health officer, there are many other medical men with experience and training in administration and in the various specialties of medicine. In the larger organizations many of these will be specialists in public health and preventive medicine and will limit their practice to this field. Others serve the department of health in a part-time capacity, devoting the remainder of their time to private practice. The professional personnel participating in a municipal health program may include dentists, veterinarians, sanitary engineers, statisticians, chemists, bacteriologists and educators. The largest professional group in the health department is the public health nursing group. In most municipal health departments the public health nurses constitute approximately one half of the total staff. Another important component of a health department staff is made up of sanitary inspectors under the supervision of trained sanitary engineers. In the larger cities, public health laboratories are maintained which include bacteriologists, chemists and a wide range of specialists in diagnostic procedures. In some of the very large cities, there are

divisions of research which have carried on more or less elaborate programs of research in the communicable diseases and other phases of public health activity. In a few cities, biological laboratories are maintained for the production of certain types of biological products important in the maintenance of the public health.

The size of the staff of a city health department depends primarily upon the size of the population to be served. There are certain basic standards which have been established for the various types of health department personnel. It is generally recognized that at least one medically trained staff member is required for each 50,000 of the population, at least one public health nurse for each 5,000 and one sanitarian for each 10,000 to 15,000 under the adequate supervision of a sanitary engineering division, with sufficient specialized medical personnel to meet the clinical needs of the community based on the prevalence of such diseases as tuberculosis and venereal diseases, and on the general economic status of the community.

If the personnel employed by a municipal health department is to effectively carry out the functions assigned to it, there must be adequate provision for organization and supervision of the many and varied professional skills. This organization must bring together a group of health workers having widely varied training and experience and integrate this program into a co-ordinate whole. The executive officer of a municipal health department is responsible for the development of a well-organized and a well-rounded program of services in many specialized fields of health activity. Professional and technical personnel must be employed and trained, and facilities must be supplied for the efficient operation of many types of activities. In the plan of organization provision must be made for all types of services, and competent business management must be provided to assure efficient operation. In a municipal health department these activities are usually under the immediate direction of the health officer. Also under the immediate direction of the municipal health officer are certain generalized services necessary for the efficient planning and operation of a municipal health department. These include such activities as the collection and dissemination of vital statistics, the maintenance of adequate laboratory facilities for the diagnosis of infectious diseases, the distribution of necessary biological products, the maintenance of the necessary relationships with other municipal departments, and satisfactory public relations.

The city health department provides direct services to the population under basic guiding principles established by the state. The service organization of the municipal health department depends to a great degree upon the size of the city. The organizational pattern is based upon the various types of skills required in rendering direct service. Environmental control in all except the smallest cities is under the direction of a sanitary engineer, with a staff of subprofessional personnel carrying out the various inspection services to maintain adequate sanitary precautions. The clinical services in the smaller cities are under the direction of the health officer himself and in the larger cities, there are varying degrees of specialization. Depending upon the size of the city, there may be a division of communicable disease control which may include tuberculosis and venereal disease control, or these two latter programs may be in separate divisions. Again, in the larger cities maternal and child health may be set up as a divisional activity whereas in the smaller cities these may come under the direct supervision of the medical officer of health. Nursing services are almost without exception under the direction of a

supervisor of nurses and, at the present time, with very few exceptions, this is a generalized service covering all branches of the health department's activity.

Statistical services in a municipal health department may be extensive or very limited, depending upon the size of the community and upon the public health laws of the state. Usually, in the very large cities, there is a division of vital statistics which maintains a system of recording births, deaths, marriages and divorces, reporting to the state health department. In smaller cities, there is usually a local registrar who receives at least birth and death certificates and transmits these to the state health department, maintaining little or no provision for analysis. Municipal health departments vary considerably in the provision of laboratory services. In the larger cities, complete diagnostic service may be offered by the city laboratory, and there may be provision for the distribution, if not the production, of biological products. Medium-sized cities not infrequently maintain a branch laboratory of the state health department, and in the smaller cities reliance is placed upon the state laboratory for all except the simplest laboratory procedures. In recent years, there has been a growing tendency for city health departments as well as other levels of public health administration to develop programs in the field of chronic diseases. These services may include cancer detection clinics, cardiac classification services, diabetic clinics and, with increasing frequency, the so-called multiphasic screening programs. In a few cities, chronic disease hospitals have been established for the provision of institutional care for the chronically ill. In a limited number of municipalities the provision of medical care for the indigent has been made a responsibility of the municipal health department.

The size and complexity of the organization of these activities in any health department depend upon its resources and vary, in general, directly with the size of the city. In the smaller cities the organization is comparatively simple, while in a great metropolis it becomes exceedingly complex. In the large cities, the problems of organization are complicated not only by the number and the diversity of personnel and of function but by the factor of geography. The distances to be traversed by physicians, nurses and inspectors reporting for duty and then proceeding to their fields of work, the mass of records to be kept in the central office, and the isolation from the actual field activities of the principal executives of the department, all become serious obstacles to effective and economical operation. To meet these conditions, some of the larger cities in the United States have set up a system of decentralization. A large city is thus divided into districts of appropriate areas with populations varying from 100,000 to 300,000 persons. Each district becomes in a sense the health department serving the population of the district with its own health officer and its own staff. This district staff works under the general control of the central office which is responsible for the development of general policy, while the district staff is responsible for the provision of direct services. There are certain services which do not lend themselves readily to decentralization. For example, milk sanitation in a large municipality requires a field inspection program in rural areas and a highly technical service for the inspection and approval of pasteurization plants which not infrequently serve the entire city. Supervision of water supplies and sewage disposal systems do not readily adapt themselves to decentralization. Even in the acute communicable diseases, there are certain difficulties in delegating authority to a local district, in that an epidemic may be city wide or may

not recognize district lines. Service programs which include maternal and child health, public health nursing, restaurant sanitation, health education and chronic disease programs do, however, lend themselves readily to a program of decentralization with administrative authority in the district health office. The age-old problem of line and staff relationships not infrequently makes decentralization a serious problem in many cities but the advantages of the development of a feeling of community pride in its health program and the possibility of community organization on a district level make this type of organization desirable in all except the smaller cities.

With the increase in clinical activities in the health department, there is a need to bring these clinical facilities to the people. This has been done through the development of a network of clinics throughout the city. With decentralization, there were many advantages in the creation of a health center. This health center may become a community center which houses the district administration and the clinical services and serves for general community organization. Health centers should be located at strategic points throughout the city, with consideration given to the location of the population having the greatest need for the service of the health department, and with due attention to lines of transportation. The number of health districts per unit of population depends upon the density of the population. In some cities, there may be need for one health center per 50,000 to 75,000 of population, whereas in a city such as New York City a health center may serve a population of from 200,000 to 300,000 people.

Health centers must be designed to meet the specific needs of the area to be served. Adequate space and functionally planned clinics to provide all of the direct personal services of the health department are extremely important. Another important consideration is the housing of closely related services. It has been found of great advantage to provide space in the district health center for certain non-official agencies, such as the visiting nurses service and certain of the voluntary health agencies dealing with specific diseases, such as the tuberculosis association and cancer and heart societies, etc. The close proximity of these agencies to the official health agency tends to produce much closer and much more effective working relationships.

There is a growing tendency for municipal health work to be supported jointly by municipal appropriations, state aid and, indirectly, federal aid to local health services. This is a natural tendency with the concentration of the taxing power in the state and federal governments. Not many years ago a per capita expenditure of \$1.00 was considered reasonably adequate, but with the general inflationary tendencies in the United States and with the rather general expansion of the scope of health services, per capita costs have gone up. Two and a half dollars per capita has been reached by a number of cities exclusive of any hospital costs and these costs are still rising and approaching \$3.00 per capita in some cities.

### RURAL HEALTH ADMINISTRATION

Rural health services have developed slowly in the United States in spite of the fact that local boards of health have been in existence in certain states for more than 150 years. One of the obstacles has been the lack of uniformity in local

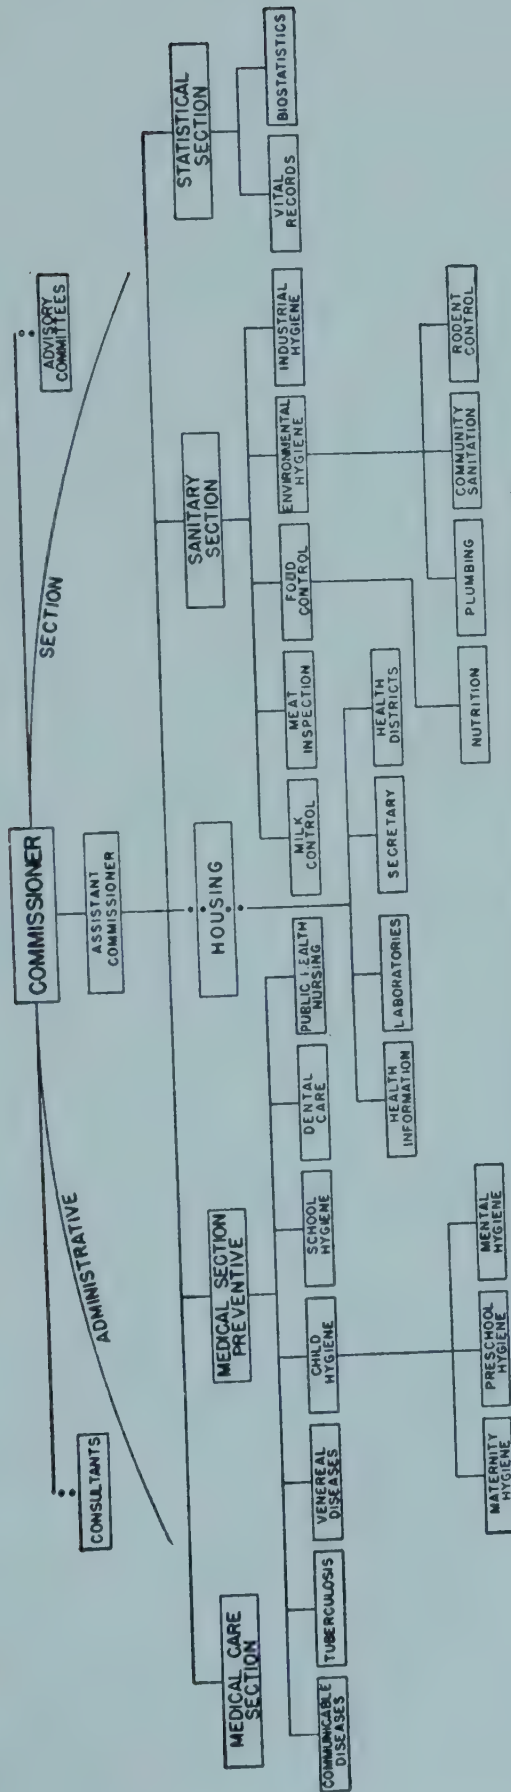

Fig. 49-1. Organizational chart—Baltimore City Health Department.

political subdivisions within states. In the New England States, the town, township or village has been the important unit of local government whereas in the southern and western states, the county is the unit. It is generally recognized that full-time health services require, in most instances, a population unit approximating 50,000 persons. Most of the towns and villages and many of the counties are much smaller than this. There has been an increasing pressure for combinations of local units in order to provide adequate health facilities. This movement, however, because of local pride and other factors, has progressed very slowly. Another factor that may have been important has been the rather prevalent belief, at least until fairly recently, that rural areas were inherently healthful and that the health services recognized as necessary in urban areas were not needed in rural areas. This fallacy has been largely dispelled through the publicizing of actual morbidity and mortality statistics for these areas. Furthermore, the importance of the problem of rural health in any national program is emphasized by the proportion of the population living in rural areas. Approximately 65 per cent of the population of the United States, according to the census of 1940, resided in unincorporated or in incorporated areas of less than 50,000 population.

The first permanent county health organization was established in Yakima County, Washington, in 1911 and, like most specific movements for the improvement of the health, it was the result of a disastrous epidemic. At the present time, between one third and one half of the counties in the United States have established full-time county units and it is estimated that approximately one third of the population of the United States still does not have the benefit of even the minimal standard of rural health service. Various methods have been tried to bring local health services to rural communities, the most important and the most effective of which has been the county health department. A few states have attempted to provide rural health services through state districts in which the state health department gave a certain amount of direct service to rural communities which has been supplemented usually by county, town or village health services, particularly in the public health nursing field. It is now quite generally agreed that the minimal population which can support an adequate health service is 50,000 and efforts have been made to group counties of lesser population together as a unit. Another movement is the tendency to develop a joint health department program for cities and the surrounding rural areas.

In the organization of county health departments or multi-county district units, there are certain basic standards that are now generally accepted. Minimum requirements for efficient operation are one medical officer of health per 50,000 of population, one trained public health nurse for every 5,000 of the population if bedside nursing is not included in the program and one to every 2,000 to 3,000 of the population if bedside care is provided, one sanitarian to 10,000 to 15,000 of the population (provided there is adequate supervision from the sanitary engineering division of the state health department), and sufficient supplementary clinical personnel to meet the basic needs of the community. The program of a county health department or a county health district includes the basic services for the protection of the public health. Provision must be made for environmental sanitation with special emphasis on the safeguarding of individual water supplies and sewage disposal systems, the protection of individual and small public milk supplies, and the prevention of

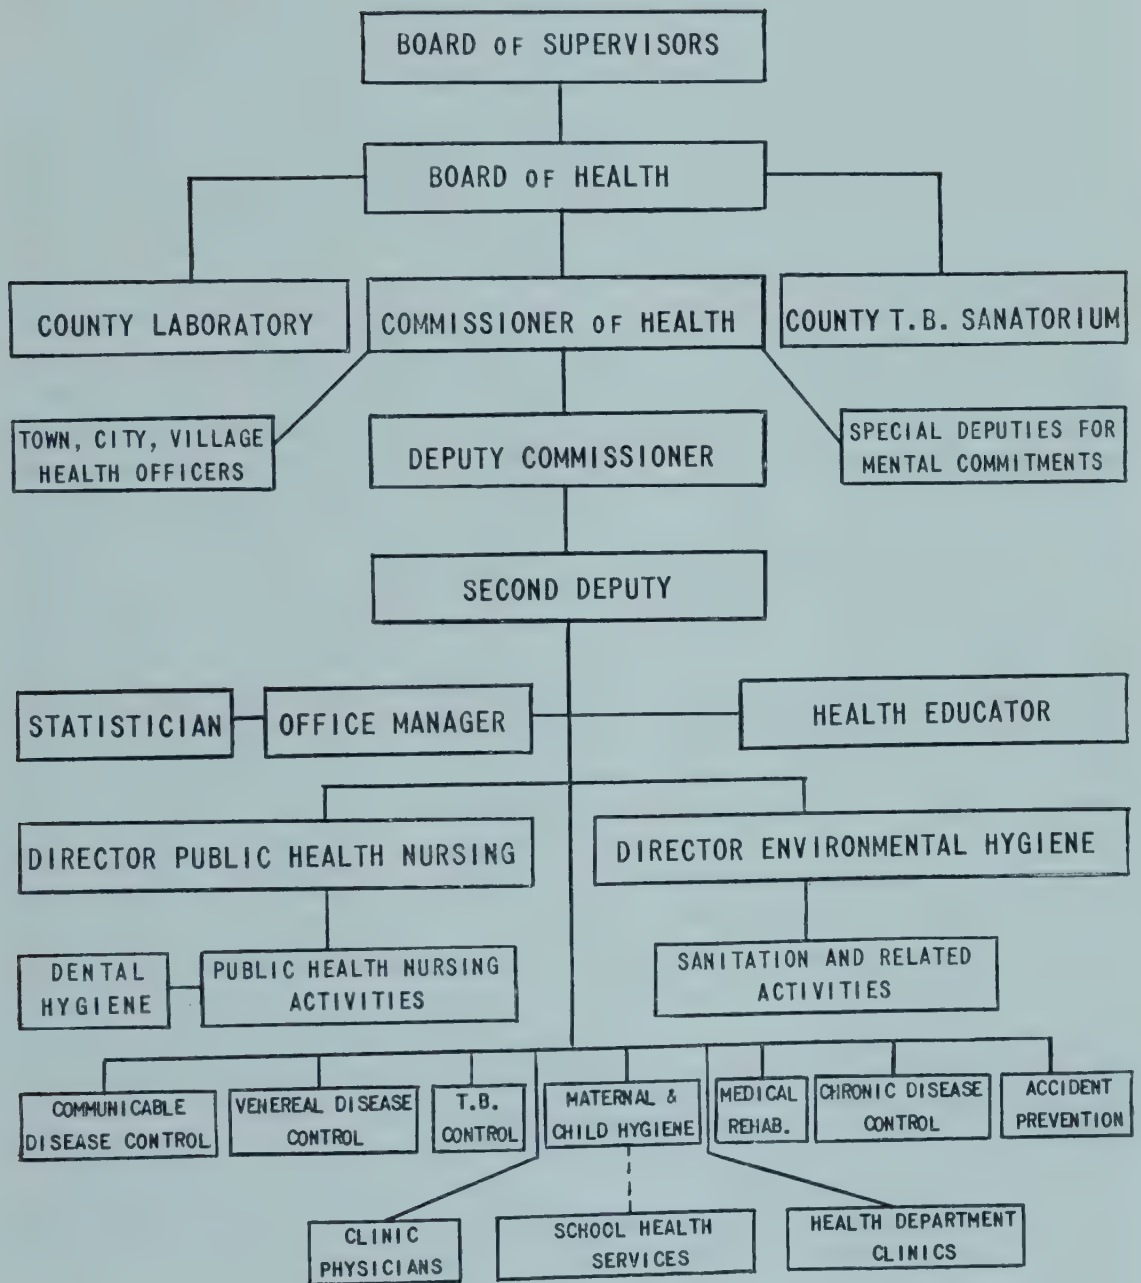

Fig. 49-2. Organizational chart—Rensselaer County Health Department, Rensselaer County, New York.

nuisances. In some communities this can be primarily an educational and consultative function; in others, such as in the southern United States, an active program to develop safe and protected individual water supplies and the building of sanitary privies is an important activity. In communicable disease control, the basic principles are the same as in their application in urban communities, complicated only by the distances to be traveled. The requirements of the county in the program of tuberculosis control, venereal diseases control, and adult hygiene, as well as maternal and child hygiene, include the provision of clinical services adequate for the population. This may involve either the establishment of small rural health centers or, under certain circumstances, traveling clinics.

The health department designed to serve a county should be an integral part of the county government and the county should contribute to its support. County government in the United States has traditionally been carried on by boards of commissioners or supervisors and there is seldom any real executive authority under which the health department may operate. It is usually advisable, therefore, to create a county board of health under whose supervision the health department may be placed. Such a board should not be given any executive or administrative powers that might hamper the health officer in the conduct of his work. As in all other fields of health activity, every effort should be made to remove the health department insofar as possible from partisan political influence. Since county government is usually supported by taxes levied on real property and since real property no longer constitutes the principal form of national wealth, it is exceedingly difficult for the counties to finance the expanding programs of social service of which health is such an important part. It becomes necessary, therefore, for the states to use their taxing powers to supplement those of the counties and to contribute to the support of these services. The federal government may also use its taxing powers and contribute funds to the states for these purposes.

Various inducements have been offered to stimulate the development of county health departments. Almost all states now make some provision for financial aid to county health programs. The amount of state aid varies very widely and is not infrequently on a graduated scale, giving the greatest support to the counties least able to maintain an adequate county health service from local funds. The per capita cost of maintaining an adequate county health program varies considerably in different parts of the United States. With the 1950 value of the dollar an expenditure of less than \$1.00 per capita would almost certainly be inadequate and an expenditure of from \$2.00 to \$2.50 per capita is not unusual.

## INTERNATIONAL HEALTH ORGANIZATION

Since ancient times, the spread of epidemic disease from country to country has shown the need for international cooperation for health protection. The great epidemics of the Middle Ages were thought to have been introduced into Europe from the East, and local or national quarantine was established in an effort to prevent the spread of plague or cholera. Venice, in 1328, established what seems to be the first formal quarantine organization for this purpose and was followed by many city states but there seemed to be no coordinated effort in this direction until 1831 when, with the threat of the reintroduction of plague through the Middle East, the Egyptian Quarantine Board was formed. This Board was made up of the consular authorities of European nations in Alexandria and served as an advisory body to the local government but had no authority and was shortlived. The repeated appearance of cholera in Moslem pilgrims to Mecca was recognized as a serious threat to Europe, and upon the insistence of a number of European nations a "Superior Health Council" was created in Turkey in 1838 consisting of four Turkish representatives and one representative of each of the major European powers. This Council established quarantine regulations and supervised shipping from Turkish ports to ports in Europe. The Council went through periods of varying activity until it was finally abolished in 1923. Similar efforts were made in various parts of eastern Europe but were for the most part temporary and stimulated only by immediate threat of introduction of epidemic disease.

The first formal International Health Conference was held in Paris in 1851. This Conference was attended by representatives of 12 nations and the first treaty dealing with sanitary conventions was drawn up and signed by the representatives attending. However, this treaty, designed to limit the spread of epidemic disease with certain limitations upon commerce, was ratified by only three nations, two of which renounced it later. This first Conference was followed by a series of similar conferences, the primary purposes of which were the drafting of international quarantine regulations.

## L'OFFICE INTERNATIONALE D'HYGIÈNE PUBLIQUE

There was, however, growing recognition of a need for a more formal and more permanent international health organization and at the Conference in Rome in 1907, approval was given for the establishment of a permanent International Health Organization with offices in Paris and with a professional secretariat. The purposes defined for such an organization were to receive notification of such diseases as plague, cholera, smallpox, typhus, and yellow fever from the partici-

pating nations and to transmit this information to the member nations through diplomatic channels. A further purpose was the study and development of sanitary conventions and quarantine regulations on shipping and train travel. In 1909, L'Office Internationale d'Hygiène Publique was established in Paris to carry out the above functions. L'Office was maintained through financial contributions made by the member states. It continued to function after a fashion until it was absorbed by the World Health Organization in 1947.

In the Americas, international health organization may be said to have been initiated by a Regional Health Conference held in Rio de Janeiro in 1887 at which Argentina, Brazil, and Uruguay approved a regional sanitary convention dealing with quarantine regulations, particularly relating to yellow fever.

### PAN AMERICAN SANITARY BUREAU

The first International Conference of American States, held in Washington in 1889 to 1890, approved of the provisions of the Rio de Janeiro convention for general application to the American states. The second Conference of American States, held in Mexico City in 1901 and 1902, authorized the establishment of an International Health Organization. This Conference adopted the following resolutions:

1. That the governments represented at this Conference shall cooperate with each other . . . towards securing and maintaining efficient and modern sanitary conditions in all their respective ports and territories to the end that quarantine restrictions may be reduced to a minimum and finally abolished.

2. That a general convention of representatives of the health organizations of the different American Republics shall be called . . . that said convention shall provide for the holding of subsequent sanitary conventions at such regular times and at such places as may be deemed best by the convention, and that it shall designate a permanent executive board to be known as the International Sanitary Bureau with permanent headquarters at Washington, D. C.

3. That the office expenses of special investigations together with those for the translation, publications, and distribution of reports shall be paid from a special fund to be created by annual appropriation by the republics represented in such convention.

As a result of this action, the first general International Sanitary Conference of the American Republics met at Washington in 1902 and organized the International Sanitary Bureau. Since that time, the Pan American Sanitary Conference has met periodically and has considered all matters pertaining to the public health within the member nations. The International Sanitary Bureau became the Pan American Sanitary Bureau in 1924 when it became a regional office of the Health Section of the League of Nations. The specified functions of the Pan American Sanitary Bureau include the following:

1. To collect and disseminate epidemiological information.
2. To act as a consulting bureau to all of the member states.
3. To improve health administration in all of the member states.
4. To promote liaison between health organizations of the member states.
5. To prevent epidemics.
6. To establish quarantine measures of a minimal nature consistent with the prevention of spread of disease.

In 1924, the Pan American Sanitary Code was drafted, establishing the Bureau as a more or less independent agency operating under the direction of the Pan

American Sanitary Conference. The Bureau is a technical international organization directly responsible to member states through technical representatives of those states. The original appropriation for the International Sanitary Bureau was \$5,000.00 per annum contributed by the various member states. Since 1924, the Bureau has grown tremendously and has undertaken increasingly important activities for the development of sound practices throughout the American Republics. On May 24, 1949, an agreement was signed between the World Health Organization and the Pan American Sanitary Bureau designating the Pan American Bureau as a regional office of the World Health Organization.

## THE HEALTH SECTION OF THE LEAGUE OF NATIONS

Considerable interest was evidenced in international health at the Paris Peace Conference and the need for a permanent operating agency in the international health field was recognized at a conference held in 1920 at which time the plan for the Health Section of the League was drawn up and adopted by the 1923 League Assembly. The Health Section was an integral part of the League of Nations and was not an autonomous agency. As set up by the League of Nations, it consisted of three major divisions: (1) a general advisory health council, made up of representatives of some 50 governments having membership in the League of Nations; (2) a standing health committee of 12 medical experts appointed as individuals and not as governmental representatives; (3) the secretariat of the Health Section, consisting of medical and health experts, not necessarily from member nations of the League of Nations, who were an integral part of the general League secretariat. The functions of the Health Section of the League of Nations consisted of the following:

1. **EPIDEMIC INTELLIGENCE.** This provided for notification of epidemic disease direct from the national health agencies to the secretariat of the Health Section and for direct communication between the secretariat and the national health authorities; thus, for the first time, epidemic disease notification did not have to pass through regular diplomatic channels. An office was maintained in the central headquarters in Geneva and an Eastern Bureau was maintained at Singapore. This gave a much more effective epidemic intelligence than had ever been developed on an international scale before.

2. **CONSULTATION SERVICE.** Consultation service was provided to all member nations upon request and a comparatively large and competent staff of consultants was developed which gave extensive service, particularly in Greece and in China. In the early years, very serious epidemics swept over a large part of Europe and the League carried on the activities of the epidemic commission. Under these auspices numerous expert committees in various epidemic disease problems were created. These special committees included commissions on malaria, smallpox, leprosy, and syphilis. These committees and commissions carried on research and planning for the control of these diseases. The importance of nutrition was recognized as a public health factor and studies were carried on in various parts of the world which stimulated interest in the improvement of general nutrition. Partly as a result of the activities of this section, a joint commission of the various sections, necessarily involved in the improvement of nutrition, was formed which carried out important studies of these problems throughout the world.

3. **INTERNATIONAL BIOLOGICAL STANDARDIZATION.** Recommendations for the creation of a laboratory for biological standardization were made and, in 1924, a permanent commission on biological standardization was established. Standardization of serums, vaccines, drugs, and vitamins was carried out in various selected laboratories throughout the world and the results of these standardizations were coordinated at the Serum Insti-

tute in Copenhagen and at the Hampstead Institute in England. The International Conference on biological standardization in 1935 set up two permanent commissions on biological and drug standardization—one for standards adopted for sera and bacterial products and one for standards for certain therapeutic substances, vitamins, and hormones. The standards established by these commissions were known as League of Nations Units. This work had a tremendous influence throughout the world in maintaining adequate and uniform standards of prophylactic and therapeutic products.

4. **EDUCATION AND TRAINING.** The Health Section embarked upon an extensive program of education and training in the health field. An extensive health and medical library was developed which was available to all nations upon request and was extensively used. The Section also developed a fellowship program providing for the training in public health of workers from all parts of the world. In addition to the support of the Rockefeller Foundation, extensive interchange of health personnel between various countries was made possible through travel fellowships.

5. **RESEARCH.** Through its expert committees and commissions the section actually carried out and stimulated extensive research in the infectious and epidemic diseases, nutrition, and health administration.

### THE UNITED NATIONS RELIEF AND REHABILITATION ADMINISTRATION

World War II created such extensive destruction of property and so completely disrupted normal activities and brought about such extensive displacement of persons, that it was early recognized that the postwar period would be fraught with great dangers, not only economic and social in nature, but also of tremendous health significance. The memory of the epidemics following World War I was still clear and the health organization developed between the two wars was almost completely destroyed. Recognizing the need for early action, the United States suggested in 1943 the development of an international relief organization. Forty-four nations met and set up the United Nations Relief and Rehabilitation Administration. Each uninvaded nation pledged 1 per cent of its national income for the year ending June, 1943, creating an initial fund of nearly two billion dollars. Extensive plans were developed for the relief of suffering in devastated countries, including the rehabilitation of medical and health services and the provision of medical supplies and facilities for epidemic control. Medical and health officers were recruited from all over the world and material and technical assistance was provided to the devastated nations to carry out extensive immunization programs and to re-establish national health services. Health missions were established in Western Europe, the Far East, Greece, and in Italy. An important activity of this administration was the handling of displaced persons in such a way as to prevent the spread of disease. UNRRA was responsible for the conference of public health experts, held in Paris in March and April of 1946, which developed plans for the international congress, held in New York in June, 1946, at which was drafted the constitution of the World Health Organization.

### WORLD HEALTH ORGANIZATION OF THE UNITED NATIONS

At the San Francisco conference in 1945, when the charter of the United Nations was drawn up, it was recognized that there should be an international health organization. In the following year, the World Health Conference in New York

drafted a constitution for the World Health Organization of the United Nations which was signed by all representatives of the nations participating. An interim commission was set up to develop the World Health Organization in accordance with the constitution, pending the necessary ratification by a sufficient number of nations. Ratifications having been obtained, the World Health Organization was formally established in September, 1948. WHO, as such, is a specialized agency of the United Nations. It is supported by the nations which ratified the constitution of the World Health Organization, regardless of their membership in the United Nations.

The purposes of the World Health Organization as defined in its constitution are:

1. To assist governments upon request in strengthening health services.
2. To promote improved standards of teaching and training in the health, medical and related professions.
3. To provide information, counsel and assistance in the field of health.
4. To promote, in cooperation with other specialized agencies where necessary, the improvement of nutrition, housing, sanitation, recreation, economic or working conditions, and other aspects of environmental hygiene.
5. To promote cooperation among scientific and professional groups which contribute to the advancement of health.
6. To promote maternal and child health and welfare, to foster the ability to live harmoniously in a changing total environment.
7. To foster activities in the field of mental health, especially those affecting the harmony of human relations.
8. To promote and conduct research in the field of health.
9. To study and report, in cooperation with other specialized agencies where necessary, administrative and social techniques affecting public and medical care from preventive and curative points of view, including hospital services and social security.

Health, as it is defined in the constitution of the World Health Organization, is "A state of complete physical, mental and social well-being and not merely the absence of disease or infirmity." As the definition of health and the stated purposes of the World Health Organization indicate, this agency undertakes international cooperation in a much broader and yet a more specific sense than any previous international health organization.

The work of the organization is carried out under the direction of the World Health Assembly, which is composed of representatives from the member states. At the present time, there are 68 member states, although the U.S.S.R., the Ukraine, Byelorussia, Bulgaria, Rumania, Albania, Czechoslovakia and Poland have signified their wish to withdraw from the organization. There being no provision in the constitution for withdrawal, they may be considered as a nonparticipating group of members of the organization.

The assembly consists of official delegations from the member states who are usually accompanied by nonvoting technical advisors. Since the establishment of the organization, the assembly has met annually but it is proposed that in the future it might meet every two years. Direction is given to the operation of the organization between meetings of the assembly by an executive committee consisting of 18 members. The administration of the organization is through a director general, a deputy director general and staff. The major subdivisions of the organization are the departments of Central Technical Services, Administration and Finance,

Advisory Services and the Regional Offices. The Department of Central Technical Services comprises divisions of epidemiology, health statistics, therapeutic substances, editorial and reference services; the Department of Administration and Finance contains a division of administrative management and personnel and the division of budget and finance; the Department of Advisory Services has divisions of communicable disease services, organization of public health services and professional and technical education. Each division is broken down into sections dealing with specific public health problems.

The first World Health Assembly agreed upon the creation of six regional organizations to carry out the detailed functions of the World Health Organization in different parts of the world. These areas were: (1) eastern Mediterranean area with headquarters in Alexandria; (2) southeast Asia with headquarters at New Delhi; (3) the Americas (the Pan American Sanitary Bureau) with headquarters in Washington; (4) Africa, (not yet organized); (5) the Western Pacific (not yet organized); and (6) it was agreed that the Geneva office should serve as a regional office for Europe.

The first World Health Assembly selected a number of projects for the program of the organization. It was decided that first consideration was to be given to diseases which lend themselves to international action, and that the program should aim at the solution of health problems which exist in large areas of the world. On this basis, the following were selected as priority fields.

1. Malaria control.
2. Tuberculosis control.
3. Venereal disease control.
4. The promotion of health by such positive means as concentration on measures aimed at improving the health of mothers and children.
5. Amelioration of environmental conditions which until now have been responsible for a significant proportion of all deaths throughout the world.
6. The improvement of nutrition, an essential condition to the betterment of health for both children and adults.

The second World Health Assembly, held in 1949, specifically emphasized the role of mental health as an important component of the world health problem and authorized the development of health demonstration areas.

The budget of the World Health Organization for the first year after the establishment of the permanent organization (1949) was five million dollars. The budget for 1950, approved by the second World Health Assembly, was \$7,500,000.00 but a program was outlined for the organization requiring the appropriation of \$17,000,000.00. This was based on the assumption that approximately \$10,500,000.00 might be raised by voluntary contributions from member states willing to participate in the development of the program in underdeveloped countries. Unfortunately, not all of the member nations have contributed the full amount budgeted.

One of the most important functions of the organization is the provision of advisory services, which consist largely of:

1. Assistance to professional and technical education through assistance to educational institutions, provision of fellowships, the exchange of scientific information, and the distribution of medical literature and teaching materials.

2. Consultation and advisory service in specialized fields to medical and related subjects as requested.

3. Demonstration projects, particularly in underdeveloped areas.

These advisory services are offered to governments through the regional staff of the organization. In order that the advisory services might have available most complete knowledge in specialized fields, a number of expert committees have been created. These expert committees, composed of outstanding individuals in specialized fields from all parts of the world, meet to consider specific disease problems and to pool all available knowledge and to consider specific questions submitted to them. These reports are made available to all member nations. Through this mechanism WHO benefits by the advice of leading specialists from all parts of the world and these experts benefit from the exchange of ideas made possible through meeting with experts from other parts of the world. The following expert committees have been appointed:

Environmental sanitation, hygiene of seafarers, which is joint with the International Labor Organization; insecticides; malaria; maternal and child health; mental health; nursing; nutrition, which is joint with the food and agricultural organization; professional and technical education; public health administration; tuberculosis and venereal disease.

Special subcommittees have been appointed to deal with certain specific questions within the field of an expert committee, as, for example, in school health, problems of prematurity, the use of streptomycin in tuberculosis, etc.

One of the most serious problems faced by national health organizations throughout the world is the shortage of trained technical personnel. The World Health Organization has undertaken to provide advice and assistance in the development of training programs in various parts of the world. Assistance has been given in the development of educational opportunities in the fields of medicine, public health, nursing, nutrition, medical social work and related sciences. An important part of the program to improve professional and technical education is through its fellowship program. This fellowship program was begun under the Interim Commission and has continued and expanded. In selecting fellows, priority is given to those individuals who will be in a position to contribute most to their respective health programs and who will further the program of education through teaching upon completion of the fellowship period. One of the most important activities of the World Health Organization is the exchange of scientific information, which is carried out through the medium of the expert committees and through specific exchange programs. In addition to this, a program of seminars on special subjects has been arranged for personnel in a group of related countries. Upon request assistance is also given to the various countries for material aid in the development of library facilities, and the exchange of medical literature and teaching materials, such as film strips, slide projectors, charts, etc.

Because of the limited resources of the World Health Organization it was decided that the organization could not undertake to provide medical supplies to countries unable to obtain these because of currency problems, except in very unusual circumstances, such as the cholera epidemic in Egypt. The World Health Organization maintains close relationships with other United Nations specialized agencies, particularly the United Nations Children's Emergency Fund. Through

an agreement with this organization the World Health Organization provides medical and technical advice and directions to specific projects financed by the United Nations International Children's Emergency Fund. Nutrition projects are handled jointly with the food and agricultural organization, and activities in the field of occupational health and the hygiene of seafarers are conducted in cooperation with the international labor organizations.

Because of financial limitations, the Executive Board of the World Health Organization has set up the following criteria for the selection of projects under the advisory services:

1. Programs established by the World Health Assembly or by the United Nations and its specialized agencies.
2. Projects recommended by expert committees.
3. Problems of importance to the whole health program of the requesting country and inability of the country itself to provide the services required as measured by the availability of trained personnel.
4. The probability of achieving successful and useful results.
5. Assurance of participation and cooperation on the part of the government throughout the program, including contributions to the program by meeting such costs within the country as can be met with domestic currency.
6. Reasonable assurance from the government, where appropriate, that the program will be continued.
7. Equitable distribution among the various countries seeking assistance when the requests exceed the available budget.

A division of therapeutic substances was established in the World Health Organization; this division includes sections on biological standardization, unification of pharmacopoeias, drugs and drug addictions and coordination of research. All of these activities call for the pooling of knowledge and experience obtained in various countries and the development of standards of control measures applicable and acceptable to all governments. The section on biological standardization continues the work initiated in 1921 by the Health Section of the League of Nations. International standards have been established for a number of biological products which have been accepted by the majority of nations throughout the world. Continuing studies are carried out as to the efficacy of various biological products and a large number of national laboratories participate in the program of standardization.

The need for standardization in the field of therapeutic substances other than biologicals has been increasingly recognized. In 1947, the Interim Commission of the World Health Organization established an expert committee charged with the responsibility "to draft an international agreement for the unification of pharmacopoeias modifying and extending the existing agreement for the unification of all the formulae for potent drugs. To present the draft agreement as an international pharmacopoeia similar in form to the present national pharmacopoeias."

This committee has worked continuously since that time and is developing the first volume of an international pharmacopoeia. This volume will include drugs of an established therapeutic value common to the various national pharmacopoeias. The rapid advances in medical science will perhaps make it difficult to define fixed standards for many of the newer drugs, but the publication of such an international pharmacopoeia will be of great value in international health work.

The section on addiction-producing drugs carries on the work which was previ-

ously the responsibility of the Health Section of the League of Nations. This section is in L'Office Internationale d'Hygiène Publique. The expert committee on addiction-producing drugs made rather extensive studies of new synthetic substances and has tested the addiction-producing character of many of these new drugs. Standardization of the nomenclature is also an interest of this section. It is interesting that alcoholism has been included in the activities of this section, alcohol being recognized as an addiction-producing substance.

The division of health statistics maintains sections on statistical studies, morbidity statistics, and the international nomenclature of disease. This division continues the epidemiological intelligence carried out by the Health Section of the League of Nations and undertook the revision of the International List of Diseases, Injuries and Causes of Death which was due in 1948. The expert committee on health statistics considers matters pertaining to uniform presentation of statistical material, the definition of terms, such as stillbirths and fetal deaths, and maintains a continuing interest in classification of disease. This section is also available for consultation services for the development of more adequate statistical services in the national health program.

### BILATERAL INTERNATIONAL HEALTH ACTIVITIES

**The Institute for Inter-American Affairs.** The United States Government has upon occasion, primarily for political reasons, given assistance to less well developed nations in the organization of a health program. As a part of what was called the "Good Neighbor Policy," the United States Government established the Institute of Inter-American Affairs in 1942 as an emergency measure to assist in the development of Latin American Nations. Under this program, health needs were recognized and a health division was established to provide assistance to Latin American Nations in the development of a more adequate health service. This has been given both as technical advice and as financial assistance on a cooperative basis. This program was approved by a conference of Ministers of Foreign Affairs of the American Republics in January, 1942.

This body resolved:

1. To recommend that the governments of the American Republics take individually, or by complementary agreements between two or more of them, appropriate steps to deal with problems of public health and sanitation by providing, in accordance with ability, raw materials, services and funds.
2. To recommend that to these ends there be utilized the technical aid and advice of the national health services of each country in cooperation with the Pan American Sanitary Bureau.

Established as a temporary organization for a five-year period, the Health Section was continued at the end of the five-year period and the organization has recently been re-established.

### THE POINT FOUR PROGRAM

In his message to the Congress of the United States in June, 1949, President Truman called attention to the need for technical assistance to underdeveloped areas of the world and proposed that the United States should offer such technical

assistance, either directly or through the United Nations. As a result of the initiative of the United States, the World Health Organization prepared a supplementary budget for 1950, and again for 1951, for the utilization of funds which might be made available under the technical assistance program. The technical assistance program is not designed primarily to improve health work but only as health may contribute to the improvement of the economic level of the area concerned. The economic and social council of the United Nations has established a technical assistance board which has been active in drawing up the terms of reference for technical assistance programs and in stimulating member states to contribute to the fund proposed by President Truman. Approximately 20 per cent of the funds for technical assistance of the United Nations has been made available to the World Health Organization for health programs. In addition to the contributions by the United States to the United Nations, considerable sums are made available for bilaterally contracted programs. Under Public Law 535, the enabling legislation for the Point Four Program, provision is made for extensive technical assistance to underdeveloped countries in the development of health programs. This program is administered by the Department of State and the Economic Co-operation Administration.

#### UNITED NATIONS INTERNATIONAL CHILDREN'S EMERGENCY FUND

The United Nations International Children's Emergency Fund, which was created in December, 1946, by the General Assembly of the United Nations, is not an autonomous technical organization as is the case with the World Health Organization. It is directly dependent upon the General Assembly of the United Nations.

During its first three years of operation, this organization was allocated \$418,000,000.00, in large part through special appropriations made by governments. These contributions have come from 43 governments in various parts of the world, 24 of which receive aid from the same organization. The initial program of U.N.I.C.E.F. was confined to supplementary feeding of children in war-devastated areas. As resources increased and the emergency needs of these countries declined, the organization extended its field of operations to other countries and to programs stressing child health and maternal and child care. Through mutual agreement the World Health Organization gives technical advice to the U.N.I.C.E.F. medical and health programs. In certain areas of the world, where medical and technical staffs are not available within the World Health Organization, U.N.I.C.E.F. has developed a technical and health program.

## THE VOLUNTARY HEALTH ORGANIZATIONS

During the past half century there has been very rapid development of voluntary health organizations in the United States. These organizations have had a marked effect upon health services. For the most part, voluntary agencies are incorporated bodies of citizens interested in the improvement of some particular phase of health service. As philanthropic organizations they are tax-free and are financed by contributions or by special fund-raising devices. Their general purpose is to augment the services rendered by the official agencies and their functions vary according to the purpose for which they were established. The most commonly encountered functions are the following:

1. Direct service in the control of some specific disease.
2. Demonstrations to stimulate interest in certain health programs with the idea that, having been demonstrated to be of value, they would be provided by the official agency.
3. Public health education in a specific or generalized field.
4. Consultation in regard to a specific disease problem.
5. Support of the official agencies.

Many of the voluntary agencies began as direct philanthropies. As an example, the settlement nursing services were established to augment and make more effective material assistance rendered to the poor. Out of this grew a preventive nursing service which has become the public health nursing services of today. In this sense, the voluntary agency was a pioneering group, demonstrating the values of public health procedures which later were taken over, in part at least, by the official agencies.

Another example of the outgrowth of a primarily philanthropic activity was the baby milk stations or the baby milk funds developed in many cities. In providing for the poor, the urgent need for milk to supplement the diet of infants was recognized and these philanthropic agencies were set up to provide a safe quality of milk to the recipients of material aid. Since babies were brought to these milk stations to obtain the milk and were observed not only to be undernourished but also greatly in need of medical supervision, nursing and, eventually, medical services were added to the baby milk stations. They were the forerunners of the well-baby clinics of the modern health department.

### CATEGORICAL ASSOCIATIONS

**The National Tuberculosis Association.** Public-spirited citizens, observing the lag in the application of knowledge, organized voluntary health agencies devoting

their attention to the prevention of specific diseases. One of the first of these was the National Tuberculosis Association. The first tuberculosis association was developed in Pennsylvania and was known as the Pennsylvania Society for the Prevention of Tuberculosis. This Society, established in 1892, was apparently a great success. In 1904, there were some 23 tuberculosis associations or societies, and a group of prominent citizens, recognizing the need for public education and public support for more adequate treatment and prevention of tuberculosis, organized the National Tuberculosis Association. This organization has stimulated the development of associations in the 48 states and in a large proportion of the counties of the states. It adopted the Christmas seal sale as a means of providing financial support early in its history and this has proved a constantly increasing source of funds. There are some 3,000 local branches and the large bulk of the income from the Christmas seal sale is retained in the local communities to support activities for the prevention and the care of tuberculosis.

**The American Social Hygiene Association.** The American Social Hygiene Association, established in 1914, was a combination of a number of national and local societies interested in the prevention of syphilis and gonorrhea and, since its establishment, has been a potent influence in rousing public interest in, and support for, official programs of venereal disease control.

**The American Society for the Control of Cancer.** In 1913, the American Society for the Control of Cancer was established with the objective "to disseminate knowledge concerning the symptoms, diagnosis, treatment and prevention of cancer, to investigate the conditions under which cancer is found and to compile statistics in regard thereto." The society carried on a very limited program until recently when it was reorganized and has undertaken, through an extensive fund-raising campaign, to provide funds for research and education for the prevention of cancer.

**The American Heart Association.** In 1933, the American Heart Association was established by a merger of a number of other agencies interested in the study and control of this major cause of death. It, too, has within recent years been reorganized and has undertaken an extensive fund-raising campaign.

**The National Foundation for Infantile Paralysis.** The National Foundation for Infantile Paralysis, established in 1938 following a series of fund-raising campaigns in connection with President Roosevelt's birthday, has become one of the most successful of the voluntary agencies directing efforts toward a specific disease.

**Other Associations.** Numerous voluntary agencies have been created in recent years for specific diseases. Among these are the American Diabetic Association and the National Multiple Sclerosis Society. Other special interests have also been recognized in the formation of voluntary agencies, such as the National Society for the Prevention of Blindness, the American Society for the Hard of Hearing, the National Dental Hygiene Association, the Planned Parenthood Federation, and various associations for crippled children and mental hygiene. Many fraternal organizations, such as Rotary, the Shriners, Kiwanis, etc., also maintain health activities, particularly for crippled children.

The American Red Cross, while not primarily a voluntary health agency, carries on many fields of activity directly or indirectly related to public health. Within recent years the development of the national blood program represents a major

activity in the field of public health. It has also traditionally carried on both public health and bedside nursing services, and has maintained an extensive home-nursing training program. It also maintains a nutrition service, first aid and water safety programs, and accident prevention service. At the present time it has been assigned extensive responsibility in relationship to the civil defense, much of which involves health services.

There can be little doubt that the voluntary health agencies in the United States have been important in the development of general health services. These agencies augment and supplement the programs of the official agencies and have continuing important functions to serve, particularly in the field of public education and in demonstration of new methods of attack upon problems of disease and disability. On the other hand, certain dangers arise with the very rapid development of more and more agencies. There is need for some method of coordination of their activities in order to avoid competition, duplication and waste. There is also need for periodic evaluation of their programs. One mechanism which has been suggested is a voluntary interchange of ideas and joint planning through health councils or associations. At the national level this is attempted through the mechanism of the National Health Council, which is itself a voluntary agency with membership consisting of the majority of the national voluntary agencies. This council stimulates the development of local health councils, made up of local representatives of national and other local agencies, for joint planning and for well-rounded services in the community.

The extent of the services provided by the voluntary agencies is indicated by the sums of money contributed each year by the people of the United States. It is estimated that the contributions in 1950 for health purposes alone was well in excess of one hundred million dollars.

## THE GREAT FOUNDATIONS

Of great importance in the development of the health field, both in the United States and at the international level, have been the great foundations.

One of the first activities of The Rockefeller Foundation in the health field was the establishment, in 1909, of the Hookworm Commission. Out of this grew an extensive health program supported by the Foundation both in this country and abroad. Through its divisions, The General Education Board, The International Health Division and The Division of Medical Sciences, support has been given to programs for the control of many diseases, for the strengthening of health services in this country and throughout the world, for the improvement of medical education and for the support of training of public health personnel, both through the establishment of schools of public health and through a fellowship program.

The Milbank Memorial Fund has stimulated and improved public health practice through numerous demonstrations in this country and has supported basic studies in nutrition and demography. In recent years the Fund has given important support to the development of international health organization.

The Commonwealth Fund has also contributed greatly to the development of rural health services through research and demonstration, has carried out an exten-

sive program of rural hospital development and has financed studies on the quality of medical care and hospital services.

The Kellogg Foundation has carried on similar activities both in the United States and abroad.

### PROFESSIONAL SOCIETIES

Various professional societies related to public health make a very direct contribution to public health administration in the United States. The American Public Health Association, through its standing committees, carries on important activities for the improvement of public health. The Committee on Research and Standards evaluates new developments in the scientific field as they relate to public health and recommends standard procedures for the operation of health services. The publication of *Standard Methods* brings together in readily available form standard procedures that have been evaluated by experts in the various fields. The Committee on Professional Education establishes recommended qualifications for public health workers and has developed and improved methods for merit system examinations. Through this committee, the Association has established an accreditation system for schools of public health and for field training areas. The Committee on Administrative Practice carries on a program of research in administration and a system of evaluation of administrative practices.

The American Medical Association, through certain of its councils, has had an important influence on the general health of the country. The Council on Medical Education and Hospitals has, over many years, stimulated improvement in medical education through its program of accreditation of medical schools and has stimulated the improvement in teaching of preventive medicine. Through its program of approval of hospitals for internship and residency this Council has had a tremendous influence on the improvement of graduate medical education and of general medical services. The Council on Pharmacy and Chemistry has carried a valuable function in the standardization of therapeutic agents and, through its control over extravagant claims for therapeutic products, serves as a safeguard against the exploitation of the public. The Council on Foods and Nutrition has made important studies in the general nutrition field and has promoted standardization, particularly of vitamin products.

The American Dental Association, through its Council on Dental Health and Dental Therapeutics, has had an influence in improving general dental care and has stimulated the development of preventive services in health departments. Through its Council on Accepted Dental Remedies it has attempted to remove the dangers from the use of harmful dental products.

The American Hospital Association, through its Commission on Education, has stimulated interest on the part of hospital administrators in the development of a well-rounded public health service centered in the hospital.

These four professional associations, through the interassociation council, carry out joint planning in the general health fields. Other professional societies also have a direct influence upon development of health services. Important among these is the National Organization for Public Health Nursing, which carries out an active program of research and study in the fields of public health nursing and also serves as an accrediting agency for schools of public health nursing.
